ICCR 2024

XXth International Conference on the use of Computers in Radiation therapy

Proceedings

8 - 11 July 2024

Lyon - France

20th edition

www.iccr2024.org

Table of Contents

Treatment Planning and Dose Monitoring - Co-chairs: *Peter Remeijer, Wolfgang Tomé* **18**

Treatment Error Classification With Time-Resolved EPID Images With Multiple Instance Learning.
Vyacheslav Yarkin, Evelyn De Jong, Rutger Hendrix, Frank Verhaegen, Cecile Wolfs 18

A Novel Iterative Reconstruction Algorithm for Imaging of Multi-Field Proton Treatments With PET.
Keegan McNamara, Marina Béguin, Günther Dissertori, Judith Flock, Cristian Fuentes, Jan Hrbacek, Tony Lomax, Shubhangi Makkar, Christian Ritzer, Damien C. Weber, Carla Winterhalter 22

Evaluation of Algorithms for Dose Reconstruction From Prompt-Gamma Radiation in Proton Therapy.
Beatrice Foglia, Chiara Gianoli, Takamitsu Masuda, Elisabetta De Bernardi, Thomas Bortfeld, Katia Parodi, Marco Pinto 26

An Analytical Approach to Predict 3D Positron Emitter Distribution in Carbon Ion Therapy.
Tianxue Du, Julia Bauer, Katia Parodi, Marco Pinto 30

Simultaneous Optimization of Multiple Plans Within One Treatment Course for Temporally Feathered Radiation Therapy.
Jenny Bertholet, Julius Arnold, Chenchen Zhu, Gian Guyer, Silvan Mueller, Marco F M Stampanoni, Peter Manser, Michael K Fix 34

The Relationship Between Treatment Plan Complexity and Dosimetry Quality: An Analysis of Three Stereotactic Treatment Planning Challenges.
Nick Hardcastle, Mathieu Gaudreault, Alisha Moore, Benjamin Nelms, Jordi Saez, Victor Hernandez 38

Addressing the Gap in Oncologist Training: Generating Clinically Realistic, Suboptimal Dose Distributions Through Geometry Aware Convolutions.
Skylar Gay, Mary Gronberg, Raymond Mumme, Christine Chung, Meena Khan, Chelsea Pinnix, Sanjay Shete, Brent Parker, Tucker Netherton, Carlos Cardenas, Laurence Court 42

Image Segmentation I - Co-chairs: *Andre Dekker, Gerd Heilemann* **46**

Feasibility of Training Federated Deep Learning Oropharyngeal Primary Tumour Segmentation Models Without Sharing Gradient Information.
Leroy Volmer, Ananya Choudhury, Aiara Lobo Gomes, Andre Dekker, Leonard Wee 46

Follow the Leader - a General Template-Guided Deep Learning Framework for Adaptive Radiotherapy Target Delineation.
Mahdieh Kazemimoghadam, Qingying Wang, Mingli Chen, Xuejun Gu, Weiguo Lu 50

Clarifying the Dosimetric Impact of Autosegmentation Inaccuracies.
Joëlle Van Aalst, Tomas Janssen, Ilse Van Bruggen, Jelmer Wolterink, Roel Steenbakkers, Stefan Both, Johannes Langendijk, Charlotte Brouwer 54

Team Work Makes the Dream Work: An Ensemble Learning Approach for Segmentation With Convolutional Neural Networks and Vision Transformers.
Anne Andresen, Slavka Lucakova, Yasmin Lassen-Ramshad, Christian Rønn Hansen, Nadine Vatterodt, Jesper Kallehauge 58

Data Harvesting vs Data Farming: A Study of the Importance of Variation vs Sample Size in Deep Learning-Based Auto-Segmentation for Breast Cancer Patients.
Emma Skarsø Buhl, Else Maae, Louise Wichmann Matthiessen, Mette Holck Nielsen, Maja Maraldo, Mette Møller, Stine Elleberg, Sami Aziz-Jowad Al-Rawi, Birgitte Vrou Offersen, Stine Korreman 62

Development and External Validation of a DL-Based CTV Segmentation Model on a Large Multicentric Dataset in the Case of Whole-Breast Radiotherapy Treatment.
Maria Giulia Ubeira Gabellini, Gabriele Palazzo, Martina Mori, Alessia Tudda, Luciano Rivetti, Elisabetta Cagni, Roberta Castriconi, Valeria Landoni, Eugenia Moretti, Aldo Mazzilli, Caterina Oliviero, Lorenzo Placidi, Giulia Rambaldi Guidasci, Cecilia Riani, Andrei Fodor, Nadia Gisella Di Muzio, Robert Jeraj, Antonella Del Vecchio, Claudio Fiorino 66

Leveraging Network Uncertainty to Identify Regions in Rectal Cancer CTV Auto-Segmentations Likely Requiring Manual Edits.
Federica Carmen Maruccio, Rita Simões, Charlotte Brouwer, Jan-Jakob Sonke, Tomas Janssen 70

Prediction Models I - Co-chairs: *Angela Davey, Stine Korreman* **74**

Virtual Patient-Specific Quality Assurance: a Prospective Two-Year Analysis.
Alon Witztum, Phillip Wall, Emily Hirata, Gilmer Valdes 74

Model Size Reduction in CNNs Through Sparse Regularization: Balancing Efficiency and Diagnostic Accuracy in Medical Imaging.
Carlos Garcia Fernandez, Wilmer Arbelo-Gonzalez, Jerome Friedman, Gilmer Valdes 77

The Implementation of Gaussian Process Regression to Inform Voxel-Based Analysis When Dealing With Sparse and Irregular Time-Series Longitudinal Data.
Jane Shortall, Eliana Vasquez Osorio, Andrew Green, David Wong, Tanuj Puri, Peter Hoskin, Ananya Choudhury, Marcel Van Herk, Alan McWilliam 81

Voxel-Wise Causal Inference to Detect Location and Dose-Response of Organs at Risk in Lung Cancer.
Marcel Van Herk, Azadeh Abravan, Alan McWilliam, Eliana Vasquez Osorio 85

Pelvic Bone Marrow Dose-Volume Predictors of Late Lymphopenia Following Pelvic Lymph Node Radiation Therapy for Prostate Cancer.
Maddalena Pavarini, Lisa Alborghetti, Stefania Aimonetto, Angelo Maggio, Valeria Landoni, Paolo Ferrari, Antonella Bianculli, Edoardo Petrucci, Alessandro Cicchetti, Bruno Farina, Paolo Salmoiraghi, Eugenia Moretti, Barbara Avuzzi, Tommaso Giandini, Fernando Munoz, Alessandro Magli, Giuseppe Sanguineti, Justyna Magdalena Waskiewicz, Luciana Rago, Domenico Cante, Giuseppe Girelli, Vittorio Vavassori, Nadia Gisella Di Muzio, Tiziana Rancati, Cesare Cozzarini, Claudio Fiorino 88

Image Registration - Co-chairs: *Kristy Brock, Jamie McClelland* **92**

Inter-Patient Registration Methods for Voxel-Based Analysis in Lung Cancer.
Chloe Min Seo Choi, Jue Jiang, Maria Thor, Joseph Deasy, Harini Veeraraghavan 92

Modelling Progressive Anatomical Changes and Their Variability During Radiotherapy Treatment.
Poppy Nikou, Eliana M. Vasquez Osorio, Marcel Van Herk, Teresa Guerrero Urbano, Anna Thompson, Andrew Nisbet, Sarah Gulliford, Jamie McClelland 96

An Anatomically-Informed Correspondence Initialisation Method to Improve Learning-Based Registration for Radiotherapy.
Edward G. A. Henderson, Marcel Van Herk, Andrew F. Green, Eliana M. Vasquez Osorio 100

DiffuseRT: Learning Likely Deformations of Head and Neck Radiotherapy Patients From Data.
Luciano Rivetti, Andreas Smolders, Nadine Vatterodt, Stine Korreman, Antony Lomax, Manju Sharma, Andrej Studen, Damien Weber, Francesca Albertini, Jeraj Robert 104

Choice of Colourmaps for Radiotherapy.
Alex Davies, Mark Fleckney, Marcel Van Herk 108

Radiomics and Voxel-Based-Analysis - Co-chairs: *Mathieu Hatt, Charlotte Robert* **112**

Genetically-Based Analysis of Dose Surface Maps for Assessing Toxicity Post-RT.
Tiziana Rancati, Eliana Gioscio, Michela Carlotta Massi, Nicola Rares Franco, Petra Seibold, Barbara Avuzzi, Alessandro Cicchetti, Ananya Choudhury, Barry Rosenstein, David Azria, Dirk De Ruysscher9, Maarten Lambrecht, Elena Sperk, Christopher J Talbot, Ana Vega, Liv Veldeman, Adam Webb, Paolo Zunino, Anna M Paganoni, Francesca Ieva, Andrea Manzoni, Sarah L Kerns, Alison Dunning, Jenny Chang-Claude, Catharine L West 112

Prediction of Survival Outcomes and Relevant Tumor Immune Infiltrates Using Radiomic Network Analysis.
Jung Hun Oh, Aditya Apte, Harini Veeraraghavan, Amita Shukla-Dave, Joseph Deasy 116

Radiomic Extraction and Analysis for DICOM Images to Refine Objective Quality Control (READII-2-ROQC): An Open-Source Foundation for Head and Neck Radiomics.
Katy L. Scott, Sejin Kim, Jermiah J. Joseph, Matthew Boccalon, Mattea Welch, Mogtaba Alim, Umar Yousafzai, Ian Smith, Chris McIntosh, Katrina Rey-McIntyre, Shao Hui Huang, Tirth Patel, Tony Tadic, Brian O'sullivan, Scott V. Bratman, Andrew J. Hope, Benjamin Haibe-Kains . . . 119
Predicting Radiation Pneumonitis Using Pre-Radiotherapy CT Scans by Radiomic and a Pre-Trained CNN Based Feature Extraction.
Matthew Gil, William Nailon, Stephen Harrow, Paul Murray, Sorcha Campbell, Ai Wain Yong, John Murchison, Gillian Ritchie, Stephen Marshall . . . 123
Integrating Radiomics Harmonization and Deep Survival Analysis for Enhanced Predictive Modeling in a Multicentric Context.
Nassib Abdallah, Jean-Marie Marion, Pierre Chauvet, Clovis Tauber, Thomas Carlier, Mathieu Hatt . . . 127
Can Bootstrapping Increase Robustness of Voxel-Based-Analysis?
Alan McWilliam, Marcel Van Herk, Chloe Pratt, Eliana M. Vasquez Osorio . . . 131

Hadrontherapy Planning - Co-chairs: *Francesca Albertini, George Dedes* **135**
Trading Robustness? Introducing Total Variance Objectives to Pareto Surface Approximation Techniques for Radiotherapy.
Remo Cristoforetti, Philipp Süss, Niklas Wahl . . . 135
Mid-Range Proton Arc Therapy.
Qingying Wang, Mingli Chen, Mahdieh Kazemimoghadam, Xuejun Gu, Weiguo Lu . . . 139
From Concept to Clinic: How Our In-House Automated Planning System Augmented the Commercial TPS for Treating Over 10,000 Patients.
Masoud Zarepisheh, Gourav Jhanwar, Ying Zhou, Qijie Huang, Hai D. Pham, Jie Yang, Laura Cervino, Jean M Moran, Joseph O. Deasy, Linda Hong . . . 143
Fully-Automated Integrated Multi-Criterial Optimisation of Transmission Pencil Beams in IMPT for Penumbra Sharpening.
Wens Kong, Merle Huiskes, Steven Habraken, Eleftheria Astreinidou, Coen Rasch, Ben Heijmen, Sebastiaan Breedveld . . . 147
Interactive Dose Modification: a Novel Approach to Proton Beam Therapy Treatment Planning.
Matthew Lowe . . . 151
Simultaneous Reduction of Number of Spots and Energy Layers in Intensity Modulated Proton Therapy for Rapid Spot Scanning Delivery.
Anqi Fu, Vicki Taasti, Masoud Zarepisheh . . . 155

Poster Session, Odd IDs **159**
1 - Ameliorate Immune Suppression During Radiation Therapy to Advanced Stage Lung Cancer via a Predictive Algorithm.
Krishni Wijesooriya, Cam Nguyen, Grant Williams, Marco Baessler, Constance Hodge, John Morgan, Ryan Gentzler, Nilanga Liyanage . . . 159
3 - Comparing Two Methods of Using Toxicity Outcomes to Study Dose-Response Mapping of Bladder and Rectum in Prostate Cancer Patients Undergoing Radiotherapy.
Tanuj Puri, Marcel Van Herk, Eliana Vasquez Osorio, Tiziana Rancati, Petra Seibold, Eliana Gioscio, Andrew Green, Andrew P. Morris, Jane Shortall, Sarah Kerns, David Azria, Marie-Pierre Farcy-Jacquet, Jenny Chang-Claude, Alison Dunning, Maarten Lambrecht, Barbara Avuzzi, Dirk De Ruysscher, Elena Sperk, Christopher Talbot, Adam Webb, Ana Vega, Liv Veldeman, Barry Rosenstein, Catharine West, Ananya Choudhury, Peter Hoskin, Alan McWilliam . . . 163
5 - A Technological Pipeline for Detecting Radiation-Induced Heart Damage Mechanisms and Prevent Major Cardiac Adverse Events.
Alessandro Cicchetti, Alessandra Catalano, Silvia Meroni, Anna Cavallo, Albina Allajbej, Chiara Veronese, Paola Vallerio, Claudia Sangalli . . . 167
7 - Whole-Body Organ Dose Assessment of Cancer Patients Undergoing External Beam Radiotherapy Using Body-Size-Dependent Phantom Library for Secondary Cancer Risk Prediction.
Kyeong Hyeon Sung, Bo-Wi Cheon, Hyung-Joo Choi, Soo Min Lee, Saerom Seong, Yoon Seo, Donghyouk Kim, Hyun Joon Choi, Chul Hee Min . . . 171

9 - Towards Gaussian Processes Modelling to Study the Late Effects of Radiotherapy in Children and Young Adults With Brain Tumours..
Angela Davey, Arthur Leroy, Eliana M. Vasquez Osorio, Kate Vaughan, Peter Clayton, Marcel Van Herk, Mauricio A Alvarez, Martin McCabe, Marianne Aznar . . . 175
11 - Explainable Artificial Intelligence for the Prediction of Non-Small Cell Lung Carcinoma Recurrence.
Lorna Tu, Herve Choi, Haley Clark, Samantha Lloyd . . . 179
13 - Is Comorbidity Associated With Interruption of Radiotherapy in Patients With HNSCC Cancer?
Golnoosh Motamedi-Ghahfarokhi, Azadeh Abravan, Eliana M. Vasquez Osorio, Marcel Van Herk, James Price, Hitesh Mistry, Gareth Price . . . 183
15 - Prediction of Acute Pulmonary Toxicity Events With 3D Convolutional Neural Networks From Radiotherapy Dose Maps.
Pedro Juan Soto Vega, Vincent Bourbonne, Wistan Marchadour, Gustavo Andrade-Miranda, François Lucia, Martin Rehn, Ulrike Schick, Dimitris Visvikis, Franck Vermet, Mathieu Hatt . . . 186
17 - Deep Learning Based Three-Dimensional Radiation Dose Prediction With Dose Level Guidance - a Spine SBRT Example.
Tushar Shinde, Gregory Arthur Szalkowski, Cynthia Chuang, Lei Wang, Lianli Liu, Scott Soltys, Erqi Pollom, Elham Rahimy, Quoc-Anh Ho, Neelan Marianayagam, David Park, Ulas Yener, Antonio Meola, Hao Jiang, Mingli Chen, Zi Yang, Weiguo Lu, Xuejun Gu . . . 190
19 - Can Input Reconstruction Be Used to Directly Estimate Uncertainty of a Dose Prediction U-Net Model?
Margerie Huet Dastarac, Dan Nguyen, Steve Jiang, John Lee, Ana Barragan-Montero . . . 193
21 - Investigation of Unsupervised Race-Based Predictive Modeling Strategies to Improve Prediction Power of Tumor Recurrence in Head and Neck Cancer Patients in Diverse Racial Groups.
Hassan Bagher-Ebadian, Marissa V. Gilbert, Farzan Siddiqui, Benjamin Movsas, Kundan Thind, Indrin J. Chetty . . . 197
23 - Robust Models for Esopohageal Toxicity Prediction From Radiation Dose Maps.
Matthew Gil, William Nailon, Stephen Harrow, Paul Murray, Stephen Marshall . . . 201
25 - Improving Dose Volume Histogram (DVH) Based Analysis of Clinical Outcomes Using Modern Statistical Techniques. A Systematic Answer to Multiple Comparisons Concerns.
Mirek Fatyga, Jiuyun Hu, Jing Li . . . 205
27 - On the Implementation and Evaluation of Loss Functions for Robust Multiple Anatomy Segmentation on CT Images.
Chengyin Li, Rafi Ibn Sultan, Hassan Bagher-Ebadian, Yao Qiang, Kundan Thind, Indrin Chetty . . . 209
29 - Scripted Dosimetric Validation of AI Auto-Contouring in Prostate Radiotherapy.
Daniel Warren, Adam Chalkley, Ian Stronach . . . 213
31 - Implementing a Simple, Dynamic and Controllable AI Delineation Tool in Clinical Settings.
Nis Sarup, Maximilian Konrad, Marie Louise Madsen Lange Sevdal, Simon Long Krogh, Christian Rønn Hansen, Irene Hazell, Ebbe Laugaard Lorenzen, Carsten Brink . . . 216
33 - A Robust Auto-Segmentation Approach to Accelerate Adaptive MRI-Guided Radiotherapy for Pancreatic Cancer Patients.
Mehdi Shojaei, Bjoern Eiben, Jamie McClelland, Simeon Nill, Alex Dunlop, Uwe Oelfke . . . 220
35 - A National Infrastructure for Sharing AI Segmentation Tools.
Simon Long Krogh, Ruta Zukauskaite, Ebbe Lorenzen, Nis Sarup, Maximilian Konrad, Janne Nørlykke Drudgaard, Mette Klüver-Kristensen, Eva Samsøe, Mohammad Farhadi, Thomas Hinz-Berg Johansen, Carsten Brink, Christian Rønn Hansen . . . 224
37 - Use of Complementary Multispectral Data for Improving the Accuracy of Deep Learning Solution for Bioluminescence Tomography Reconstruction in Glioblastoma Tumor Models.
Behzad Rezaeifar, Cecile Wolfs, Natasja Lieuwes, Rianne Biemans, Brigitte Reniers, Ludwig Dubois, Frank Verhaegen . . . 228
39 - Monte Carlo Photons Simulation From Alpha-Emitter Radionuclides.
David Sarrut, Ane Etxebeste, Jean Létang . . . 232
41 - A Full GATE/Geant4 Model of a Helical Radiotherapy Device.
Sheraz Blas, Luc Simon . . . 235
43 - Impact of Temporal Structure of Electron, Proton and Photon on (H2O2) Concentration Using Montecarlo Simulation Toolkit (TOPAS-NBio).
Mustapha Chaoui, Othmane Bouhali, Tayalati Yahya . . . 239

45 - Log File-Based Patient Specific QA Using GPU-Accelerated Monte Carlo Simulation for Proton Pencil Beam Line Scanning Therapy.
Chanil Jeon, Sung Hwan Ahn, Jungwook Shin, Hoyeon Lee, Youngyih Han . . . 243
47 - A Fast 3D Range-Modulator Delivery Approach: Sensitivity of the Resulting Dose Distribution on Potential Setup Misalignments.
Yuri Simeonov, Miriam Krieger, Michael Folkerts, Gerard Paquet, Pierre Lansonneur, Petar Penchev, Klemens Zink, Uli Weber . . . 245
49 - Benchmark of Geant4 Hadronic Models for Carbon-Therapy Within the CLINM Project.
Marie Vanstalle, Lévana Gesson, Claire Reibel, Nicolas Arbor, Aurélia Arnone, Christian Finck, Catherine Galindo, Stéphane Higueret, Thé-Duc Lê, Arshiya Sood, Quentin Raffy, Philippe Peaupardin, Marco Pullia 248
51 - Monte Carlo Modeling of Elekta VERSA HD for Out-of-Field Dose Characterization.
Maxime Jacquet, Thomas Baudier, Eric Deutsch, Charlotte Robert, David Sarrut . . . 252
53 - Deformable Voxel Geometry for Photon and Electron Monte Carlo Dose Calculations.
Björn Zobrist, Hannes A Loebner, Jenny Bertholet, Daniel Frei, Werner Volken, Florian Amstutz, Marco F M Stampanoni, Peter Manser, Michael K Fix . . . 256
55 - A GPU-Based Patient-Specific CT Dosimetry Tool Combining Monte Carlo Calculations and ML-Based Segmentations.
Ronan Lefol, Yannick Lemaréchal, Jonathan Boivin, Philippe Despres . . . 260
57 - Accuracy Comparison Between GATE and TOPAS for 6MV Varian CLINAC IX.
Zakaria Ait Elcadi, Othmane Bouhali . . . 264
59 - Can Low-Cost Magnetic Resonance Distortion Phantoms Be 3D Printed?
Haley Clark . . . 268
61 - Automatic Contour Quality Assurance (CAT-QA) to Speed up Online Adaptive Radiotherapy.
Lisa Fankhauser, Andreas Smolders, Renato Bellotti, Damien Charles Weber, Antony John Lomax, Francesca Albertini . . . 271
63 - QATrack+: An Open-Source Routine Quality Assurance Platform.
Randle Taylor, James Kerns . . . 275
65 - Big Data Methods for CT Doses Analysis and Monitoring.
Pierre-Luc Asselin, Philippe Despres, Jonathan Boivin, Yannick Lemaréchal, Gabriel Couture, Samuel Ouellet 279
67 - AutoMRISimQA: an Automated System for Daily Quality Control of a 3T MRI Simulator.
Aitang Xing, Gary Goozee, Gary Liney, Sankar Arumugam, Shrikant Deshpande, Anthony Espinoza, Alison Gray, Vasilis Kondilis, Doaa Elwadia, Robba Rai, Phillip Chlap, Lois Holloway . . . 283
69 - NoPAUSE: Feasibility of a General-Purpose, Physician-Initiated Automatic VMAT Treatment Planning System for Curative Treatments..
Nick Chng, Stacy Miller, Robert Olson, Maryam Golshan, Fred Cao, Quinn Matthews . . . 287
71 - A Complete Portfolio for Automated Treatment Planning for Whole Breast Radiotherapy.
Hana Baroudi, Leonard Che Fru, Deborah Schofield, Dominique Roniger, Donald Hancock, Kent Gifford, Tucker Netherton, Joshua Niedzielski, Adam Melancon, Manickam Muruganandham, Simona Shaitelman, Sanjay Shete, Melissa Mitchell, Laurence Court . . . 290
73 - An Open Source Multi-Criteria Optimization Framework for Radiotherapy.
Tobias Becher, Amit Ben Antony Bennan, Remo Cristoforetti, Niklas Wahl . . . 294
75 - Zero Click Treatment Preparation: From CT to Plan.
Geert Wortel, Rita Simões, Johan Trinks, Peter Remeijer, Eugène Damen, Mark Gooding, Tomas Janssen . . 298
77 - Development of Bolus Optimization System for Electron Conformal Therapy.
Sang-Won Kang, Woong Cho, Dongsan Kang, Moo-Jae Han, Jin-Beom Ching . . . 302
79 - A Python Script to Analyse Treatment Planning Throughput.
Ezhlalan Ramalingam . . . 305
81 - Development of Dynamic Collimator Mixed Beam Radiotherapy to Explore the Dosimetric Benefits of Non-Coplanar and Mixed Photon-Electron Beam Setups.
Chengchen Zhu, Gian Guyer, Jenny Bertholet, Silvan Mueller, Hannes A Loebner, Marco F M Stampanoni, Michael K Fix, Peter Manser . . . 308
83 - Online Adaptive Proton Therapy for Esophageal Cancer: Adaptation Rate and Automated Strategies Comparison.
Camille Draguet, Pieter Populaire, Macarena Chocan Vera, Karin Haustermans, John A. Lee, Edmond Sterpin, Ana Barragan-Montero . . . 312

85 - AI-Guided Unattended Plan Generation.
Christian Velten, Michael Bowers, William Martin, Madhur Garg, Julie Shade, Todd McNutt, Wolfgang Tomé 316
87 - Impact of Artificial Intelligence Solution Aiming to Accelerate MRI Acquisition on the Therapeutic Care in Oncology in Radiology and Radiotherapy Departments.
Raphaëlle Lemaire, Charlotte Raboutet, Thomas Leleu, Cyril Jaudet, Loïse Dessoude, Ferdinand Missohou, Yoann Poirier, Pierre-Yves Deslandes, Joëlle Lacroix, Ilyass Moummad, Stéphane Bardet, Juliette Thariat, Dinu Stefan, Aurélien Corroyer-Dulmont 320
89 - The Automatic Body Composition (ABC) Toolkit.
Donal McSweeney, Craig Jones, Michael Brown, Ashwin Sachdeva, Noel Clarke, Marcel Van Herk, Alan McWilliam 324
91 - OSIRIS-RT : a Minimum Data Set for Data Sharing and Interoperability in Radiation Oncology.
Vincent Le Texier, Thomas Baudier, Sébastien Guihard, Thomas Lacornerie, David Pasquier, Charlotte Robert 328
93 - Towards a Fully Automatic Workflow for Investigating the Dynamics of Lung Cancer Cachexia During Radiotherapy Using Cone Beam Computed Tomography.
Lars Daenen, Wouter Van De Worp, Behzad Rezaeifar, Joël De Bruijn, Peiyu Qiu, Justine Webster, Ramon Langen, Frank Verhaegen, Cecile Wolfs 331
95 - Enhancing CBCT Image Quality for Radiotherapy Using Multi-Channel CycleGAN for CBCT-to-CT Synthesis.
Chelsea Sargeant, Robert Chuter, Jane Shortall, Andrew Green, Jacqui Bridge, Phil Fendall Amaro, Rachael Bailey, Alan McWilliam 335
97 - Evaluating Treatment Delivery Performance of SCINTIX Biology-Guided Radiotherapy Under Non-Periodic In-Treatment Motions.
Chenyang Shen, Thomas Banks, Sagar Ghimire, Yang Kyun Park, Andrew Godley, Steve Jiang, Bin Cai . . . 339
99 - Detection and Correction of Rigid Patient Motion in SPECT With Exponential Data Consistency Conditions.
My Hoang Hoa Bui, Antoine Robert, Simon Rit, Etxebeste Ane 343
101 - Preliminary Study on Residual Motion Evaluation During Breath Hold SBRT.
Weihua Mao, Amol Narang 347
103 - Super Resolution Dose Calculation Via Implicit Neural Representation Based Blind Deconvolution.
Siqi Ye, Sheng Liu, Yu Gao, Lei Xing 350
105 - Evaluation of Organ Dose Reduction Effectiveness in Liver 3D/4D Computed Tomography Simulation Through Radiation Shielding: an Anthropomorphic Phantom Study.
Jongin Oh, Minsik Lee, Bonghyo Lee, Doohyun Lee, Min-Young Kang, Semie Hong, Jun-Bong Shin, Jeong-Woo Lee 354
107 - Artificial Intelligence Dose Calculation Engine Based Pencil-Beam for Intensity Modulated Radiation Therapy.
Zirong Li, Yaoying Liu, Xuying Shang, Huashan Sheng, Wei Zhao, Gaolong Zhang, Qichao Zhou, Shouping Xu 358
109 - Development and Evaluation of Novel Parameters for Describing Anatomical Changes and Predicting Radiotherapy Replanning for Head and Neck Cancer Patients.
Odette Rios-Ibacache, James Manalad, Aixa X. Andrade Hernandez, Kayla O'sullivan-Steben, Emily Poon, Luc Galarneau, John Kildea 362
111 - Software-Assisted Optimisation of Linear Accelerator Energy Consumption.
Genotan Reggian, Catherine Stanford-Edwards 366
113 - Deep Reinforcement Learning for Custom Applicator Design in Personalised High Dose Rate Brachytherapy.
Cedric Loiseau, Philippe Berejny, Marlon Silva, Juliette Thariat, Alain Batalla 370
115 - Angle Dependence on Positional Radioisotope Source Using Monte Carlo Simulation in Brachytherapy.
Moo-Jae Han, Sang-Won Kang, Woong Cho, Dongsan Kang, Jin-Beom Jung 374
117 - State-of-the-Art of CT Enhancement Methods for RT Planning: a Review.
Özgür Özer, Juliette Thariat, Alexandre Haut, David Gibon 378
119 - A Tool for Individualised Dose Mapping Uncertainty Quantification in the Reirradiation Setting: Head and Neck Cancer.
Chelmis Muthoni Thiong'o 381
121 - Robustness of Radiomics Features to Reconstruction Kernel Batch Effect: How Bad Is the Situation?
Elfried Salanon, Aditya Apte, Anqi Fu, Usman Mahmood, Belkhatir Zehor, Amita Shukla-Dave, Joseph Deasy 385
123 - Leveraging Hybrid FLT-PET/MR Imaging to Distinguish Tumour Progression From Radionecrosis in Brain Metastasis Patients Post-Radiosurgery.
Michael Maddalena, Adam Farag, Noha Sinno, Paula Alcaide-Leon, Benjamin Schultz, Catherine Coolens . 389

125 - Towards Fast Plan Adaptation for Proton Arc Therapy.
Benjamin Roberfroid, Ana Barragan, John A. Lee, Edmond Sterpin . . . 393
127 - Fast Robust Dose Evaluation for IMPT Using Deep Learning.
Hazem Nomer, Franziska Knuth, Joep Van Genderingen, Dan Nguyen, Margriet Sattler, Uwe Oelfke, Steve Jiang, Linda Rossi, Ben Heijmen, Sebastiaan Breedveld . . . 396
129 - Inverse Robustness to Control Uncertainties in the RBE Parameter in Proton Therapy Planning.
Mara Schubert . . . 400
131 - Machine Learning for Dose Prediction in Carbon Ion Therapy.
Miriam Schwarze, Leo Thomas, Hans Rabus, Ali Kamal, Pichaya Tappayuthpijarn . . . 404
133 - Investigating Associations Between Radiomics Features and Biomarkers in an Orthotopic Non-Small Cell Lung Cancer Mouse Model.
Gabriel Giampa, Ranjan Yadav, Liming Wang, John Kildea, Martin Vallières, Norma Ybarra . . . 406
135 - Towards Patient-Specific Computational Models of Microvasculature to Investigate Radiation Toxicity.
Sophie Materne, Luca Possenti, Alessandro Cicchetti, Francesco Pisani, Alessandra Catalano, Piermario Vitullo, Paolo Zunino, Tiziana Rancati . . . 409
137 - Modeling the Geometric Distortion and Fan Beam Imaging of an On-Rails Computed Tomography Scanner for 2D/3D Registration.
Giovanni Fattori, Riccardo Via, Antony John Lomax, Sairos Safai . . . 413
139 - Bladder Cancer Hypoxia: Combining OE-MRI and Genomics for Biomarker Discovery.
Rekaya Shabbir, Brian A Telfer, Ben Dickie, Muhammad Babur, Kaye Williams, Catharine Ml West, Ananya Choudhury, Tim Ad Smith . . . 417

Rising Stars Competition - Co-chairs: *Magdalena Bazalova, Marc Kessler* **421**

Quantifying Changes in Ventilation for Photon- and Proton-Treated Patients According to Dose and Pneumonitis Development.
Rebecca Lim, Tien Tang, Austin Castelo, Caleb O'connor, Yulun He, Zhongxing Liao, Radhe Mohan, Kristy Brock . . . 421
Introducing a Co-Creation Design Methodology for AI-Based Error Detection in Radiotherapy.
Luca Heising, Frank Verhaegen, Viola Mottarella, Yin-Ho Chong, Mariangela Zamburlini, Bas Nijsten, Ans Swinnen, Michel Öllers, Maria Jacobs, Carol Ou, Cecile Wolfs . . . 425
Dose Driven Gaze Optimization in Ocular Proton Therapy.
Daniel Björkman, Riccardo Via, Tony Lomax, Maria De Prado, Alessia Pica, Guido Baroni, Damien C. Weber, Jan Hrbacek . . . 429
Neural Graphics Primitives-Based Deformable Image Registration for On-the-Fly Motion Extraction.
Xia Li, Fabian Zhang, Muheng Li, Damien Weber, Antony Lomax, Joachim Buhmann, Ye Zhang . . . 433
Robust Optimization for Contouring Uncertainties in Adaptive Radiation Therapy.
Ivar Bengtsson, Andreas Smolders, Anders Forsgren, Antony Lomax, Damien Weber, Albin Fredriksson, Francesca Albertini . . . 437
Short-Term Mortality Prediction in SIII NSCLC: What Do Clinicians Want and Can Models Provide It?
Matt Craddock, Azadeh Abravan, Alan McWilliam, Corinne Faivre-Finn, Gareth Price . . . 441

Breathing Motion - Co-chairs: *Jenny Bertholet, Jan-Jakob Sonke* **445**

Deep Learning Autosegmentation Performance on Mid-Position and Time-Averaged Lung CT Scans.
Joren Brunekreef, Jan-Jakob Sonke . . . 445
Surrogate-Optimized Respiration Motion Model to Estimate Motion for Each Projection of 3D CBCT Scan.
Yuliang Huang, Kris Thielemans, Jamie McClelland . . . 449
Monte Carlo Robustness Analysis of Breath-Hold and Free-Breathing Photon and Proton Treatments of Small Lung Tumors Using Poisson Displacement Fields.
Nils Olovsson, Kenneth Wikström, Anna Flejmer, Anders Ahnesjö, Alexandru Dasu . . . 453
Real-Time CBCT Imaging via a Single Arbitrarily-Angled X-Ray Image Using a Joint Dynamic Reconstruction and Motion Estimation (DREME) Framework.
Hua-Chieh Shao, Tielige Mengke, Tinsu Pan, You Zhang . . . 457

Enhancing Clinical Utility of 0.55T 4DMRI in Radiotherapy Planning: Exploring Compressed Sensing, Denoising, and Auto-Segmentation.
Austen Curcuru, Young Hun Yoon, Shanti Marasini, H Michael Gach, Jianing Pang, Xinzhou Li, Xin Miao, Jin Sung Kim, Taeho Kim 461

Internal Radiation Therapy - Co-chairs: *Philippe Després, Ane Etxebeste* **465**

Reconstruction of Time-Activity Curves in MRT Therapy Using Bayesian Unfolding.
Francesca Nicolanti, Carlo Mancini Terracciano, Riccardo Faccini, Elena Solfaroli Camillocci, Silvio Morganti, Riccardo Mirabelli, Lorenzo Campana, Francesco Collimati 465

Rapid Auto-Planning for Cervical Brachytherapy: Direct Dwell Time vs. Dose Prediction With Deep Learning Networks.
Lance Moore, Karoline Kallis, Kelly Kisling, Nuno Vasconcelos, Sandra Meyers 469

Near-to-Target Organs-at-Risk Segmentation in Cervical High Dose-Rate Brachytherapy via Deep Learning.
Ruiyan Ni, Elizabeth Chuk, Kathy Han, Jennifer Croke, Anthony Fyles, Jelena Lukovic, Michael Milosevic, Benjamin Haibe-Kains, Alexandra Rink 473

Automatic Target Propagation Strategies for MRI-Guided Cervical Brachytherapy.
Rita Simões, Eva E. Schaake, Eva C. Rijkmans, Marlies E. Nowee, Tomas M. Janssen 477

Geant4 Simulation of DNA Damage Surrounding a DaRT Seed.
Laura Ballisat, Chiara De Sio, Lana Beck, Susanna Guatelli, Dousatsu Sakata, Yuyao Shi, Jinyan Duan, Jaap Velthuis, Anatoly Rosenfeld 481

Poster Session, Even IDs **485**

2 - A Pipeline for Generating Longitudinal Head and Neck Cancer Radiotherapy Datasets for Machine Learning.
Kayla O'sullivan-Steben, Odette Rios-Ibacache, Luc Galarneau, John Kildea 485

4 - Demonstration of Current Best Practice for Prognostic Model Validation Using the Manchester Score.
Charlie Cunniffe, Gareth Price, Matthew Sperrin, Fiona Blackhall 489

6 - A Non-Invansive and Self-Managed Microscope for Predicting Radiation-Induced Acute Toxicities in Cancer Patients.
Alessandra Catalano, Sophie Veronique Materne, Fabio Badenchini, Eliana La Rocca, Eliana Gioscio, Francesco Pisani, Luca Possenti, Barbara Avuzzi, Barbara Noris Chioda, Carlotta Giandini, Riccardo Roy Colciago, Maria Carmen De Sanctis, Tommaso Giandini, Alessandro Cicchetti, Tiziana Rancati 493

8 - Data Preparation Pipeline for Artificial Intelligence in Radiation Oncology: Lessons From a Large Prospective Imaging Trial.
Hannah Thomas, Amal Joseph Varghese, Manu Mathew, Devadhas Devakumar, Aparna Irodi, Joel T, Timothy Peace, Henry Finlay Godson, Rajesh Isiah, Simon Pavamani, Balu Krishna Sasidharan 497

10 - Transfer Learning for the Detection of Lung Lesions in 18F FDG PET/CT Images Using GraphNet.
Maryam Fallahpoor, Biswajeet Pradhan 500

12 - Optimising Physics-Informed CRNNs for Longitudinal Volumetric Medical Image Data.
Denis Page, Eliana M. Vasquez Osorio, Robert Chuter, Andrew Green, Alan McWilliam 502

14 - i-SART: A Prototype AI-Based Tool to Enhance Patient Safety in Radiotherapy.
Anastasia Sarchosoglou, Natalia Silvis-Cividjian, Yijing Zhou, Periklis Papavasileiou, Athanasios Bakas, Evangelos Pappas 506

16 - Deep Learning-Based Tumor Shape Variation Prediction of Lung Cancer Patient's Pre-Radiation Treatment Response.
Sangwoon Jeong, Kyungmi Yang, Youngyih Han, Hee Chul Park, Sang Hee Ahn 510

18 - Deep Learning for in Vivo EPID Dosimetry Classification: Relating Gamma Analysis and DVH Metrics for Lung Cancer Patients.
Femke Vaassen, Sebastiaan Nijsten, Richard Canters, Frank Verhaegen, Cecile Wolfs 514

20 - Adaptive Radiotherapy Dose Prediction on Head and Neck Cancer Patients With a Multi-Headed U-Net Deep Learning Architecture.
Hui-Ju Wang, Austen Maniscalco, David Sher, Mu-Han Lin, Steve Jiang, Dan Nguyen 518

22 - Prediction of Stress in Radiation Therapy Patients Using Artificial Intelligence and Biological Signals.
Sangwoon Jeong, Hongryull Pyo, Won Park, Youngyih Han 522

24 - Habitat Imaging Based on Voxel-Wise GLCM Joint Energy Clustering: Prediction of Disease-Free Survival in Localized Soft-Tissue Sarcoma..
Benoît Allignet, Benjamin Leporq, Amine Bouhamama, Frank Pilleul, Alexandra Meurgey, Vaz Gualter, Marie Pierre Sunyach, Waisse Waissi, Olivier Beuf 526
26 - A Deep Learning-Driven Framework for Automatic Target Volume Localization and Delineation in Spinal Metastases Stereotactic Body Radiotherapy.
Zi Yang, Mahdieh Kazemimoghadam, Gregory Szalkowski, Cynthia Chuang, Lei Wang, Lianli Liu, Scott Soltys, Erqi Pollom, Elham Rahimy, Hao Jiang, David Park, Amit Persad, Yusuke Hori, Jie Fu, Ignacio Romero, Laszlo Zalavari, Mingli Chen, Weiguo Lu, Xuejun Gu 530
28 - Safeguarding Clinical AI-Based Auto-Segmentation: Open-Source Models as Quality Assurance Against Catastrophic Failures.
Daniel Alexander, Rafe McBeth 534
30 - Automatic Target Segmentation and Beam Setup for Electron Skin Radiotherapy.
Rik Westendorp, Miranda Beumer, Tristan Van Heijst, Kelvin Ng Wei Siang 538
32 - Comparative Analysis of Deep Learning Models for Flap Segmentation in Head and Neck Computed Tomography Images: A Generalization Study.
Abir Fathallah, Alice Blache, Zacharia Mesbah, Romain Modzelewski, Juliette Thariat, Mathieu Hatt . . . 542
34 - An Automated Framework of Accurate Dominant Intraprostatic Lesion Delineation Based on Multimodal Images for MRI-Guided Adaptive Prostate SBRT.
Zirong Li, Xiao Liu, Qichao Zhou, X. Sharon Qi 546
36 - Medical Image Segmentation Assisted With Clinical Inputs via Language Encoder in A Deep Learning Framework.
Hengrui Zhao, Biling Wang, Deepkumar Mistry, Jing Wang, Michael Dohopolski, Daniel Yang, Weiguo Lu, Steve Jiang, Dan Nguyen 549
38 - Influence of Electron Transport Algorithm on Monte Carlo Based Treatment Planning.
Grisel Mora Paula, A Eldib, J Li, Charles Ma 553
40 - GMC [gímɪk] Then and Now: (r)evolution of a One-Variable Proton Monte Carlo Dose Algorithm..
Nicolas Depauw, Michael Williams, Benjamin Clasie, Kyung-Wook Jee, Thomas Madden, Hanne Kooy . . . 557
42 - Assessing Neutron-Induced Carcinogenesis Risk in High-Energy Radiation Therapy: a Monte Carlo and Track Structure Study Using Realistic Neutron Spectra and DNA Damage Clusters.
Sachin Dev, Felix Mathew, John Kildea 560
44 - Recent Progress in GMicroMC Package for Microscopic Monte Carlo Simulations.
Youfang Lai, Yuting Peng, Meiying Xing, Yujie Chi, Xun Jia 563
46 - Evaluation of a New Radiosurgery System (infinityARC) Using Geant4.
Patrick Johan Ngontie Ngounou, Philippe Despres, Yannick Lemaréchal 567
48 - Oxygen Effect on Tumor Response to Irradiation: Insights From GATE Simulation Studies.
Zakaria Ait Elcadi, Othmane Bouhali 571
50 - Monte-Carlo Modeling of Intratumoral Radionuclide Distribution in TAT: Comparison to Experiment.
Victor Levrague, Mario Enrique Alcocer-Avila, Etienne Testa, Michaël Beuve, Rachel Delorme 573
52 - DINo: Deep Learning Intelligence for Nuclear Reactions.
Lévana Gesson, Greg Henning, Uli Weber, Marie Vanstalle 577
54 - Development of the Low Dose Radiotherapy Machine for the Osteoarthritis: Optimization of Design Based on the Monte Carlo Simulation.
Hyojun Park, Jung-In Kim, Sang Hoon Heo, Song Yi Heo, Minjae Choi, Ju Yeol Shin, Chang Heon Choi . . 580
56 - Prompt-Gamma Timing With a Track-Length Estimator in Proton Therapy.
Jean Létang, Oreste Allegrini, Etienne Testa 584
58 - Identification of Suitable Probing Locations for a Proton Radiography-Based Quality Control of CBCT-Based Synthetic-CTs.
Måns Lundberg, Arturs Meijers, Antony Lomax, Damien Weber, Kevin Souris, Antje Knopf 588
60 - External Validation of an AI-Based Tool for the Early Detection of Radiotherapy Treatment Planning Errors-An Updated Multicentric Study.
Petros Kalendralis, Samuel Luk, Alan Kalet, Andre Dekker, Inigo Bermejo, Tomasz Piotrowski, Adam Ryczkowski, Joanna Kazmierska 592
62 - Development of an Automated Radiotherapy Daily QA System.
Marcus Tyyger, Matthew Carlisle, Jack P. C. Baldwin, Richard Homer, Phillip Rixham, Steve Weston 596

64 - Isocenter Deviation Assessment and Model for Halcyon Radiotherapy Systems.
Linda Lankinen, Antti Kulmala, Jouko Lehtomäki, Ari Harju 599
66 - Patient-Specific Quality Assurance in Radiotherapy: Prediction With Deep Hybrid Learning for VMAT Plans on Rapid Arc and IMRT Plans on Halcyon Machines.
Noémie Moreau, Christine Boutry, Laurine Bonnor, Cyril Jaudet, Nadia Falzone, Alain Batalla, Laetitia Lechippey, Cindy Bertaut, Aurélien Corroyer-Dulmont 603
68 - Analysis of a Decade's Worth of Oncology Information System Data From a Large US Healthcare System.
Christian Velten, Ping Yan, Madhur Garg, Wolfgang Tomé 607
70 - Fast Many-Scenario Robust IMPT Planning Through Constrained Dose-Mimicking.
Franziska Knuth, Michelle Oud, Wens Kong, Hazem Nomer, Joep Van Genderingen, Linda Rossi, Steven Habraken, Ben Heijmen, Sebastiaan Breedveld 611
72 - DeepTuning: Tune Radiotherapy Plan Dose Distribution in Real Time by Deep Learning.
Lin Ma, Huan Liu, Mingli Chen, Weiguo Lu 614
74 - Automating Physics Plan Checks With Monaco Scripting.
Hill Paul 618
76 - Optimization in Radiotherapy Integrating a Multidisciplinary Framework With GEANT4.
Elisabetta Sergi, Mara Severgnini, Enrico Rigoni, Francesco Longo 621
78 - A Personalized Automatic Radiotherapy Plan Scoring Mechanism Based on Multi-Organ Individually-Objective Optimization.
Zirong Li, Zhenjiang Li, X. Sharon Qi, Kuo Li, Huashan Sheng, Zhigang Yuan, Yong Yin, Qichao Zhou . . . 623
80 - Dynamic Collimator Rotation Treatment Plan Optimization for O-Ring Treatment Systems.
Fix Michael, Werner Volken, Daniel Frei, Silvan Mueller, Gian Guyer, Daniel Schmidhalter, Peter Manser . 626
82 - Dosimetry for Head and Neck Radiotherapy Using Personalized Quantitative MRI.
Laura Sayaque, Benjamin Leporq, Charlène Bouyer, Frank Pilleul, Vincent Gregoire, Olivier Beuf 630
84 - IOeRT Conventional and FLASH TPS Implementation Exploiting Fast GPU Monte Carlo: the Case of Breast Cancer.
Gaia Franciosini, Angelica De Gregorio, Massimo Di Francesco, Fabio Di Martino, Giuseppe Felici, Jake Harold Pensavalle, Michela Marafini, Annalisa Muscato, Vincenzo Patera, Philip Poortmans, Adalberto Sciubba, Angelo Schiavi, Marco Toppi, Giacomo Traini, Antonio Trigilio, Alessio Sarti 634
86 - Exploring VHEE Treatment Efficacy Through In-Silico Investigations in Conventional and FLASH Irradiation Regimes.
Annalisa Muscato, Angelica De Gregorio, Daniele Carlotti, Michele Fiore, Gaia Franciosini, Teresa Insero, Valerio Marè, Sara Ramella, Alessio Sarti, Angelo Schiavi, Marco Schwarz, Vincenzo Patera 638
88 - Reconstruction Toolkit (RTK) V2, an Insight Toolkit (ITK) Module for Tomographic Reconstruction.
Simon Rit, Sébastien Brousmiche, Julien Finet, Gregory C. Sharp, Philipp Steininger 641
90 - Validation of an Open Source Contouring Tool.
Haley Clark 645
92 - Harmonizing Multicentric T1-Weighted Magnetic Resonance Imaging of Children With Ependymomas: Can Deep Learning Based Image Synthesis Help?
Soumia Bengoufa, Fatima Tensaouti, Pedro Juan Soto Vega, Stéphanie Bolle, Alexandre Escande, Xavier Muracciole, Claire Alapetite, Line Claude, Julie Leseur, Aymeri Huchet, Jérôme Doyen, Georges Noel, Stéphane Supiot, Valerie Bernier-Chastagner, Julien Welmant, Pierre Leblond, Dimitris Visvikis, Vincent Jaouen, Anne Laprie, Mathieu Hatt 649
94 - Performance Evaluation of a Pix2Pix Synthetic Xray Image Generator for Preclinical Applications.
Vasileios Eleftheriadis 653
96 - Fast and Automated Dose Verification Procedure for Reinforced Online Adaptive MRI-Guided RT.
Teo Stanescu 655
98 - Optimizing the Contrast to Noise Ratio for Tumor Tracking in the Lung Using Dual Energy Imaging Strategies for Soft Tissue Enhancement.
Nawal Alqethami, Wentao Xie, Prasannakumar Palaniappan, Felix Ginzinger, Philipp Steininger, Marco Riboldi 657
100 - Performance Evaluation of Virtual Laser-Based Surface-Guided Radiation Therapy Setup System Using Humanoid Head Phantom.
Jeong-Woo Lee, Byoung-Moon Park, Yong-Ki Bae, Min-Young Kang, Semie Hong 661

102 - Preliminary Evaluation of a Software Application for Target Tracking Without Fiducials During Cyberknife Treatment of Pancreas.
James Bedford, Simeon Nill, Uwe Oelfke . . . 664

104 - The Impact of Training Dataset Size and Model Size on the Accuracy of Deep Learning Dose Prediction.
Joep Van Genderingen, Dan Nguyen, Franziska Knuth, Hazem Nomer, Luca Incrocci, Abdul Sharfo, Uwe Oelfke, Steve Jiang, Linda Rossi, Ben Heijmen, Sebastiaan Breedveld . . . 668

106 - Deep Learning for Instantaneous Estimation of the Out-of-Field Dose in External Beam Photon Radiotherapy. A Proof of Concept.
Nathan Benzazon, Mohammed El Aichi, Alexandre Carré, François De Kermenguy, Stéphane Niyoteka, Pauline Maury, Julie Colnot, Meissane M'hamdi, Cristina Veres, Rodrigue Allodji, Florent De Vathaire, David Sarrut, Neige Journy, Claire Alapetite, Vincent Gregoire, Eric Deutsch, Ibrahima Diallo, Charlotte Robert . . . 672

108 - Accurate Selection of Calculation Grid Size for Radiation Plans With Small Brain Tumors in Intracranial Stereotactic Radiotherapy.
Tagreed Alalawi, Mazen Al-Gaoud, Elham Rashaidi, Nesreen Shorbaji . . . 676

110 - To Calibrate or Not to Calibrate: a Decision Support Approach Using Microcontroller-Based Tiny Machine Learning.
Nicolas Boussion, Lou Bosc, Gaëlle Goasduff, Yoann Jegat, Anne-Sophie Lucia, Emmanuelle Martin, Laetitia Lann, Dimitris Visvikis . . . 679

112 - Experiment of Proof-of-Principle on C-Arm CT/SPECT System for In-Vivo Dose Verification in Online Image-Guided Adaptive Brachytherapy.
Saerom Sung, Kim Hyemi, Min Chul Hee, You Sei Hwan, Choi Hyun Joon . . . 683

114 - Multiphysics Modeling and Simulations for Y-90 Liver Radioembolization.
Emilie Roncali, Carlos Ruvalcaba, Gustavo Costa . . . 686

116 - Partial-Ring PET Image Correction Using Implicit Neural Representation Learning.
Shubhangi Makkar, Siqi Ye, Marina Béguin, Günther Dissertori, Jan Hrbacek, Antony Lomax, Keegan McNamara, Christian Ritzer, Damien C. Weber, Lei Xing, Carla Winterhalter . . . 689

118 - Artificial-Intelligence Enhanced Image Reconstruction for Proton Range Verification.
Lena Setterdahl, Ilker Meric, William Lionheart, Sean Holman . . . 693

120 - Head and Neck Deformable Registration Using Self-Attention With Positional Encoding.
Elizabeth McKenzie, Taman Upadhaya, Hengjie Liu, Ke Sheng . . . 697

122 - The Prognostic Value of Foundational Radiomics and Clinical Features in Locally Advanced Non-Small Cell Lung Cancer in NRG Oncology Trial RTOG 0617.
Upadhaya Taman, Elizabeth M. McKenzie, Indrin J. Chetty, Katelyn M. Atkins . . . 701

124 - Exploring How Prostate Cancer Treatment Choices Affect Radiomic Features: A Look at Healthy Tissue vs. Dominant Lesion in MR-Guided Radiotherapy.
Aaron G. Rankin, Swinton Martin, Jim Zhong, Priya Maitre, Angela Davey, Marianne Aznar, Ananya Choudhury, Alan McWilliam . . . 705

126 - On Computational Challenges in Proton Therapy Treatment Planning.
Mohammadhossein Mohammadisiahroudi, Zou Wei, Lei Dong, Yuriy Zinchenko, Tamás Terlaky . . . 709

128 - A Neural Network-Based Dose Calculation Engine for Proton Spots Dose: a Clinical Implement Study.
Xuying Shang, Yaoying Liu, Zishen Wang, Nan Li, Chunfeng Fang, Yue Zou, Wei Zhao, Xiaoyun Le, Gaolong Zhang, Shouping Xu . . . 713

130 - JulianA.jl - A Flexible Open Source Julia Package for Pencil Beam Scanning Proton Therapy.
Renato Bellotti, Tony Lomax, Andreas Adelmann, Jan Hrbacek, Damien C. Weber . . . 716

132 - Monte Carlo Verification of Proton Treatment Planning.
Klara Badraoui Cuprova . . . 720

134 - RadiSeq: A Whole-Genome DNA Sequencing Simulation Pipeline to Investigate Radiation-Induced Carcinogenesis.
Felix Mathew, John Kildea . . . 723

136 - Detectability of Iodine Contrast Agent With Ultra-Low Concentration by Photon-Counting CT: A Simulation Study.
Xiaoyu Hu, Yuncheng Zhong, Kai Yang, Xun Jia . . . 727

138 - Unraveling Interstitial Fluid Pressure: Analyzing Drug Transport Through Cross Voxel Exchange Model and Dynamic Contrast Enhanced MRI.
Yeyoung Kim, Noha Sinno, Michael Milosevic, Catherine Coolens . . . 731

140 - Revealing Head and Neck Tumors Spatial Heterogeneity Through Quantitative MRI Protocol: Initial Findings..
Walid Dandachly, Benjamin Leporq, Laura Sayaque, Chloé Miran, Benoit Allignet, Frank Pilleul, Olivier Hamelin, Charlène Bouyer, Vincent Gregoire, Olivier Beuf . . . 735

Image Segmentation II - Co-chairs: *Charlotte Brouwer, Catherine Coolens* **739**

Segment Anything Model for Head and Neck Tumor Segmentation With CT, PET and MRI Multi-Modality Images.
Jintao Ren, Mathis Rasmussen, Jasper Nijkamp, Jesper Eriksen, Stine Korreman . . . 739

Test-Time Adaptation for Medical Image Segmentation Based on a Joint Framework With an Adaptive Wavelet-VNet and a Refine Model (WaVNet-Refine).
Xiaoxue Qian, You Zhang . . . 743

MAGIC: Multitask Adversarial Generator of Images and Contours From CBCT for Adaptive Radiotherapy.

Abstract

Recent research has investigated the classification of radiotherapy errors in time-integrated (TI) in vivo Electronic Portal Imaging Device (EPID) images with convolutional neural networks, showing promise. However, it has been observed that TI images may cancel out the error presence on γ-maps during dynamic treatments. To address this limitation, time-resolved (TR) γ-maps for each VMAT angle were used to detect realistically simulated treatment errors caused by complex patient geometries and beam arrangements. Typically, such images can be interpreted as a set of frames where only set class labels are provided, making manual analysis difficult and time-consuming. To effectively aggregate individual segment information and evaluate its contribution to error classification we applied a transformer based multiple instance learning (MIL) approach on TR EPID images.

The proposed algorithm showed excellent performance on classification of anatomical, positioning and mechanical errors. Accuracy on the hold-out test set reached 0.94 for 11 error classes.

1 Introduction

Modern radiation techniques like volumetric modulated arc radiotherapy (VMAT) enable precise dose delivery, reducing excessive dose to organs at risk. To ensure clinically acceptable doses, Electronic Portal Imaging Devices (EPID) are used for pre-treatment verification and for in vivo dosimetry (IVD) [1]. However, per-patient transit dosimetry analysis is resource-intensive. Hence, automatic error identification could improve treatment outcome and clinical workflow.

There are only a few studies that proposed to use AI-methods on IVD for VMAT [2-3]. The challenges for IVD 2D transit portal dose verification, is associated with resource-intensive per-patient dosimetry analysis, especially for time-resolved (TR) dose verification. TR γ-maps provide a significant increase of contextual and spatial information about the VMAT dose distribution but cannot be assessed manually in clinical routine due to its quantity of information complexity. Therefore, automatic error identification could benefit this process, and consequently aid further decision making about the patients' treatments.

In this study, we propose a novel approach of treatment error classification with 2D TR γ-maps, based on a deep multiple instance learning (MIL) approach with a transformer model [4] and convolutional neural network (CNN) multi-scale feature extraction.

2 Materials and Methods

Data. The dataset consisted of 26659 simulated 2D TR γ-maps acquired from 53 VMAT treatment plans of 47 lung cancer patients. TR γ-maps were attained by comparing simulated (original) portal dose images (PDI_o) and PDI_e (with only one known error added to treatment plans or computed tomography (CT) images) using gamma analysis. Each VMAT treatment plan contained 2 half-arcs, and each half-arc consisted of 97 beam segments. PDIs were calculated with a model based on pencil beam scatter kernels using in-house developed software [5]. Gamma analysis criteria were set to 3% dose difference and 3 mm distance-to-agreement. In this work, we simulated a wide range of clinically realistic errors, that can occur during radiotherapy treatment (Table 1). Not all treatment errors are expected to manifest for each of the VMAT arc angles, so each of the 97 segments of the whole 2D TR γ-maps could contain a different error representation (Figure 1).

Error Class	Error magnitudes, increment and units
Mediastinum shift	[2 .. 16, 2] mm
Pleural effusion	[5 .. 50, 5] mm
Tumor regression	[10 .. 90, 10] %
Tumor shift	[3 .. 30, 3] mm
Collimator rotation	[0.2 .. 2, 0.2] degrees
MLC shift Random	[0.2 .. 2, 0.2] mm
MLC shift systematic	[0.2 .. 2, 0.2] mm
MU scaling random	[1 .. 10, 1] %
MU scaling systematic	[1 .. 10, 1] %
Positioning rotation	[0.2 .. 1, 0.2] degrees
Positioning translation	[3 .. 21, 3] mm

Table 1: Simulated error classes, and magnitudes of errors applied on CT and treatment plans. Minimum and maximum value provided with the increment size. For instance, anatomical mediastinum shift was acquired with shifting the relative voxels on CT image from its original position to right or left with a magnitude from 2 to 16 mm with a step of size 2 mm.

Deep learning model design. In this study we focused on treatment error classification (multi-class classification) and modified the multiple instance learning (MIL) framework

[6] with vision transformers (ViT) [7]. A pre-trained convolutional neural network (CNN) [1] was adopted for per-segment feature extraction from TR γ-maps. Segment features were treated as tokens for a transformer encoder, to account for the dependencies among all segment representations. MIL exploits an attention-based operator to weight the contributions of each segment embedding.

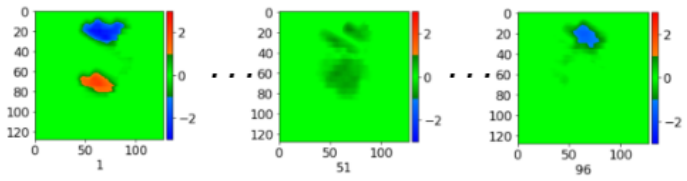

Figure 1: Examples of three individual TR segments of a simulated 21 mm upward tumour shift along the axial plane. Higher γ values coincide with the regions from where the tumor was shifted, causing a higher dose difference (γ value >1, red), in contrast to blue regions with lower dose values than the plan (γ value < -1). The segments with the index 51 does not contain pixels with absolute γ values higher than 1 and these are considered segments where the simulated error has less influence on the dose distribution.

Vision Transformers. ViT use a multi-head self-attention mechanism (MHSA) to process image patches, that are non-overlapping image sections. These patches are transformed into learnable matrices. Multiple heads of the self-attention mechanism are applied in parallel to capture dependencies between different image patch representations. The ViT includes adding a classification token that summarizes class features, as well as a positional token for position-dependent information, with the final step involving the separation of the classification token for prediction.

Multiple Instance Learning. To allow each individual segment to contribute to error classification, we propose a MIL framework. In the context of 2D TR γ-maps, the core principle of MIL revolves in gathering information from the individual segments to make the whole γ-map prediction with an aggregation operator, e.g. a max operator that selects the maximum value among segments and assigns an error class to whole γ-map based on this segment. In this work, to avoid using only one segment to base the classification of the whole TR γ-map on, we used attention-based aggregation to weight each segment representation [8]. Implementation of the transformer MIL involves the following steps: 1) generate feature embeddings of individual segments for the transformer encoder using a pre-trained CNN, 2) model the dependencies along all features with the transformer encoder, 3) aggregate the encoder embeddings with size $n \times d$, where the n = 97 segments segment embeddings of size d, to obtain a whole γ-map representation and 4) transform the aggregated representation to error class probabilities with a linear layer (Figure 2).

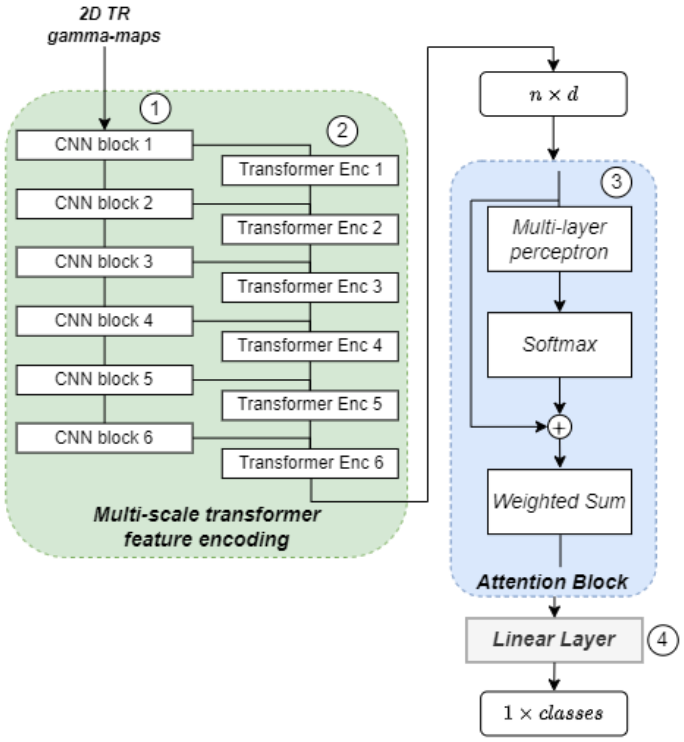

Figure 1: Schematic representation of the transformer MIL architecture. Features are extracted with a CNN from each segment of TR γ-map (1); a transformer encoder models the dependencies among low-dimensional segment embeddings (2); MIL attention aggregates all segment representations (3); whole γ-map level classification is performed (4).

Experimental design and evaluation metrics.
The dataset was partitioned in training, validation and test datasets, so that each patient's simulated TR γ-maps belonged to the same split. Split proportions were therefore set to 70%, 12%, 18% for training, validation and test sets, respectively. The training and validation sets were used for model optimization and tuning hyperparameters. The hold-out test set was only used for model inference, to evaluate the resulting classification performance.

The model was trained with Cross Entropy loss with weight regularization and the Adam [9] optimizer with weight decay set to 0.02. We set an initial learning rate of 6×10^{-5} and gradually decreased it using a cosine learning rate scheduler for 30 epochs. The transformer dropout rate was set to 0.2. The model capacity had approximately 11.4×10^{6} parameters.

For the evaluation metrics, we used accuracy and receiver-operating characteristic (ROC) area under the curve (AUC) to evaluate the treatment error classification. The resulting performance is evaluated on a hold-out test set.

3 Results

Training time for 30 epochs was ~60 hours, training and validation accuracy reached 0.98 and 0.97, respectively. Excellent performance on the hold-out test set on classification of 11 error classes is supported with 0.94 average class accuracy score. The AUC score was 0.98. The majority of misclassifications were seen for mediastinum shift and pleural effusion (Figure 3). In the latter case, 86% of samples that belong to pleural effusion were correctly predicted, while 14% were incorrectly predicted as other anatomical errors. The model demonstrated highest per class accuracy on machine related errors, with MU random and MU systematic accuracy scores of 1.0.

4 Discussion

In this paper we implemented a novel approach of utilizing ViT and MIL for IVD treatment error classification on 2D TR γ-maps. Results show excellent performance on the hold-out test set for a set of simulated errors. The lowest per-class accuracy was 0.86 for pleural effusion, but the model misclassified this error as other anatomical error classes. For tumor regression and tumor shift, misclassifications were found only between these two classes. However, precision for tumor regression was the lowest (0.71) among other classes, with 29 % percent of false positives related to other anatomical error classes. This possibly means that introduced anatomical errors form specific pattern on γ-maps, that the model was able to take into account.

In this study, we focused on TR data, and we assume that additional per-segment spatial information could resolve the issue of averaged out errors in time-integrated (TI) dosimetry [10]. To overcome the limitations of TI data, enormous amount of TR data is effectively leveraged with proposed model architecture. Transformer MIL focuses on error patterns on each individual segments. This is achieved through a transformer encoder, that models the dependencies among segment representations on multiple feature levels. By doing so, the model is effectively capturing the interrelationship between segments that could show different error patterns. Individual patches contribution is enabled with attention aggregation, which is frequently overlooked by transformer based models. Consequently, TR data is effectively utilized and enhance the error classification models on TI data.

Further research could be connected with model interpretation. The possible solution could be to study the transformer's attention matrix due to its ability to capture the dependencies among all segments. Existing approaches focus on visualization of raw attention weights or functions of attention weights. Intuitively, we can extract raw attention matrix of transformer's multi-head self-attention and identify the index of the segment the most contributed to the error classification. However, within the number of encoder layers, the complexity of interactions also raise, and could provide less reliable explanations [11]. Accordingly, the research on more advanced interpretation methods beyond attention-based techniques is needed. This would help to acquire interpretable descriptions on Transformer MIL model decisions.

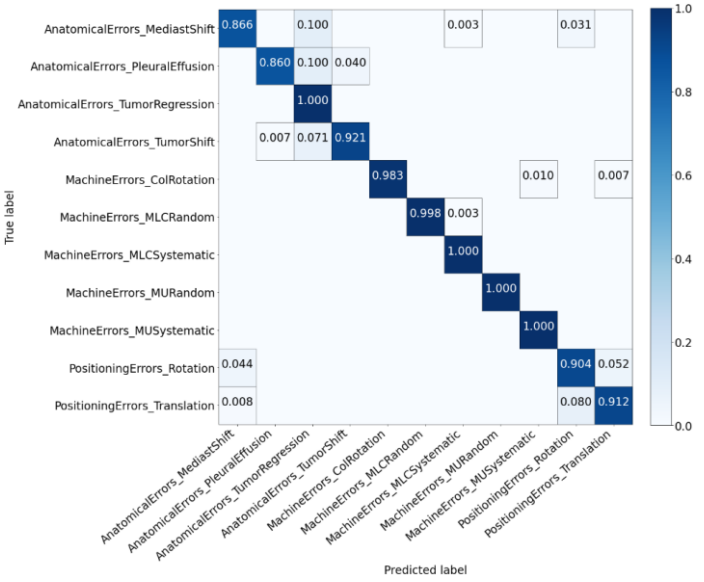

Figure 3: Confusion matrix for treatment error classification. Diagonal values represent the fraction of correctly classified samples of a class out of samples of that class. Empty spaces show no misclassifications for a particular class.

5 Conclusion

In this work we adopted a MIL approach that can automatically enhance dose verification during radiotherapy. Transformer MIL was implemented to explore the spatial information between each of the arc segments of TR images. The following novel contribution was made: we adopted pre-trained CNN for per-segment feature extraction, implemented the transformer-based MIL to account individual segments contribution for error classification. We evaluated the method on a synthetic sample of 2D TR γ-maps with introduced 11 classes of treatment errors with an average accuracy of 0.94.

Abstract Treatment verification of multi-field proton therapy using PET imaging may allow for comprehensive verification capabilities through range measurements for each delivered field. We introduce a novel maximum-likelihood expectation maximization (MLEM) algorithm which combines PET data recorded following delivery of each field in a multi-field treatment plan and reconstructs the expected activity distribution induced by each field. We showcase an example use case through simulation of a 3-field treatment plan delivered to a brain tumour, imaged using the open-ring PETITION PET detector. Our novel MLEM approach produced activity distributions with better agreement to the expected positron annihilation distributions for each field, with a decrease in normalised root mean square error by 0.4%-9.7% and an increase in structural similarity index by 4.4%-17.3% when compared to a simplified calculation of the expected activity. We show reduced noise, and the potential for better range predictions for each field using iso-activity analysis along the beams-eye-view.

1 Introduction

Positron emission tomography (PET) imaging of proton therapy patients during treatment provides a potential method for the validation and verification of delivered dose, with the imaging of positron emitting isotopes generated within the patient during treatment serving as a surrogate for delivered dose [1]. The move towards in-beam imaging with novel detector designs, such as the recent open-ring PET detector developed as part of the PETITION (PET for InTensive care units and Innovative protON therapy) project [2], creates the unique opportunity to image multiple treatment fields as they are delivered to the patient. The complex composition, timing structure, and overlap of fields, creates challenges for using the data recorded during a treatment for verification purposes.

The primary goal of this work is to image the activity induced by individual treatment fields delivered to a patient, with the goal being the validation of proton range for each field. In the planning target volume the lateral fall off of one field may overlap with the distal edge of another, or fields may be delivered anti-parallel from one other. As such, disentangling the activity induced by each field presents a unique problem. Low count rates due to the low overall induced activity leads to noisy images, such that a simple subtraction of individual images is not necessarily reliable for the determination of activity induced in each field.

We introduce a novel maximum-likelihood expectation maximization (MLEM) method for reconstruction of the activity induced in patients by multiple treatment fields and imaged using multiple imaging positions. We present an example use case for a brain tumour patient treated with 3 fields. We consider a scenario in which the open-ring PETITION PET scanner is capable of rotating around the patient head, such that the opening of the scanner aligns with the beam direction during delivery of each treatment field.

2 Computational implementation

We consider delivery of N treatment fields to a patient. The delivery of each field induces a particular isotope distribution within the patient geometry for a series of positron emitting isotopes, e.g. ^{10}C, ^{11}C, ^{13}N, and ^{15}O. We denote the activity induced by field f in voxel v by the isotope i by A^f_{iv}. The total number of decays expected in voxel v during imaging period p, from time t_{p0} to t_{p1}, due to isotopes generated by field f is then

$$\lambda^f_{vp} = \sum_i A^f_{iv} \int_{t_{p0}}^{t_{p1}} dt\, e^{-(t-t_f)\ln 2/t_{i,1/2}}, \tag{1}$$

where t_f is the time that field f finished delivery, $t_{p0} > t_f$, and $t_{i,1/2}$ is the half life of isotope i. We make the simplifying assumption that the activity distribution of all isotopes generated by a treatment field are identical up to a scale factor, i.e. $A^f_{iv} = w_i A^f_v$, such that we can write the total number of decays expected during imaging period p to be

$$\lambda_{vp} = \sum_f A^f_v d_{pf} \tag{2}$$

where $d_{pf} = 0$ if $t_{p0} < t_f$, otherwise

$$d_{pf} = \sum_i w_i \int_{t_{p0}}^{t_{p1}} dt\, e^{-(t-t_f)\ln 2/t_{i,1/2}}. \tag{3}$$

We consider imaging of the induced activity by a maneuverable PET scanner, such that during each imaging period p the PET scanner is in a different imaging position, denoted by α_p. In our case the open-ring PET scanner rotates during the time between delivery of each treatment field into a new

imaging position. The number of expected coincidences in line of response (LOR) j acquired during each period is

$$\tilde{y}_{jp} = \sum_v c_{jv}^{\alpha_p} \lambda_{vp}, \quad (4)$$

where $c_{jv}^{\alpha_p}$ is the system matrix describing the probability of detecting a positron annihilation in voxel v in LOR j while in imaging position α_p. Comparison to the recorded number of coincidences y_{jp} using the standard Poissonian likelihood function, along with the standard derivation of the MLEM method, leads us to the iterative update procedure

$$A_v^{f,(k+1)} = A_v^{f,(k)} \frac{1}{\sum_{pj} d_{pf} c_{vj}^{\alpha_p} a_j^{\alpha_p}} \sum_{pj} \frac{y_{jp} d_{pf} c_{vj}^{\alpha_p}}{\sum_{v'f'} A_{v'}^{f',(k)} d_{pf'} c_{v'j}^{\alpha_p}}, \quad (5)$$

where we also include attenuation correction via the term $a_j^{\alpha_p} = \exp\left(-\sum_v l_{jv}^{\alpha_p} \mu_v\right)$, which is the attenuation of LOR j in imaging position p through the patient geometry, defined by the mu map μ_v. This algorithm is unique, in that the activity induced by all fields influences the determination of the activity of all others.

The computational implementation of our algorithm now requires the system matrix of the scanner in multiple positions. We use the rotational, mirror, and translational symmetries of the scanner to generate the system matrix at each position α_p from only 3 stored system matrices, reducing the storage requirements by a factor of 25.5. The matrix elements $c_{vj}^{\alpha_p}$ are generated using a multi-ray approach, which accounts for the possible interaction points within each crystal. Inter-crystal scatter, scatter correction, and random corrections are not applied.

Data: $y_{jp}, c_{vj}^{\alpha_p}, w_i, t_{p0}, t_{p1}, \sum_j a_{vj}^{\alpha_p} c_{vj}^{\alpha_p}$

Calculate d_{pf} from t_{p0}, t_{p1};
$s_v^f = \sum_{pj} d_{pf} a_{vj}^{\alpha_p} c_{vj}^{\alpha_p}$;
Initialise all A_v^f;
for $k \leftarrow 1$ **to** N_{it} **do**
  $m_v^f \leftarrow 0$;
  for j, p; *s.t.* $y_{jp} \neq 0$ **do**
    Load $c_{vj}^{\alpha_p}$;
    $c \leftarrow \sum_{vf} A_v^f d_{pf} c_{vj}^{\alpha_p}$;
    $m_v^f \leftarrow m_v^f + \frac{1}{c} y_{jp} d_{pf} c_{vj}^{\alpha_p}$;
  end
  $A_v^f \leftarrow \frac{A_v^f m_v^f}{s_v^f}$;
end

The algorithm is implemented as indicated above. The measured and time stamped list mode data, y_{jp}, are read in, indicating which matrix elements $c_{vj}^{\alpha_p}$ must be loaded into memory. The assumed isotope composition along with the timing for the fields and imaging periods are used to calculate d_{pf}. The time and isotope weighted sensitivity maps are calculated. Following this, N_{it} MLEM iterations are applied.

3 Results

We simulated treatment of a brain tumour using 3 treatment fields, performed at a fixed Gantry angle of 90°, and couch angles -75°, 0°, and 90°. Following the delivery of each field the open-ring PET scanner is rotated by 90° in order to align with the next treatment delivery position. Treatment delivery and activation of the patient are simulated using the GPU accelerated Monte Carlo engine FRED [3, 4]. We scored production of ^{10}C, ^{11}C, ^{13}N, ^{14}O, ^{15}O, ^{30}P, and ^{38}K. The scored isotopes are then used as input in the Monte Carlo tool Gate [5], which simulates the decay of isotopes and the detection of produced gammas by the PET detector. The coincidences per second are shown in Fig. 1. It is clear that a significant portion of the counts recorded in the second and third imaging periods are due to the previously delivered fields. We also note that the count rate does not follow a typical exponential decay, as the rotation of the scanner moves the field of view of the PET scanner such that the higher sensitivity region overlaps with the activated region of the patient.

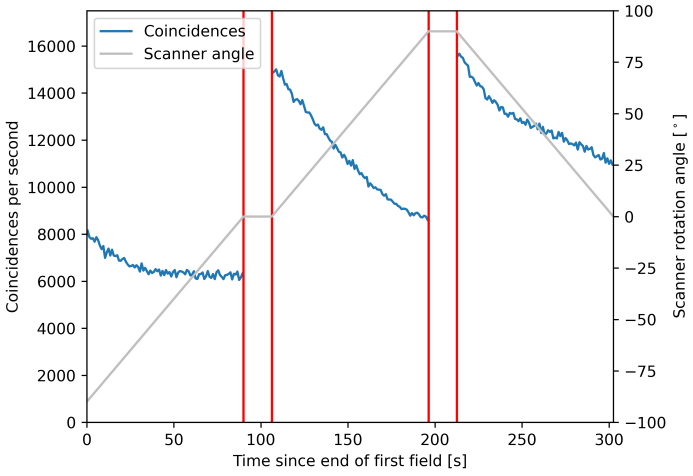

Figure 1: Coincidence rate and position of scanner over time. The red lines indicate the start and end of beam-on time.

We compare our novel MLEM algorithm to a simplified method which may be used to determine the activity induced by each individual field. The simplified method uses an image reconstructed from each imaging period, i.e. a direct reconstruction of λ_{vp}. Inversion of Eq. 2 then gives an estimation of A_v^f. The inversion of Eq. 2 is not strictly positive definite. 10 MLEM iterations were used for reconstructions using the simplified solution, while 30 iterations were used for the novel MLEM method. As the novel approach solves all 3 fields simultaneously, this leads to a comparable number of iterations for both techniques. We compare deduced images of A_v^f based on our technique

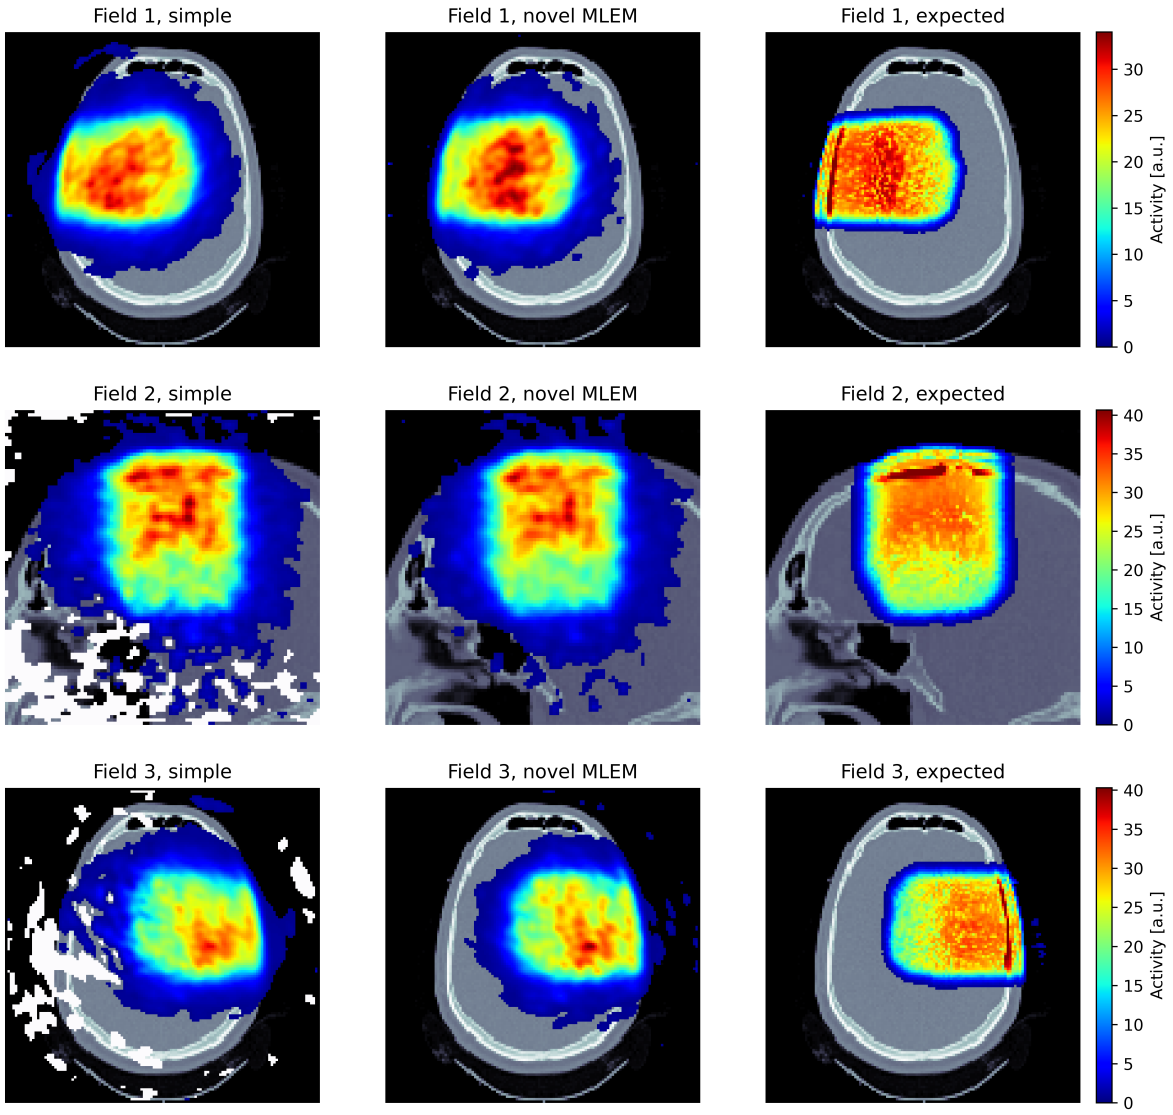

Figure 2: Reconstruction of A_v^f based on (left) a simplified solution to Eq. 2, and (middle) the novel MLEM algorithm proposed. The reconstructions are compared to the normalised predicted activity induced by each field (right). The activity predicted by the simplified solution for field 2 and 3 is negative in some regions, shown in white.

and a simplified approach in Fig. 2. The expected results shown in Fig. 2 are calculated using the distribution of the positron annihilation locations predicted by GATE.

Fig. 2 shows a reduced signal to noise ratio in all images using the novel MLEM, while showing comparable predicted distal fall off for all fields. In table 1 we the consider normalised root mean square error (NRMSE) and structural similarity index (SSIM) between the reconstructions and the predicted activity. For all fields the novel MLEM method has lower NRMSE by 0.4%-9.7% than the simplified method, while the SSIM is higher by 4.4%-17.3%.

As the intention of the reconstructed images is range verification in proton therapy, we also consider the range that may be assigned for each field. In order to assign a range we transformed the reconstructed images into beams eye view (BEV), and calculated the isoactivity surface along the beam direction. This gives a range value for each point in the plane tangent to the beam direction. Due to a lack of scatter correction, activity between 0-5 a.u. distal to the beam did not agree well with the expected activity distribution. We found that an isosurface at 16 a.u. gave good agreement across all fields, corresponding to approximately 50% of the high activity region in brain. The difference between the range assigned by the reconstructions and the expected distribution is shown in Fig. 3. In table 2 the average shift of the BEV

Table 1: NRMSE and SSIM between the expected activity distribution and the reconstructed activity using the novel MLEM approach and a simplified subtraction.

	Field 1	Field 2	Field 3
Novel MLEM (NRMSE)	0.253	0.216	0.266
Simple (NRMSE)	0.254	0.239	0.281
Novel MLEM (SSIM)	0.439	0.466	0.411
Simple (SSIM)	0.421	0.398	0.390

images are shown. For field 1 and 3 the range predicted by the novel MLEM is closer on average to the expected result, while for all fields the standard deviation in the shift is lower with the novel MLEM.

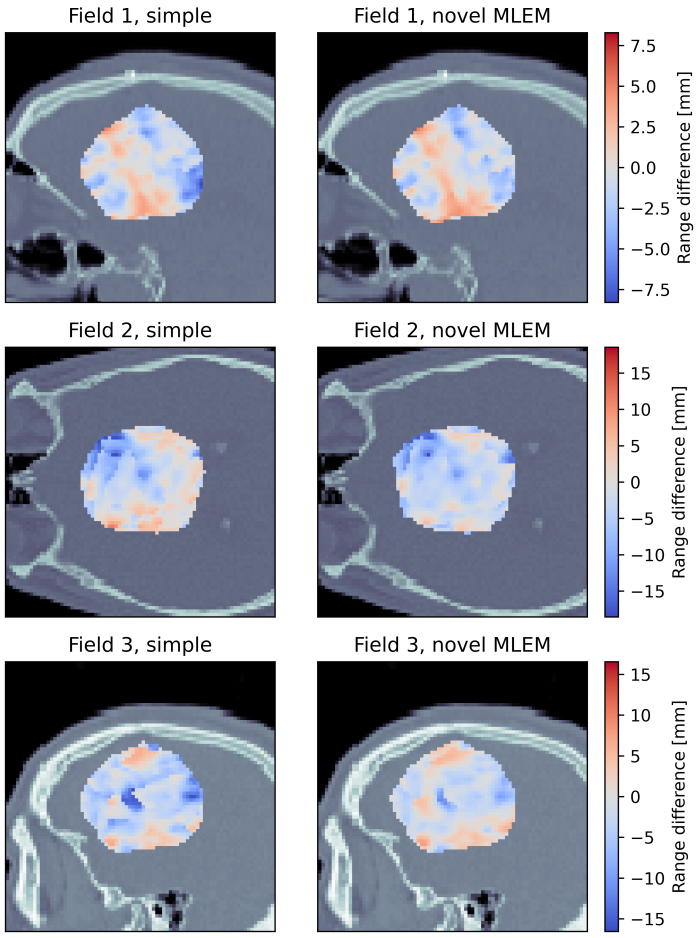

Figure 3: Difference in range assigned along the BEV at a fixed isoactivity curve. Difference is between the reconstructions and predicted total activity as shown in Fig. 2.

Table 2: Average (standard deviation) of the difference in range assigned for the isoactivity curves as shown in Fig. 3. All values in mm.

	Novel MLEM	Simple
Field 1	-0.2 (1.9)	-0.7 (2.0)
Field 2	-3.4 (3.6)	-2.1 (4.6)
Field 3	-1.0 (3.0)	-2.7 (4.0)

4 Discussion

Our algorithm introduces a possible approach for validation of the range of each field delivered in a multi-field proton therapy plan via PET imaging. The ability to disentangle the activity induced by each field may allow for verification of stopping power predictions, CT calibration, or even detection of anatomical changes between fractions.

We considered imaging of a 3 field proton plan, with imaging taking place over a 90 second period following each field delivery. This imaging scheme would allow for minimal interruption to the treatment workflow, as imaging occurs during the time required for couch and gantry movements. We found that our novel MLEM generated images with less noise than those generated via a simplified calculation of the activity. The NRMSE was between 0.4%-9.7% lower than the simplified approach, while the SSIM was higher by 4.4%-17.3%. The range predicted by both methods was comparable, however thanks to the lower noise we saw a lower standard deviation in the assigned range for all fields using the novel approach.

Throughout we have only considered a single patient example, and note that further work is required to assess the capabilities in different scenarios. Fields delivered at comparable angles may have significant overlap, and further work is required in order to test the capabilities of our algorithm to disentangle the activity of each field.

5 Conclusion

We have presented a novel MLEM algorithm for reconstruction of the PET activity induced by individual fields in multi-field proton therapy treatments. Use of a rotating open-ring scanner, such as the one recently built as part of the PETITION project, gives a unique opportunity for such in-beam and inter-field measurements. The determination of range on a field by field basis may allow for greater sensitivity and further applications of PET for treatment verification in proton therapy.

Abstract Dose and range monitoring with secondary radiation, like prompt-gammas, can help minimizing the range uncertainties in proton therapy. This work aims at the reconstruction of the delivered proton dose from prompt-gamma distributions. Some techniques have already been proposed in the literature to reconstruct the dose from secondary radiation, mostly positron emitters. Among them, very promising methods are the analytical deconvolution approach, the evolutionary algorithm and the maximum-likelihood expectation-maximization algorithm. Only the evolutionary algorithm has been applied to prompt-gamma distributions so far. Within this work, the applicability of these approaches to prompt-gamma distributions was assessed with simulated mono- and polynergetic proton beams irradiating homogeneous and heterogeneous phantoms. The reconstructed depth-dose profiles were compared with their corresponding simulated dose distributions using different metrics. Overall, the reconstructed dose profiles match the simulated ones, and range differences evaluated at different distal dose levels were found to be lower than or in the order of 1 mm.

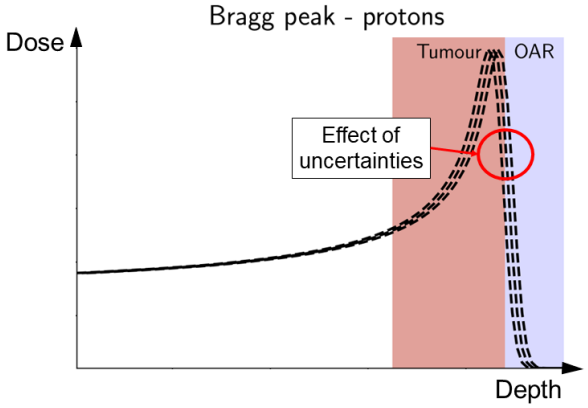

Figure 1: Effect of uncertainties on the dose deposited by protons.

1 Introduction

In cancer therapy, the characteristics of protons are in principle favourable compared to the ones of photons. The dose deposited by protons is lower in the entrance channel, it increases until a maximum, known as Bragg peak, is reached, and then it rapidly fall-off at the end of the particle path, better known as range [1]. The Bragg peak position can be tuned changing the initial beam energy. These properties allow the delivery of high doses to the tumor, while sparing the surrounding healthy tissues.

However, many factors can cause proton range uncertainties in clinical practice, among them the patient positioning, possible anatomical changes and the conversion from X-ray computed tomography (CT) numbers (measured in Hounsfield units) into tissue stopping power ratio relative to water. These uncertainties limit the achievable maximum potential of proton therapy [2, 3], as shown in figure 1. To achieve a more conformal dose distribution in the tumour target, it is necessary to monitor and, where needed, correct for such uncertainties. This is why *in vivo* range verification techniques were proposed in the past few years.

One possibility for range verification is through the detection of secondary prompt-gammas (PG), first proposed by [4] and then experimentally verified by [5]. The emission of PG is correlated with the penetration path of protons in tissue, and the measurement of PG can be used to draw conclusions on the proton range.

For range verification purposes, the expected PG signals related to planned dose distributions are needed. The expected PG distributions can be, for example, modelled by means of Monte Carlo simulations or by a filtering approach. The latter was introduced by Parodi and Bortfeld [6] to relate the positron emission tomography (PET) activity profile (i.e. 1D signal) to the depth-dose profile of proton irradiation. The main idea behind the filtering is the possibility to determine a PET profile from the convolution of a dose distribution with a so-called filter function f. Validation of this approach and its extension to 3D distributions and PG monitoring came with successive works [7–10].

Getting a direct information on the deposited dose from the PG emission is not straightforward: the underlying mechanisms of these two physical phenomena are different, governed by electronic and nuclear interactions, respectively. Using an inverse filter function f^{-1} to obtain the actual delivered dose from the PG distribution represents an ill-posed deconvolution problem. To face this challenge, several deconvolution techniques have been proposed in the literature. In this regard, three different approaches were chosen for their inherent use of the filtering formalism: the analytical deconvolution method [11], the evolutionary algorithm [12–14] and the maximum-likelihood expectation-maximization (MLEM) algorithm [15, 16]. These strategies were all applied to reconstruct dose delivered by protons from PET data, while the evolutionary algorithm also explored PG distribu-

tions [12, 14]. In the present work, the mentioned algorithms are applied to reconstruct dose deposited in homogeneous and inhomogeneous (slab) phantoms, for simulated pristine Bragg peaks and spread out Bragg peaks (SOBPs). The perfomance of the techniques are evaluated and compared in terms of different metrics.

2 Materials and Methods

The 1D signal $P(z)$ of PG emitted along the proton beam propagation depth z in a homogeneous target can be obtained from the corresponding 1D dose distribution $D(z)$ by convolving (i.e. filtering) the dose profile itself with a filter function $f(z)$:

$$P(z) = D(z) * f(z) \tag{1}$$

The filter functions can be calculated exploiting the so-called $\tilde{Q}_\nu$ functions, defined as convolutions of Gaussian and power-law functions. For the filter calculation, its properties and the extension to inhomogeneous targets, please refer to [6, 9, 10]. The analytical deconvolution approach [11], consists of an iterative maximum *a posteriori* approach (MAP) based on the minimization of the functional J:

$$J[D(z)] = S[D(z)] + \lambda R[D(z)] \tag{2}$$

S is a similarity term and its choice depends on the underlying noise distribution. For this work, a least-squares (LS) term was chosen:

$$S_{LS}[D(z)] = \int |D(z) * f(z) - P(z)|^2 dz \tag{3}$$

R is a regularization term, weighted against S by a factor λ. R considers a prior knowledge of the signal to stabilize the ill-posed deconvolution problem by adding some constraints to restrict the amount of the possible solutions. The Tikhonov-Miller (TM) regularization was chosen for this work, since its use was well motivated in the literature [11, 13]:

$$R_{TM}[D(z)] = \int |\nabla D(z)|^2 dz \tag{4}$$

In [11] it is pointed out that the noise amplitude in the reconstructed dose reflects the noise in PET signals. The same concept remains valid for PG signals. In this work, an attempt in trying to eliminate the noise was made exploiting the $\tilde{Q}_\nu$ functions formalism. One or more $\tilde{Q}_\nu$ functions can be used to fit dose and PG profiles. So, instead of optimizing bin by bin in the dose distribution as in [11], the optimization is carried out only in terms of $\tilde{Q}_\nu$ functions' parameters.
To define convergence of these deconvolution algorithms, in this work a tolerance value was defined, which sets the acceptable error on both the optimized variable (i.e. $D(z)$) and the minimized cost function (i.e. $J[D(z)]$). A tolerance equals to 10^{-10} was used in the deconvolution approach implemented as in [11], while a value of 10^{-6} was used for the optimization carried out only in terms of $\tilde{Q}_\nu$ functions' parameters.

The evolutionary algorithm consists of iteratively mutating a population of N depth-dose profiles $D_j(z)$, which are convolved with the filter functions, in order to obtain predictions of depth-PG profiles $P_j(z)$. Each of these j-th depth-PG predictions is compared to the ground-truth one, potentially measured. The agreement of each comparison j at every iteration i is assessed by a quantity called fitness value f_j^i:

$$f_j^i = \frac{1}{1 + NRMSE[D_j^i(z)] + \lambda R[D_j^i(z)]} \tag{5}$$

$NRMSE$ is the normalized root mean squared error for the j-th individual, R is the regularization term and λ the balancing factor. To select which individuals will be propagated in the following iteration $i+1$, a fitness selection is applied. In this work, for the evolutionary algorithm a maximum number of iterations equals to 1500 was enough to reach convergence. The algorithm was anyway stopped earlier if the difference between the NRMSE calculated on the depth-PG profiles between successive iterations was lower than a defined tolerance value, set to 10^{-8}.
In the MLEM algorithm, the convolution used to calculate the filter is expressed in its equivalent matrix product form. A system matrix C based on the filter functions is built. The dose reconstruction algorithm is based on the maximization of the likelihood, defined as the probability that a certain PG distribution at the voxel i obtained from applying the filtering to a dose distribution corresponds to the related measured signal P_i. If the dose in a certain voxel j at the iteration k is defined as δ_j^k, the regularization term as R and the balancing factor as λ, the likelihood maximization brings to the MLEM formula:

$$\delta_j^{k+1} = \frac{\delta_j^k}{\left[1 + \lambda \left(\frac{dR}{d\delta^k}\right)_j\right] \sum_i C_{ij}} \sum_i \frac{P_i C_{ij}}{\sum_j C_{ij'} \delta_{j'}^k} \tag{6}$$

The convergence criterion for the MLEM algorithm applied in this work was similar to the one used for the evolutionary algorithm. The maximum number of iterations was set at 150, while the tolerance value was equals to 10^{-6}.
The simulated depth-dose and PG emission profiles were obtained with the general purpose MC toolkit Geant4 [17], version 10.07.p03. The performances of the algorithms were compared via evaluation of different metrics to assess the match between the simulated and the reconstructed dose profiles: the NRMSE, evaluated over the entire curve and also only on the distal area; the $|\Delta R_{80}|$, $|\Delta R_{50}|$ and $|\Delta R_{10}|$, where $|\Delta R_{\%}|$ is defined as the absolute difference between the distal positions corresponding to the defined percentage (%) of the dose of the two compared curves; the peak (for single Bragg peak cases) or plateau (for SOBP) width (pw) percentage difference $\Delta pw(\%)$ between the reconstructed curve (rec) and the simulated (ground truth, GT) one, defined as

$$\Delta pw(\%) = 100 \cdot \frac{pw_{rec} - pw_{GT}}{pw_{GT}} \tag{7}$$

3 Results

Examples of obtained results related to the reconstruction of SOBP curves in the slab phantom are shown in figure 2. Table 1 collects the different metrics used to compare the reconstructed distributions in figure 2 with the simulated one.

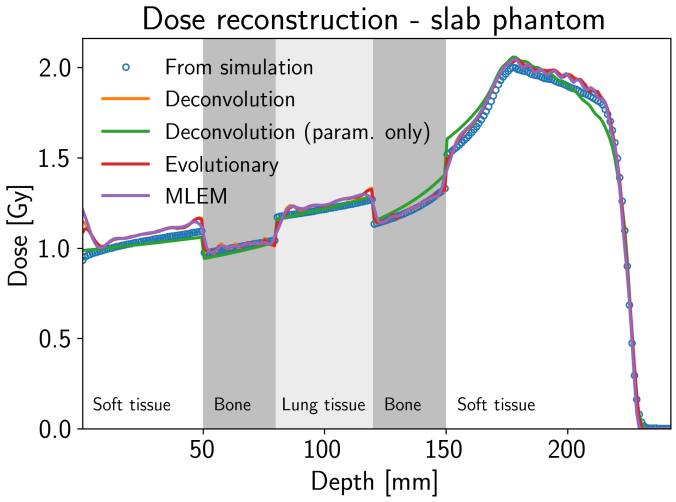

Figure 2: SOBP reconstruction in the slab phantom.

Table 1: Metrics used to compare the SOBP reconstructed in the slab phantom with the simulated one.

Metric	Deconvolution	Deconvolution (param. only)	Evolutionary	MLEM
NRMSE ($\times 10^{-2}$)	3.2	3.3	3.1	3.5
NRMSE plateau ($\times 10^{-2}$)	2.7	3.92	2.6	2.8
$\lvert\Delta R_{80}\rvert$ (mm)	0.37	1.18	0.39	0.58
$\lvert\Delta R_{50}\rvert$ (mm)	0.07	0.19	0.12	0.32
$\lvert\Delta R_{10}\rvert$ (mm)	0.18	0.07	0.17	0.36
Δpw (%)	-0.79	-17.75	0.24	-4.29

4 Discussion

Three algorithms already applied in the literature to reconstruct depth-dose profiles from PET signals were applied in this work to depth-PG distributions: the deconvolution approach, the evolutionary algorithm and the MLEM algorithm. The feasibility of the methods in the context of PG monitoring was validated via application to simulated depth-dose and depth-PG profiles in homogeneous and inhomogeneous (slab) phantoms, for pristine Bragg peaks and SOBPs. Looking at the metrics, the range differences $|\Delta R_{\%}|$ at different distal percentages of the dose maximum are generally lower than 1 mm (only one value is higher).

The reconstructed dose profiles exhibit noise, which reflect the noise present in the PG distributions. The analytical deconvolution approach in terms of $\tilde{Q}_v$ functions parameters was introduced to eliminate the noise in the reconstructed curves. This method has also the advantage of speed. However, the approximations introduced in this method makes it less accurate than the other methods, as can be noticed comparing the shown plots and the values of the different metrics, especially the NRMSE. This technique can anyway still be improved and the advantages are worthwhile being futher investigated.

The evolutionary algorithm was already applied to PG data [12, 14]. However, this work is still innovative for aspects related to the generation of the filters, in particular to how their small energy dependence is tackled, and how they are applicable to inhomogeneous targets. In fact, differently from [12, 14], in this work the filters found in a homogeneous target were optimized for energy values within the entire clinically used range. Also, to deal with inhomogeneous targets, instead of performing a double evolutionary algorithm as in [14], the filter is first generated in a homogeneous space, then range conversions and factors related to tissue composition are applied.

In the MLEM application, the regularization was applied differently than in [15, 16], where the MLEM algorithm was implemented in two steps and the total-variation (TV) regularization was applied to the dose itself, in an algorithm referred to as EM-TV algorithm. In this work, a TM regularization was applied as in the other methods in order to make a meaningful comparison among them. For the same reason, instead of working on the signal itself, the regularization was applied to the objective function, i.e. the likelihood, by implementing a Bayesian reconstruction. To carry this out, the one-step-late (OSL) approximation, introduced first by [18], was used.

Future work foresees the reconstruction from detected PG data instead of emitted ones. This would allow to study more realistic scenarios, where PG noise has a major impact compared to simulations. At first, a simulated detection response is going to be implemented, following the behaviour of already commerciable available PG cameras. Measurements will be then used for algorithm validation. A study of the algorithms behaviour when different levels of noise are present is planned.

Difference metrics and criteria (i.e. number of iterations and tolerances), which were described in section 2, were applied to define the convergence of the algorithms. A comparative convergence analysis within the different algorithms, based on the same metrics and criteria, is foreseen.

A work in progress is related to the extension of the approaches to 3D distributions, and to the consideration of lateral heterogeneities, in order to be able to reconstruct the entire dose distributions from emitted PG in more complex phantoms and patients.

The emission of PG happens in a timescale below the nanosecond. This makes PG suitable for the final purpose of real-time adaptive particle therapy (RT-APT) applications, towards which the interest of the radiotherapy community is increasing. Based on benefits seen from online adaptive

proton therapy [19, 20], RT-APT aims at reducing proton therapy uncertainties not only between treatment fractions (inter-fraction), but also during a single fraction itself (intra-fraction). A simple scheme of how the dose reconstruction from PG would be involved in the RT-APT workflow is presented in figure 3. During the delivery, the dose distribution reconstructed from PG detected during the irradiation of each spot would be compared, in a short time frame, with the planned dose distribution. In case of mismatches, adaptation measures would be applied. This work is thought to represent a step forward this direction.

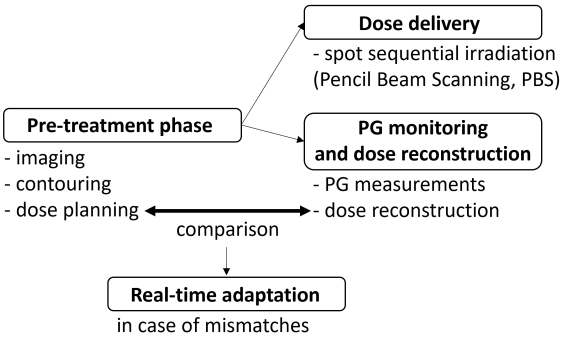

Figure 3: Scheme of RT-APT workflow.

5 Conclusion

PG yields can be exploited to tackle the challenges of dose evaluation in proton therapy. Here, the analytical deconvolution approach, the evolutionary algorithm and the MLEM algorithm, which allow to reconstruct the dose from secondary radiation, were applied successfully to perform dose reconstruction from emitted PG signals coming from simulated 1D mono- and polyenergetic beams in homogenous and heterogenous (slab phantom) targets. Extension to 3D signals and to phantoms with lateral inhomogeneities is in progress. Detected PG data will replace the emitted ones in future, and measurements will be considered for validation. This project is thought to represent a step forward real-time adaptive particle therapy.

This work is performed as part of the RAPTOR project, funded by the EU's Horizon 2020 MSCA, G.A. No. 955956.

Abstract Carbon ion therapy provides high accuracy in targeting tumors while sparing healthy tissues, and could highly benefit from possibilities of range verification due to its sensitivity to range uncertainties. Positron emission tomography (PET) is commonly used for range verification, but as PET signals are not directly proportional to dose distributions, comparing them to a predicted positron emitter distribution (PED) is one viable approach. To this end, an analytical approach was previously suggested to predict 1D PED from depth dose profiles. We revised this method by introducing finer modelling functions and considering more positron emitters, and extended it to 3D. In this contribution, we present our proposed 3D PED generation framework based on a pencil beam algorithm and ray-casting method. The method is validated in in-silico studies against full Monte Carlo calculations for several phantoms as well as realistic computed tomography (CT) scans from patient data.

1 Introduction

Carbon ion therapy, benefiting from its characteristic Bragg peak, allows a high accuracy in targeting tumors while sparing healthy tissues. Moreover, carbon ions exhibit higher linear energy transfer (LET) and relative biological effectiveness (RBE) compared to photons and protons, making carbon ion therapy a good treatment option against various cancers [1].

However, range uncertainties can lead to improper dose delivery. Therefore, range verification is highly advantageous, with positron emission tomography (PET) being the most commonly used method [2, 3]. Since the PET signal is not directly proportional to the delivered dose, the measured activity and dose distribution cannot be directly compared to each other [4]. A prediction of the positron emitter distributions (PED) can be obtained with Monte Carlo (MC) simulations, and comparing it to the measurement allows for treatment verification [5]. Despite their accuracy, MC simulations require high computational effort and are time consuming.

To overcome this, alternative analytical methods for PET prediction have been developed. An experimental-based approach predicted PED by linear superposition of positron emitter yields from different reference materials [6], and Helmbrecht et al. [7] extended this approach to 3D PED calculations, though they have limitations in predicting projectile fragment distributions. Another analytical approach, suggested by Hofmann et al. [8], modified a filtering approach originally designed for proton therapy [9] to adapt it for carbon ion therapy. This method, however, was primarily investigated in 1D or quasi-3D scenarios, and exhibited some inaccuracies especially in vicinity of air cavities.

In this work, we addressed the issues found in [8] by introducing finer modelling functions, considering more positron emitters (PE) and suggesting a mapping process for handling longitudinal heterogeneity effects for projectile PED, and extended the computational framework to 3D PED prediction. MC simulations for generation of the initial reference databases are used. A dedicated framework based on a pencil beam algorithm (PBA) to predict 3D PED is proposed, which includes improvements over the 1D PED prediction approach, the parametrization of PED's lateral properties, and methods for handling both lateral and longitudinal heterogeneity effects. In-silico validation studies using different homogeneous and inhomogeneous phantoms, as well as clinical CT data are conducted, with results discussed in section 3.

2 Materials and Methods

2.1 Generation of reference databases by Monte Carlo simulations

The MC method, considered as a golden standard for simulating radiation interactions with matter, is widely used in imaging and radiotherapy. The MC toolkit Geant4 [10] version 10.07.p04 is used in this work to simulate the production of PE by carbon ion irradiation. The physics list QGSP_BIC is selected for the modelling of physical processes.

MC simulations were preformed in a cylindrical phantom of a homogeneous reference material. The so-called reference material consists of six elements (H, C, N, O, P and Ca) which contribute to the main production of PE in human tissue, ans its properties are shown in table 1. In the simulations, mono-energetic and mono-directional carbon ion pencil beams with initial lateral sigma σ_0 of 3 mm hit the surface center perpendicularly, and five isotopes ^{11}C, ^{10}C, ^{15}O, ^{13}N and ^{14}O were considered and scored. Among the five PE considered, ^{11}C and ^{10}C were further categorized into projectile and target contributions based on their kinetic energy. The simulations were performed for 36 initial energies

Material	Ref.	Brain	Bone	Water
Mass density (g·cm^{-3})	1.54	1.04	1.85	1.00
Electron density (10^{20} cm^{-3})	4.71	3.45	5.91	3.34
Mass abundances				
Hydrogen (H)	2%	11%	6%	11%
Carbon (C)	31%	15%	28%	-
Nitrogen (N)	26%	2%	3%	-
Oxygen (O)	38%	71%	41%	89%
Phosphorus (P)	1%	-	7%	-
Calcium (Ca)	3%	-	15%	-

Table 1: Properties of the materials considered for the phantoms and for the reference material (Ref.)

from 80 to 430 MeV/n with increments of 10 MeV/n and for a total 5×10^8 carbon ion primaries. The number of PE and dose were sampled with cylindrical scoring at 0.2 mm radial binning and at 0.5 mm in depth.

2.2 Framework for Calculating 3D PED

A dedicated framework based on a pencil beam algorithm (PBA) was developed to construct 3D PED. This framework required a similar input structure to the PBA[11] used for 3D dose computation, including the laterally integrated depth positron emitter distribution (IDPED), lateral distribution, and material and beam information.

IDPED was derived using analytical functions combined with a filtering approach on the laterally integrated depth dose (IDD) at corresponding energies in the reference material. The parameters of these analytical functions were predefined using IDD and IDPED data from MC simulations in the reference material. In practical applications, IDD in the reference material is reconstructed from the 3D dose distribution per ion beam spot. Following this, IDPED is predicted by applying the filtering approach to the reconstructed IDD, and then utilizing the analytical functions.

The lateral properties of PED were parameterized using Gaussian distributions. For projectile PE, a single Gaussian distribution was used to account for the lateral off-axis contributions. For target PE, a double Gaussian parametrization method was adopted. The resulting sigma parameters were corrected by quadratic subtraction of the initial beam σ_0.

Predicting PED in heterogeneous media required adaptations for longitudinal and lateral heterogeneity effects. For the longitudinal heterogeneity, one needs to consider residual ranges across different materials and the contributions of different reaction channels to the total PE density. The depth in heterogeneous media was converted into a reference-material-equivalent depth for prediction in reference space. As the production of PE is influenced by the nuclear density of target nuclei and the characteristics of the tissue, a local factor $g_i(z)$[9] is employed to adjust the weight of different production channels for target PED. For projectile PED, a mapping process was conceptualized, associating each voxel

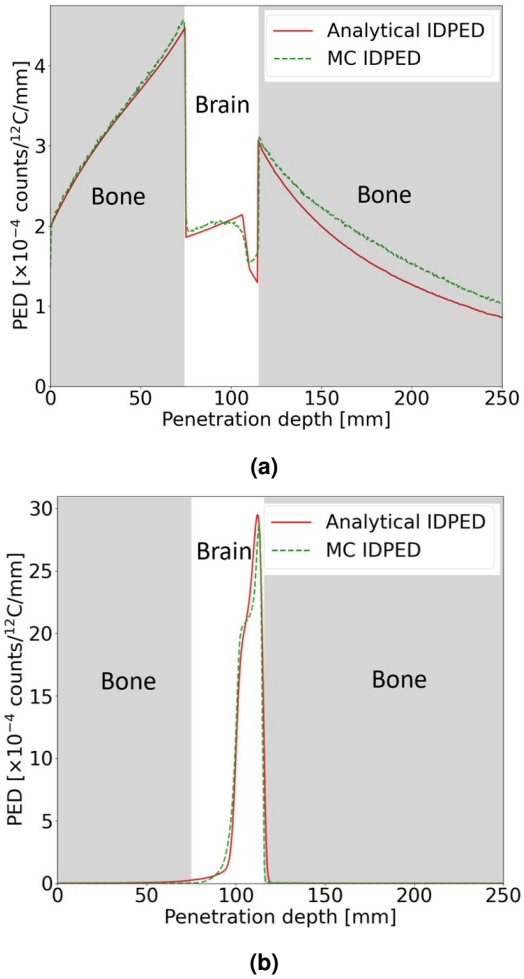

Figure 1: IDPED for (a) $^{11}C_{target}$ and (b) $^{11}C_{proj}$ of a ^{12}C ion beam of 300 MeV/n in a heterogeneous slab phantom by analytical method and Geant4 MC simulation. Slabs were created with brain and compact bone materials shown in table 1.

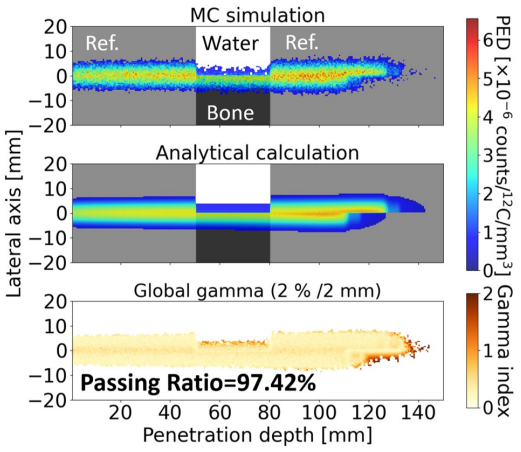
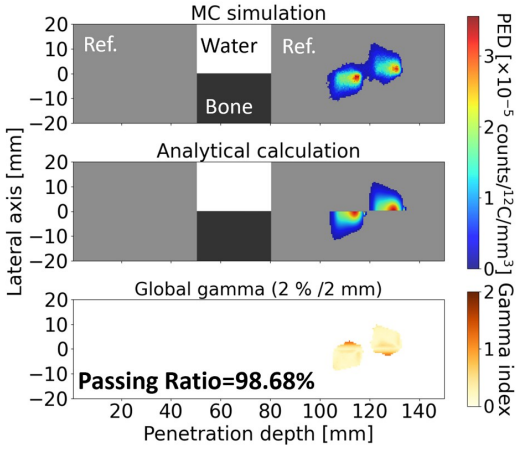
where projectile PE eventually stop (stopping voxels) with the voxels that originally produce them (producing voxels). The material effect on PE's production at each producing voxel was counted by the same $g_i(z)$ factor, then the produced PE at producing voxels was arranged into stopping voxels based on the established mapping relationship. For the lateral heterogeneity, the ray-casting method [12] is used.

2.3 In-silico Validation Studies

Validation studies were conducted using MC simulations and our analytical approach's calculations with several phantom configurations, including slab like inhomogeneous phantoms and patient based on CT data from the Heidelberg Ion-Beam Therapy Center (HIT) [13]. Mono-energetic and mono-directional ion pencil beams with initial sigma σ_0 of 3 mm was adopted for the cases with the slab phantoms, and several spots extracted from actual patient treatment plans from HIT were simulated.



(a)



(b)

Figure 2: 2D PED for (a) $^{11}C_{target}$ and (b) $^{11}C_{proj}$ of a ^{12}C ion beam of 300 MeV/n with FWHM of 7.1 mm in a laterally heterogeneous phantom by analytical method and MC simulation.

3 Results

Figure 1 shows the slab phantom arranged in a bone-brain-bone composition. We used the two materials with significant elemental differences to validate our method in addressing the impact of longitudinal heterogeneity on the distribution of target and projectile PE. Figure 1(a) and (b) displays the IDPED results for $^{11}C_{target}$ and $^{11}C_{proj}$ by analytical method and MC simulation. These profiles' trends and heights in different regions are in reasonable agreement with the simulation results. To quantify their differences, we calculated their normalized root-mean-square error (NRMSE) as 0.0534 and 0.0313, respectively, which were normalized by the difference between maximum and minimum. The brain region contains the distal fall-off positions of both the $^{11}C_{target}$ and $^{11}C_{proj}$ profiles, where the analytical results and simulation results show sufficiently close falling positions. The noticeable difference in Figure 1(a) is in the tail part, mainly due to deviations in the amplitude of the tail modelling function when initially constructing the IDPED in the reference space compared to the simulation results.

Figure 2 presents the two-dimensional results for $^{11}C_{target}$ and $^{11}C_{proj}$ in the presence of lateral heterogeneity. Slabs composed of water and bone are inserted vertically in the middle of the phantom, one on top of the other. The discrepancies between analytical and simulation results were evaluated through global gamma analysis. For the 2%/2 mm criteria, the passing ratios were 97.42% and 98.68%, respectively. The satisfactory passing rates demonstrate the effectiveness of using the ray-casting method to address longitudinal heterogeneity. However, there are noticeable differences in the longitudinal distribution in Figure 2(b): the analytical result shows clear boundaries due to lateral heterogeneity, while the simulation results do not. This is because particles undergo scattering, causing blurring at the boundaries, whereas the ray-casting method can only consider heterogeneity in a straight-line propagation manner, making the boundaries clearer [12]. However, for heavy ions, their scattering is relatively minor, so the errors introduced by the ray-casting method are acceptable.

Figure 3 shows the total distribution of all the five PE produced by one ion pencil beam of 192.13 MeV/n extracted from an actual treatment plan from HIT [13] calculated by MC simulation and our analytical approach. The ion beam's delivery was implemented using the phase space of [14]. The discrepancies between analytical and simulation results were evaluated through global gamma analysis. For the 2%/2 mm criteria, the passing rate is 99.91%. For the 1%/1 mm criteria, the passing rate is 91.75%.

4 Discussion and Conclusion

This work improves upon and extends [8] to three-dimensional PED calculation. Hofmann et al. [8] primarily explored the possibility of predicting 1D PED by combining a filtering method [9] with analytical modelling. Our work first improves upon this method, considering a more comprehensive range of energies and types of positron emitters, along with proposing more detailed one-dimensional analytical modelling functions. Additionally, we extended the improved one-dimensional method to three dimensions based on the pencil beam algorithm. The lateral properties of PED are obtained through Gaussian fitting. This ensures that the lateral properties of PED considered both the primary and secondary fluence.

The feasibility of our approach was demonstrated by our in-silico studies. In terms of clinical interest, we also demonstrated the predicted results of a beam spot's PED using patient data, which verified the feasibility of our method under more practical conditions.

Our next step will involve MC simulations and analytical predictions based on complete treatment plans, coupled with measured PET data, to facilitate a more comprehensive validation of our method.

Abstract Temporally feathered radiation therapy (TFRT) is a new technique where several iso-curative sub-plans deliver an alternance of high and low doses to the same number of feathered organs-at-risks (OARs) to exploit the dynamic recovery process of healthy tissues. The goal is that each OAR receives, in alternance, one high dose and four low doses where enhanced repair can take place to offset the sub-lethal damage caused during the high dose fraction. The aim of this work is to enable simultaneous optimization of multiple sub-plans within one treatment course for TFRT planning. A clear high to low dose pattern was achieved for an academic case according to different TFRT planning objective variations (soft, medium, and hard). Feathering was also achieved for a clinically motivated head and neck case with high to low dose patterns and/or reduction in total mean dose for the ipsilateral parotid and submandibular glands, pharynx, oral cavity, and larynx.

1 Introduction

In radiation therapy, the same treatment plan is generally delivered five days per week for several weeks with spatial distribution of the dose being a crucial aspect of treatment plan quality. Highly conformal dose distributions can be obtained using inverse planning for intensity-modulated treatment techniques. Nevertheless, we may be reaching a limit in our capability to shape the spatial dose distribution. New approaches have been proposed to optimize the temporal dimension through which radiation therapy is delivered: different dose distributions are delivered on different treatment days. For example, in temporally feathered radiation therapy (TFRT), five sub-plans are created to deliver a homogeneous dose to the target volume for each sub-plan (iso-curative) with an alternance of high and low doses to five feathered organs-at-risks (OARs) to exploit the dynamic recovery process of healthy tissues [1]. The goal is that each feathered OAR receives each week one high dose and four low doses where enhanced repair can take place to offset the sub-lethal damage caused during the high dose fraction. A potential additional benefit of TFRT is that, for the same number of beams/arcs delivered per fraction, the total physical dose in the composite TFRT plan may be lower than in a standard non-feathered plan because there are more degrees-of-freedom to solve the optimization problem when five different plans are optimized instead of one. However, currently, all sub-plans have to be created independently and then combined for evaluation which is cumbersome and may result in sub-optimal solutions.

Here, we implement simultaneous optimization of multiple plans within one treatment course in an in-house optimizer. We simultaneously optimize five TFRT sub-plans for one academic and one clinically motivated head and neck case.

2 Materials and Methods

Our in-house optimizer uses Monte Carlo calculated beamlet doses and direct aperture optimization (DAO) to optimize the apertures shape and monitor unit (MU)-weights for a variety of treatment techniques, deliverable on standard linacs [2,3]. The optimization's goal is to minimize the cost-function consisting of upper and lower dose-volume objectives, generalized equivalent uniform dose objectives (gEUD) [4], and normal tissue objectives.

2.1. Multi-optimization workflow

In this work, the in-house optimizer was modified by including a MultiManager class that simultaneously handles multiple sub-plans, each with their set of apertures, and dose distribution for a given number of fractions. Each sub-plan has a cost-function consisting of objectives on the sub-plan dose distribution and "total objectives" evaluated on the composite dose distribution (the sum of all sub-plans dose distributions).

As illustrated in figure 1, in each DAO iteration, all sub-plans are cloned (clones 1-5). The aperture with the steepest gradient on the cost-function is added and the resulting sub-plan cost-function is updated for each clone in parallel (F_i', i = 1-5). The total cost-function, F_{tot}, is calculated based on the updated cost-function for the cloned sub-plan and the current cost-function for the other sub-plans. The clone that offers the best total objective function is selected and the corresponding sub-plan is updated; the other clones are deleted.

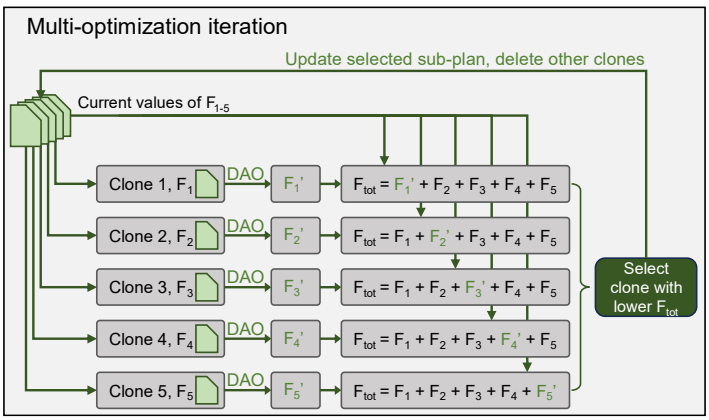

Figure 1: In each multi-optimization iteration, apertures are added/modified in the sub-plan that offers the best total cost-function F_{tot}. F_{1-5} consists of objectives on the sub-plan dose distribution as well as on the total dose distribution.

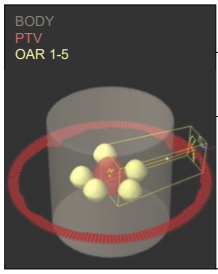
2.2. TFRT planning

An academic case (figure 2) was designed to test the multi-optimization workflow for TFRT planning. The phantom is cylindrical with a planning target volume (PTV) surrounded by five spheroid OARs, arranged asymmetrically.



Structure	Dimensions [cm]	Center of mass position [cm]			Distance to PTV [cm]
		x	y	z	
Body	25.0 Ø	0.0	0.0	0.0	
PTV	7.0 Ø axial, 8.6 SI	1.6	-0.9	0.0	
OAR1	5.0 Ø	-2.0	-5.6	-1.2	0.2
OAR2	5.0 Ø	5.0	-5.7	0.4	-0.1 (overlapping)
OAR3	5.0 Ø	7.5	0.7	-0.3	0.1
OAR4	5.0 Ø	1.6	5.0	-0.7	0.0 (abutting)
OAR5	5.0 Ø	-3.9	0.6	1.3	0.0 (abutting)

Figure 2: Academic case description. SI: superior-inferior.

A standard volumetric modulated arc therapy (VMAT) plan was created as reference. Three variations (soft, medium, hard) of TFRT plans were created using VMAT, with the multi-optimizer. Individual sub-plan objectives and total objectives were used as described in table 1. The three TFRT variations have increasing difference in high to low mean dose objectives (gEUD with t = 1). Note that the average of one high and four low dose objectives is the same in all three variations and corresponds to the objectives of the standard plan and the total objectives for the TFRT optimization.

A standard and TFRT plan were also created for a clinically motivated head and neck case on an anthropomorphic phantom (locoregionally advanced oropharyngeal carcinoma with unilateral elective nodal volume [5]) prescribed 50 Gy to 95% of the PTV in 25 x 2 Gy.

Table 1. Mean dose objectives (in % of prescribed dose) to the OARs for the standard plan and three TFRT variations.

	Standard	TFRT variations		
		soft	medium	hard
Objectives for dose from individual sub-plan				
High dose	-	36	44	52
Low dose	-	26	24	22
Objectives for total dose distribution				
All OARs	28	28	28	28

The feathered OARs were the ipsilateral parotid gland, ipsilateral submandibular gland, pharynx, oral cavity and larynx. The average of the high/low mean dose objectives in the subplans equaled the total objectives for the TFRT optimization and the standard plan (table 2).

Table 2. Mean dose objectives (in % of prescribed dose) to the feathered OARs for TFRT and standard plan for the clinically motivated case. PG: parotid gland, SMG: submandibular gland, OC: oral cavity, IL: ipsilateral

	PG R	SMG R	Pharynx	OC	Larynx
High dose	62.0	84.6	90.0	66.0	84.6
Low dose	42.0	64.6	70.0	46.0	64.6
Standard / total TFRT	46.0	68.6	74.0	50.0	68.8

Standard and TFRT plans are compared based on OAR dose in the sub-plans as well as on the total dose distribution.

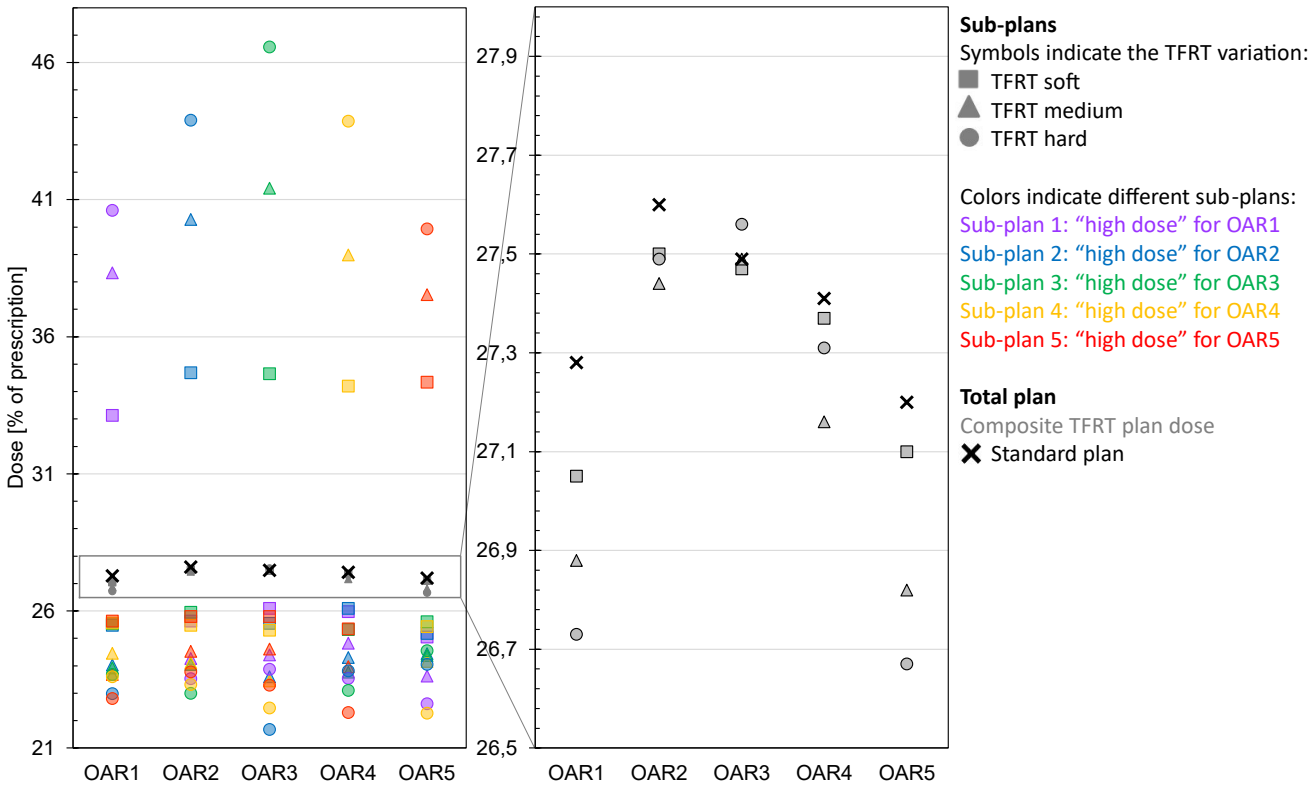


Figure 3: Dose received by the five OARs of the academic case in the three different TFRT variations (different symbols). Each color shows the dose received by all OARs for one sub-plan with high dose to a specific OAR. The right panel shows a zoom on the values for the reference standard plan and the composite TFRT plan.

3 Results

All sub-plans were iso-curative for the academic case. Figure 3 shows the dose received by each OAR in the TFRT sub-plans (colors) and composite plans (grey) as well as in the standard plan (crosses). The high to low dose alternance is visible in the color pattern. The greater differences achieved between high and low doses from the "soft" to the "medium" and to the "hard" TFRT variations are also visible in the symbol pattern. The dose for the composite TFRT plan (grey symbols) is lower than for the standard plan for OARs 1, 2, 4, and 5. For OAR3, the doses are similar in all composite TFRT and in the standard plans.

Figure 4 shows the DVHs for the feathered OARs and the PTV for each TFRT sub-plan (scaled to full prescription),

Mean dose (% of prescribed dose) to the feathered OARs.

	TFRT 1	2	3	4	5	tot	standard
IL PG	51.5	49.1	52.4	49.9	57.3	51.5	53.2
IL SMG	70.7	70.9	71.1	79.4	69.4	71.5	71.7
Pharynx	78.7	76.9	80.6	77.7	78.7	77.8	79.2
OC	56.1	60.3	56.1	54.7	53.4	55.6	55.2
Larynx	74.8	68.7	69.5	69.4	71.3	70.1	70.9

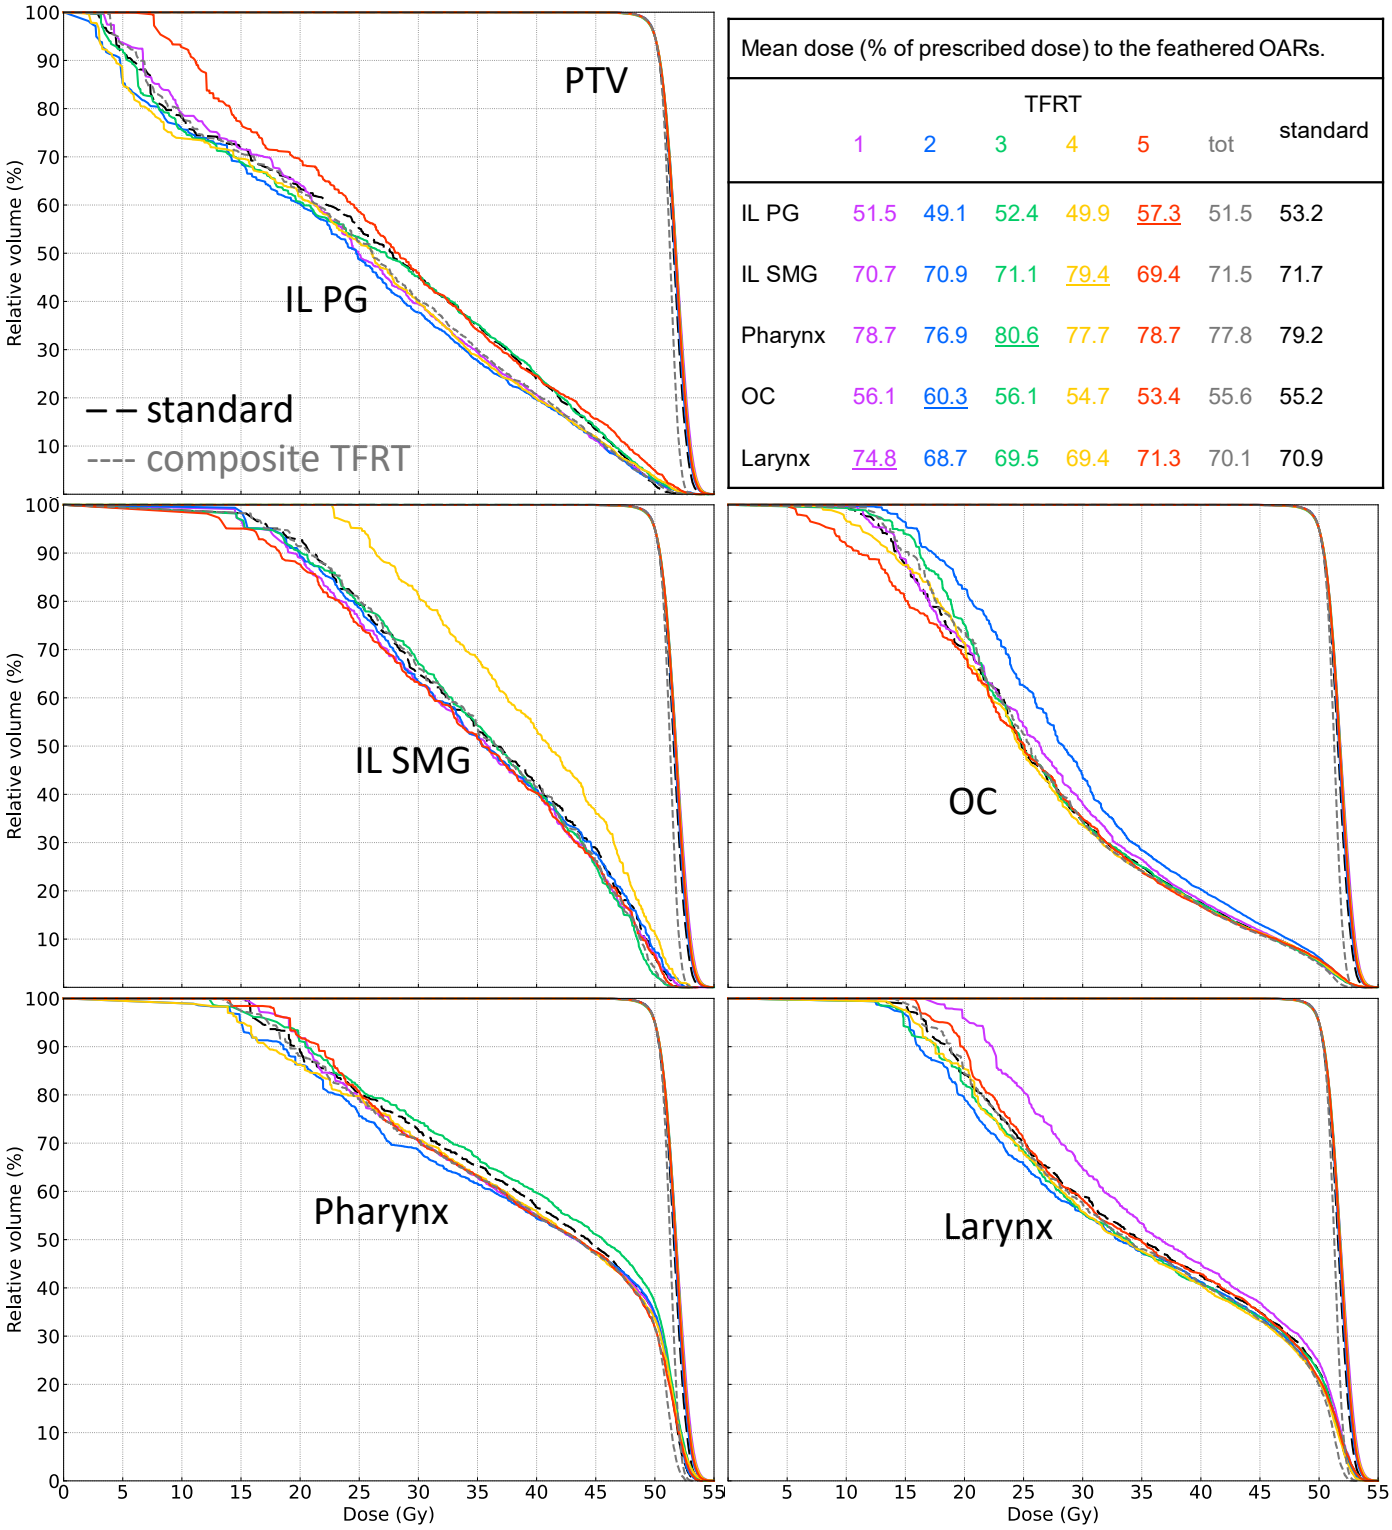

Figure 4: DVHs for the feathered OARs in the clinically motivated plan. The achieved mean dose to the feathered OARs in each sub-plan, in the total TFRT plan and in the standard plan are reported in the table. PG: parotid gland, SMG: submandibular gland, OC: oral cavity, IL: ipsilateral. Each color represents a sub-plan, the thin dashed grey line represents the composite TFRT plan and the black dashed line represents the standard plan.

the composite TFRT plan, and the standard plan for the clinically motivated case. The mean doses to the OARs are indicated in the table with the OAR receiving the high dose in each sub-plan underlined.

The TFRT sub-plans are iso-curative but have slightly less homogeneous PTV coverage than the standard plan, however the composite TFRT plan is the most homogeneous.

The high and low dose pattern is evident for the submandibular gland, oral cavity, and larynx. For these three OARs, the mean dose in the composite TFRT plan is close to that of the standard plan with 35.9 Gy (standard) and 35.7 Gy (TFRT) for the submandibular gland, 27.6 Gy (standard) and 27.8 Gy (TFRT) for the oral cavity, and 35.5 Gy (standard) and 35.1 Gy (TFRT) for the larynx.

The high and low dose pattern is less marked for the parotid gland and the pharynx although still noticeable. However, the mean dose in the composite TFRT is lower than in the standard plan with 26.6 Gy (standard) and 25.8 Gy (TFRT) for the parotid gland, and 39.6 Gy (standard) and 38.9 Gy (TFRT) for the pharynx.

4 Discussion

We have successfully implemented DAO-based simultaneous optimization of multiple plans within one treatment course in our in-house optimizer. The different plans are optimized using standard upper, lower, generalized equivalent uniform dose, and normal tissue objectives, but these can be applied (and combined) to the individual sub-plan dose distribution and to the total dose distribution. In each DAO iteration, an aperture is added to the sub-plan where most benefit over the overall objective function is expected.

We have characterized the high to low dose pattern and the resulting composite TFRT dose for an academic case with a PTV surrounded by five OARs. The high to low dose alternation was well correlated with the differences in high and low dose objectives (soft, medium, and hard TFRT variations) applied to the sub-plans. This alternation is expected to have a biological benefit on healthy tissue repair [1].

In addition, the mean dose in the composite TFRT plan was lower than in the standard plan for four out of the five feathered OARs despite the fact that they had the same total dose objectives. This can be explained by the greater number of degrees-of-freedom for the optimization: for TFRT, five times one VMAT arcs are optimized and the pool of possible apertures is therefore five times greater than for the standard plan with one VMAT arc. This advantage might vanish if the standard plan used 5 arcs or more, however, delivery time would be increased.

The TFRT optimization method was also successfully applied to a clinically motivated case, despite a more complex geometry with substantial PTV/OAR overlap.

Although five OARs and five sub-plans were considered, the multi-optimizer can handle an arbitrary number of sub-plans and number of fractions per sub-plan. Another potential application is to simultaneously optimize the phases of a sequential boost plan.

Future developments will include the design of objectives that consider the difference in mean dose to the OARs between two sub-plans to further optimize the high to low dose alternance.

5 Conclusion

We have successfully implemented simultaneous optimization of multiple plans in our in-house optimizer and demonstrated the use of our method for TFRT planning. We achieved clear high to low dose alternance which are expected to reduce overall OAR toxicity by offsetting the damage of the high dose fractions during the low dose fractions.

Abstract Radiation therapy treatment planning challenges provide the radiation therapy community with a standardized means to compare treatment plans from different techniques, software and users. Treatment planning challenges thus provide a unique opportunity to evaluate the impact of treatment plan complexity on treatment plan quality. In this study we compared the treatment plan complexity in three stereotactic treatment planning challenges between different treatment planning systems, and determined the relationship between treatment plan dosimetric quality and complexity. There was a large variation in treatment plan complexity between treatment planning systems, MLC widths and between challenges. Although treatment plan dosimetric score was positively correlated with increasing treatment plan complexity, we have demonstrated this was not a necessity to achieve a high dosimetric score. Thus limiting treatment plan complexity should be considered when optimizing treatment plans, to minimize associated increased uncertainties with highly complex treatment plans.

1 Introduction

Radiation therapy treatment planning challenges are often used in the radiation therapy community to evaluate variations in practice, determine the impact of technology or staff training on treatment plan quality and to service as an education process for a new clinical trials with novel treatment planning scenarios[1-3]. In treatment planning challenges, typically a single CT dataset with structures is provided to all participants, along with a planning guideline. Participants aim to create a treatment plan which maximizes the score based on a priori scoring matrix in which points are awarded according to adherence to and exceeding planning objectives.

Planning challenges often provide treatment plans of high dosimetric quality, which deliver the prescription dose to the target volumes in a highly conformal manner, with very low dose to adjacent critical structures. Such plans however may be highly complex, involving not only complicated beam geometry which may be infeasible to deliver in routine clinical practice, but potentially high complexity (small or complicated beam apertures, large variations in dose rate and gantry speed). This however may reflect clinical practice; in the absence of clear guidelines on minimization of treatment plan delivery complexity, multiple rounds of optimization may result in highly conformal dose distributions with the cost of high complexity [4]. Plan complexity is a critical component of treatment plan quality and there is a wide range of complexity metrics that have been used [5-9]. Despite this, there are limited tools in treatment planning systems (TPS) to measure and optimize complexity [10].

To date, there is sparse data describing the range in treatment plan modulation complexity and how it relates to treatment plan dosimetric quality. Treatment planning challenges provide a unique opportunity to assess treatment plan complexity using standardized treatment plan dosimetric quality metrics from a range of users and vendors. In this work, we evaluate the relationships between treatment plan complexity metrics and dosimetric quality in three stereotactic treatment planning challenges.

2 Materials and Methods

Planning Challenge Data

Three stereotactic treatment planning challenges were selected for analysis covering multi-metastasis stereotactic radiosurgery (SRS), pancreas stereotactic ablative body radiotherapy (SABR) and vertebral SABR. The target and organ at risk (OAR) structures for each challenge, and representative dose distributions are shown in Figure 1. The planning challenges were performed by the Trans Tasman Radiation Oncology Group (TROG) based on TROG clinical trial protocols, and were hosted by Elekta ProKnow Systems [1, 11]. Participation in the planning challenge involved downloading a CT image and associated structure set in DICOM format from the ProKnow website, creating a treatment plan to meet the protocol, and uploading the plan and dose grid in DICOM format. For each challenge, a scoring matrix was determined prior to the start of the plan challenge and was available to all participants at the time of planning. The scoring matrix provided a plan dosimetry score out of 150 based on meeting and exceeding trial dose objectives for target and OAR structures. The DICOM RTPlan files were made available by ProKnow Systems for analysis.

Complexity metric extraction

Only VMAT plans were considered in this study, which constituted 88-90% of plans in each planning challenge. The following complexity metrics were calculated for each VMAT treatment plan submitted to the planning challenges. Complexity metrics were calculated in an in-house code developed in Matlab [9].

- The Edge Metric (EM) [12], which measures the ratio of the X (MLC leaf widths) and Y perimeters to that of the area of the MLC-defined field. In this calculation we used parameters C1 = 0 and C2 = 1.
- The Modulation Index Total (MItotal) [13], which takes into account MLC complexity, gantry speed variability and dose rate variability.

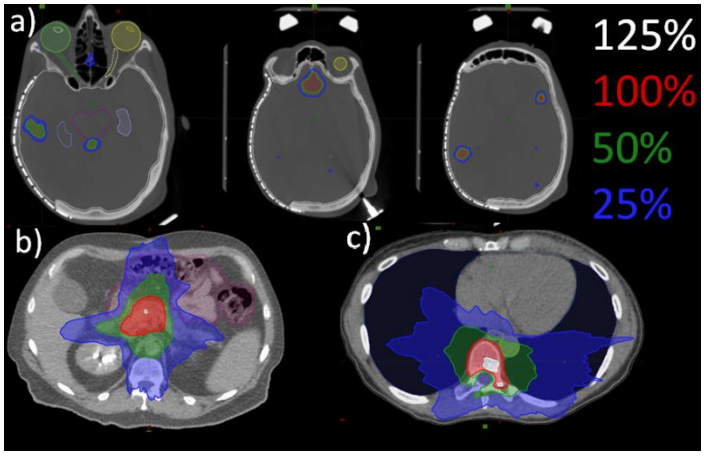

Figure 1: Target volume, critical organs and dosimetry for (a) SRS plan challenge (b) pancreas SABR challenge and (c) vertebral SABR challenge, with example dose distributions in percentage of prescription dose

The treatment plan complexity metric values were compared between different TPS using the two-sample Kolmogorov-Smirnov test. The relationship between treatment plan dosimetric quality, as defined by the plan dosimetry score in each challenge, and the treatment plan complexity, was assessed using the Spearman correlation coefficient r. A p value < 0.05 was used for statistical significance.

3 Results

Figure 2 shows the EM and MItotal for each of the plans in each planning challenge, organized by TPS and MLC width. The p value for the comparison between the distributions from each TPS for all MLCs and 5 mm MLCs only are shown in Table 1. The EM was higher (more complex) for the Eclipse TPS for all three planning challenges; this was driven in part by the high proportion of 2.5 mm MLC widths in the Eclipse treatment plans, however even when only 5 mm MLCs were considered this held for both the Pancreas and Vertebra challenges. Conversely MItotal was higher with Monaco TPS compared with the other TPS for the Pancreas and Vertebra challenges, but only higher than Eclipse for the SRS challenge. This was driven mainly by increased gantry speed and dose rate modulation in the Monaco treatment plans.

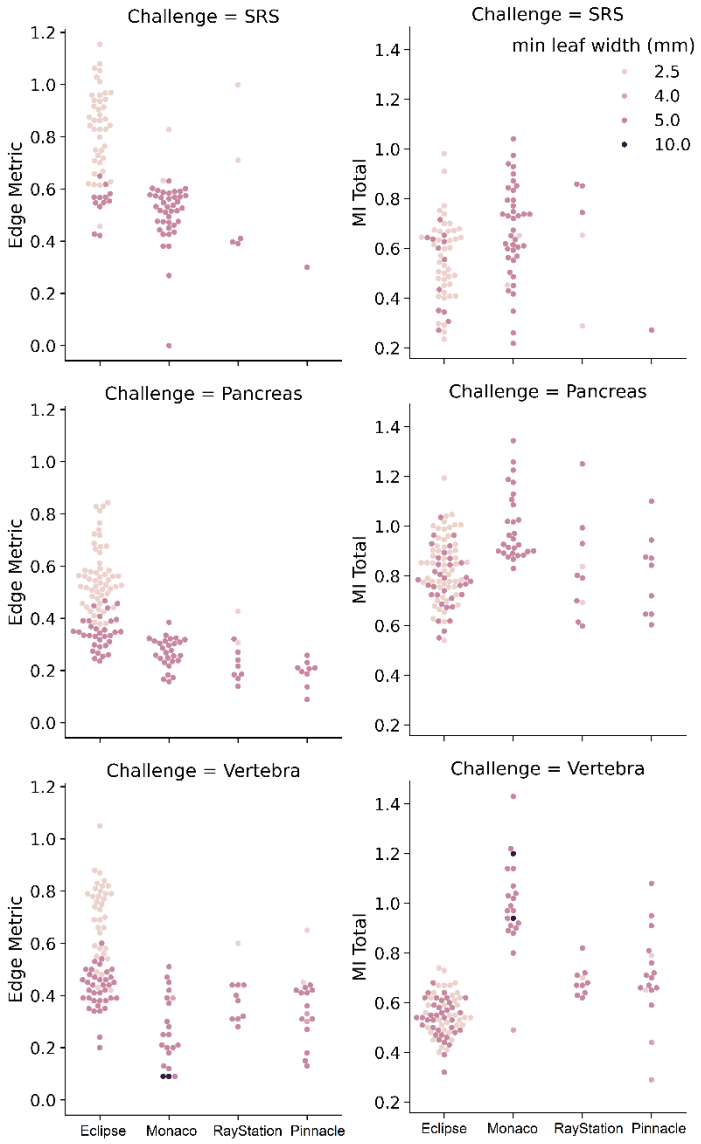

Figure 2: Edge metric and MItotal for each of the plan challenges, categorized by treatment planning system and colored by MLC leaf width.

Figure 3 shows the total plan score plotted as a function of EM and MItotal, organized by TPS. There was a positive correlation between the total plan score and the EM for all three plan challenges (r = 0.48, p < 0.005 for the SRS challenge, r = 0.38, p < 0.005 for the Pancreas challenge and r = 0.59, p < 0.005 for the Vertebra challenge). It should be noted however that although a high EM typically resulted in a higher total plan score, this was not a necessity; there were high scoring plans in all three challenges that did not have high EM. There was no correlation between the total plan score and MItotal (r = -0.12, p = 213 for the SRS

challenge, r = -0.13, r = -0.05, p = 0.561 for the Pancreas challenge and p = 0.164 for the Vertebra challenge).

Table 1: p values from the two-sample Kolmogorov-Smirnov test comparing complexity distributions between treatment planning systems. Those in bold are < 0.05.

4 Discussion

We have evaluated the relationship between treatment plan modulation complexity in three stereotactic treatment plan challenges. We observed that different TPSs control plan complexity in different ways or to different degrees, as demonstrated previously [9]. This includes increased MLC or aperture complexity, compared with increased modulation of the dose rate and gantry speed.

Although aperture complexity was correlated with high plan score in all three plan challenges, this was demonstrated to not be a necessity. Increasing plan complexity may only result in a modest increase in the score, so this dosimetric benefit must be carefully balanced against the pitfalls of increased complexity. These include increased uncertainty in dose calculation and delivery accuracy[13-18].

The critical result demonstrated here is that there were many plans which were obtained with lower plan complexity that exhibited high total scores. This highlights that often a TPS may introduce unnecessary plan complexity in the optimization process. It is important to control treatment plan complexity via any available tool in treatment plan optimization [10, 12]. It should be cautioned however that plan complexity is not prioritized over dosimetry quality; some level of complexity is expected and required to ensure a high-quality treatment plan, particularly when there is challenging spatial relationships between target volumes and adjacent critical structures. It remains a challenge to determine the optimal tradeoff between these two components for routine treatment plan optimization.

As such, it is important to continue to report complexity metrics in treatment planning studies and challenges, and to enable comparison between cohorts to enable determination of ranges of expected complexity for different tumour sites and fractionation regimes. This may be challenging for some metrics due to interpretation of complexity computation, and some level of standardization is required. Further, it is critical to continue to investigate complexity metrics to determine real-world impacts on deliverability/robustness and treatment efficiency to determine which complexity metrics are pertinent to patient outcomes.

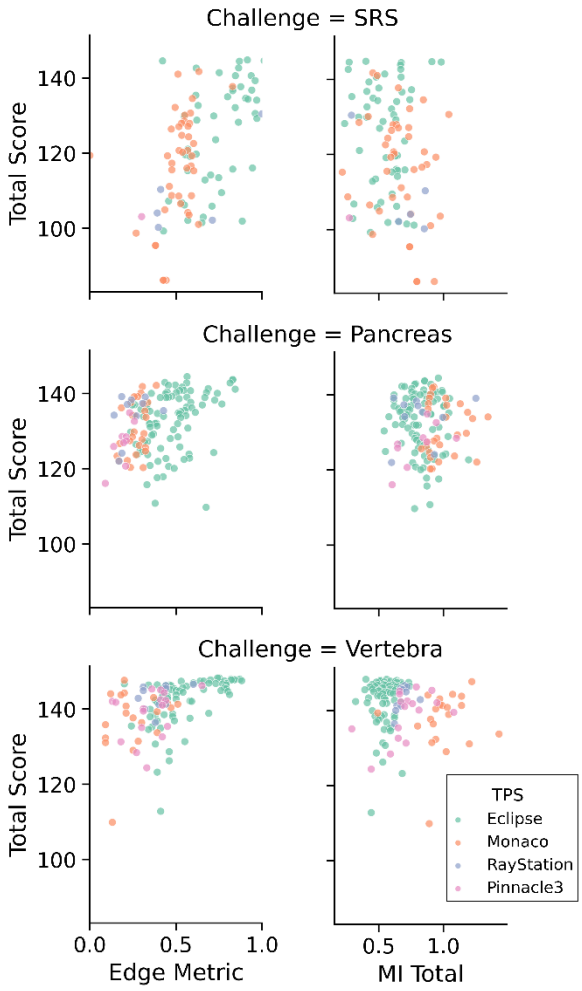

Figure 3: Total plan score as a function of Edge Metric and MItotal, colored by treatment planning system.

5 Conclusion

In three stereotactic treatment planning challenges, the treatment plan complexity varied between TPS. Treatment plan aperture complexity was associated with improved dosimetric plan quality. Treatment plan complexity taking into account aperture, gantry speed and dose rate modulation however was not associated with improved dosimetric plan quality. Further, high treatment plan dosimetric quality could be achieved with treatment plans with low complexity. This suggests that complexity should be limited in treatment planning for stereotactic radiation therapy to minimize the associated increased uncertainty with high complexity, for which appropriate software tools and standardization are warranted.

Addressing the Gap in Oncologist Training: Generating Clinically Realistic, Suboptimal Dose Distributions through Geometry Aware Convolutions

Abstract Radiation oncologists are responsible for determining the clinical acceptability of radiotherapy treatment plans. Their training typically revolves around routine clinical practice, observing the approval of patient plans. This approach depends on a sufficiently rich patient population (which is difficult for smaller clinics and less common cancer types) and is example-starved as the trainee typically only sees a single plan example for each patient. To address this, we have developed techniques to rapidly create clinically realistic plans that are suboptimal in a controllable way. These plans can then be used to train oncologists to understand what dose distributions are possible, and how to spot plans that could be improved. Here we first use a deep learning-based dose prediction to create a high-quality treatment plan (trained using only high-quality plans). We then increase dose by controllable amounts around selectable organs-at-risk. This approach is shown to generate clinically realistic, but suboptimal plans, as scored by experienced dosimetrists.

1 Introduction

Radiotherapy plan quality and radiation oncologist experience directly correlate to patient outcome and quality of life[1–4]. Therefore, it is vital that the quality of the final approved plan be high – that is, the prescription to the target be met while minimizing dose delivered to healthy tissue. Unfortunately, the literature reveals that suboptimal plans are approved frequently[5–8], even by experienced radiation oncologists. A contributing factor is the training environment during residency in which plan review is taught. Residents report the absence of examples across diverse treatment sites; the substantial clinical time pressures and high-stakes environment which make effective education difficult; and discontinuities introduced between identifying suboptimalities and making requests for edits and receiving the updated plan.

It is important to address these challenges by providing a wide range of example plans that need review and improvement in an environment that is low-stakes and without the pressure to have plans approved quickly for treatment. Simply curating lower-quality plans would be infeasible, as clinics typically have limited numbers available and inadvertent example memorization by the trainees would become common. Instead, a method of generating clinically realistic but suboptimal plans is needed. To date, however, most research has focused on generating high-quality plans[9–18]. Therefore, the current study develops a tool to create suboptimal dose distributions. These will be clinically realistic and suitable for integration into the training curriculum, providing the ability for real-time education in a low-stakes environment with virtually limitless examples.

2 Materials and Methods

In this study, suboptimal plans are modeled as potentially ideal dose distributions to which error has been added. This approach allows starting with consistent, high-quality dose distributions, and then creating areas of suboptimality around select OARs.

High-quality plans are required as the standard and what residents should be learning to achieve during plan review training. In this study, volume-modulated arc therapy (VMAT) dose distributions were predicted using the 3-Dimensional Dense Dilated U-Net model[10]. Two sets of models were used, one for head and neck (HN) radiotherapy[11] and the other for gynecological (GYN) radiotherapy[12]. Each set of models was previously trained using three-fold cross-validation on clinical data. This training data was carefully selected to be high-quality based upon both DVH metrics as well as upon physician review and consisted of planning computed tomography (CT) images, the clinical dose map from the treatment planning system, planning target volume (PTV) contours of varying prescriptions, and organ at risk (OAR) contours.

As the resultant dose distributions will be used for training, it is important that error be added to the high-quality dose predictions in a controllable manner that results in dose distributions free from obvious manipulation and appearing to have originated in the clinic. Dose changes should be localized to the OARs in which suboptimality is desired without substantial excess change elsewhere, but also without introducing visual errors such as introducing unrealistic dose gradients or other artifacts around the regions. To accomplish this, a convolutional technique was developed which adjusts changes based upon geometry –

that is, large changes in dose are only made near the desired OARs.

To start, a geometric feature λ_{OAR} was derived for each group of OARs. It describes proximity to the region in which suboptimality is desired through a combination of the Euclidean distances outside the OAR boundary and a directionally insensitive beam's eye view (BEV) angle. The geometric features were normalized to the range [0, 1], where 0 indicates least physical and angular distance from the OAR and 1 indicates greatest. Then a sigmoid-like function was applied with parameters controlling the full-width half-max (FWHM) and steepness of the sigmoid curve β, to provide additional control over the geometric space in which the dose was increased.

Equation 1

$$f(\lambda, FWHM, \beta) = \frac{\left(\lambda^{-\frac{\log(2)}{\log(FWHM)}}\right)^{\beta}}{\left(\lambda^{-\frac{\log(2)}{\log(FWHM)}}\right)^{\beta} + \left(1 - \lambda^{-\frac{\log(2)}{\log(FWHM)}}\right)^{\beta}}$$

As the target region contains the highest dose, a similar geometric feature λ_{PTV} was derived and normalized to the range [0, 0.98]. This feature indicated proximity for the PTV for which to make very small perturbations to the dose. This allowed changes to be made to the dose delivered to target, but not unrealistically large relative to the dose increase around each OAR. The final geometric feature was the 3-dimensional element-wise minimum of the OAR feature and the target feature.

Equation 23

$$\lambda = min\left(\lambda_{OAR,ijk}, \lambda_{PTV,ijk}\ \forall i,j,k\ in\ (Z,X,Y)\right)$$

Next, a kernel was designed to take this geometric information into account. There are two parameters for this kernel, geometric feature λ which varies at every step in the convolution, and the constant AUC_m, which is always 1 or greater and determines the maximum area under the curve of the kernel and therefore the resultant dose scaling.

Equation 4

$$g(\lambda, AUC_m) = s(\lambda, AUC_m) \cdot \frac{1}{\sum k} k(\lambda)$$

This may be further divided into two components. First, it is important that the overall kernel area under the curve (AUC) changes with response to geometry, so that greatest dose scaling is applied only near the OARs of interest. The linear function $s(\lambda, AUC_m) = (1 - AUC_m)\lambda + AUC_m$ controls the overall AUC of the kernel, such that it is equal to 1 as λ is largest (far from the OAR) and equal to AUC_m as λ is smallest (closes to the OAR and along the BEV angle).

The second component, the inner kernel k, is self-normalizing to AUC=1 and changes its receptive field based upon geometry. At the limits of the geometric feature, k is the identity kernel to preserve dose as-is ($\lambda = 1$), or the mean kernel to incorporate the most information from neighboring values ($\lambda = 0$).

Equation 5

$$k(\lambda) = \begin{bmatrix} 1-\lambda & 1-\lambda & 1-\lambda \\ 1-\lambda & 1 & 1-\lambda \\ 1-\lambda & 1-\lambda & 1-\lambda \end{bmatrix}$$

Finally, suboptimalities were introduced with greatest relative increase near the selected OARs through convolving the high-quality dose distribution with the geometry aware kernel.

Equation 6

$$D' = D * g(\lambda, AUCm)$$

To test this process, two datasets were used. First, a set of twenty-five HN VMAT radiotherapy cases were curated from our institution. These cases included a planning CT image, the clinical dose map from the treatment planning system, PTV contours of varying prescriptions, and OAR contours required to generate the high-quality dose predictions as described by Gronberg et al.[11] To assess translatability of our approach, an additional fourteen gynecological (GYN) VMAT cases were curated from our institution. These cases included a planning CT image, the clinical dose map from the treatment planning system, a single PTV contour prescribed to 45Gy, and OAR contours required to generate the high-quality dose predictions as described by Gronberg et al.[12]

Five HN OAR groupings were selected in this study (Table 1). The generation parameters listed in Table 1 were selected based upon preliminary experimentation to provide realistic-appearing dose distributions.

Group	*OARs*	*AUC_m*	*FWHM/β*
1	Esophagus Larynx	1.1-1.7	0.15/4
2	Brainstem	1.1-1.7	0.15/4
3	Optic Nerves Lenses	1.1-1.7	0.15/4
4	Parotids	1.1-1.7	0.15/4
5	Cochleae	1.1-1.7	0.15/4

Table 1: Groups of HN OARs for which the dose was increased in this study, with the generation parameters.

Changes to the plan dose was assessed as relative difference in structure mean dose D_{mean} between the edited plans and the predicted high-quality plans. For each OAR in Table 1,

the relative change was calculated as $\Delta D_{mean,OAR} = \frac{D'_{mean,OAR} - D_{mean,OAR}}{D_{mean,OAR}}$. A paired one-sided T-test was applied to assess significance in change to D_{mean} for each OAR, with significance taken at the $p<0.01$ level.

An experienced dosimetrist also reviewed a subset of the dose distributions, all generated with AUC_m=1.4, to assess clinical realism. To avoid bias, the dosimetrist was blinded to plan origin. A random mix of 10 clinical dose distributions and 10 suboptimal distributions was generated. The dosimetrist reviewed each dose distribution individually and answered if they thought the doses were (1) generated by a human with a treatment planning system, (2) generated by a deep learning dose prediction model, or (3) unable to determine or ambiguous.

3 Results

Dose was increased around the selected OARs in each group in a controllable way, as shown in Figure 2. This increase was statistically significant. Increasing kernel AUC_m increased mean dose as shown in Figure 1, where the relatively small error bars indicate strong control of change in dose. Figures 1 and 3 also demonstrate the localization of changes; mean dose is increased most around the OARs of interest in each group. The smaller increase in dose to other OARs are appropriate for clinical realism; while not changed as substantially as for the OARs of interest, they still exhibit realistic dose increases. While Figures 1 & 3 show a subset of groups and OARs for clarity, the general trend remains across all groups.

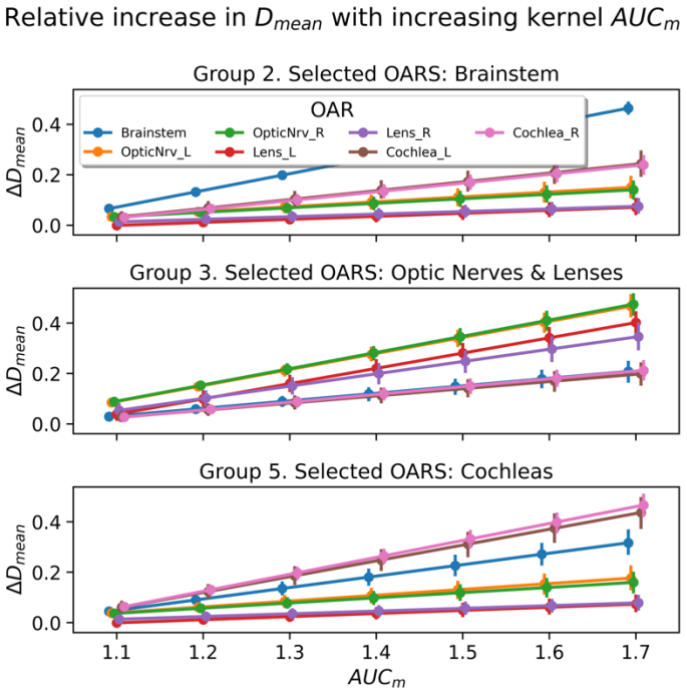

Figure 1: Relative increase in mean dose for selected OAR groups as the maximum kernel AUC increases.

The rate at which the dosimetrist was unable to determine if the dose distribution originated from a clinical treatment plan or a generated prediction was 80% for the suboptimal dose distributions, comparable to 70% for the clinical dose distributions. This indicates that the suboptimal dose distributions do not appear substantially different to plans that might be encountered in the clinic – that is, the generated plans are suboptimal but still clinically realistic.

The GYN dose distributions were edited using the same parameters as in Table 1, but with three groups of OARS: Bladder, Rectum, and the Femoral Heads together. D_{mean} was again increased for each OAR with increasing AUC_m (Table 2). This demonstrates the translatability of our approach across treatment sites.

AUC_m	*Bladder*	*Rectum*	*L. Femur Head*	*R. Femur Head*
1.1	0.02	0.01	0.07	0.07
1.2	0.05	0.03	0.13	0.14
1.3	0.07	0.04	0.20	0.20
1.4	0.09	0.06	0.26	0.27
1.5	0.12	0.07	0.33	0.34
1.6	0.14	0.09	0.39	0.40
1.7	0.16	0.10	0.46	0.47

Table 2: Relative increase in D_{mean} for the GYN cases.

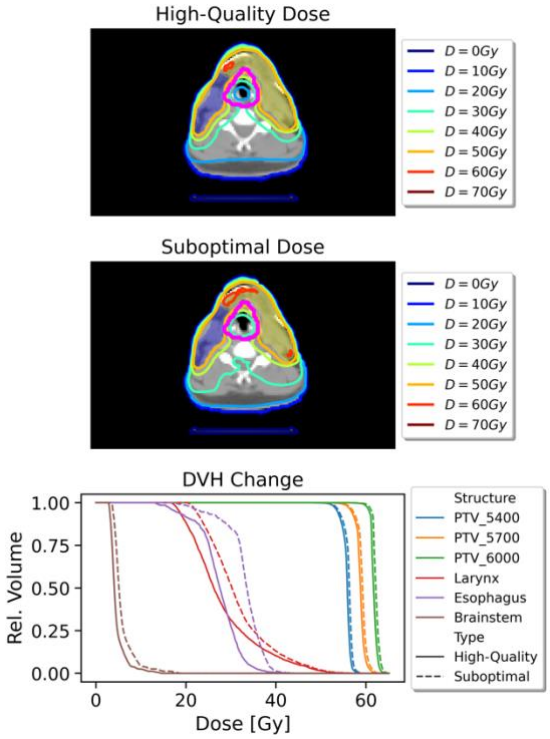

Figure 2: Comparison of the suboptimal dose distribution with the initial high-quality dose distribution. This example came from Group 1 where the larynx (magenta) and esophagus (only seen in the DVH)) were the OARs for which the changes are focused. Blue and yellow regions: low- and mid-risk PTV, respectively.

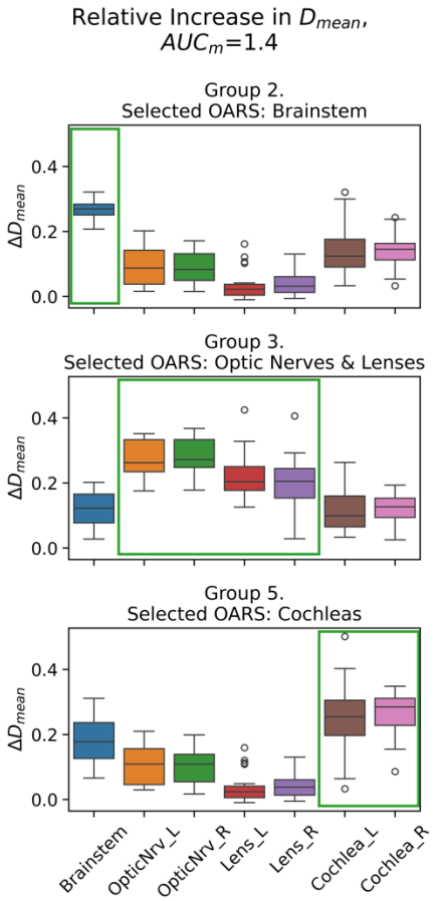

Figure 3: Distribution of relative increase in mean dose for selected OAR groups, with a single kernel AUC_m of 1.4. Green boxes indicate the selected OARs for each group.

4 Discussion

In this study, a tool for generating suboptimal but clinically realistic dose distributions was successfully developed. To our knowledge, this is the first such approach and opens the door to a range of applications for medical education and training.

The next step of this project will be to integrate this tool into the treatment planning system. Using scripting, an interactive model will be designed that presents trainees with different scenarios and asks them to identify where the treatment plan quality can be improved.

5 Conclusion

In this work, we develop a tool for generating artificial dose distributions that are clinically realistic. These dose distributions are suboptimal in predictable and controllable locations.

Feasibility of training federated deep learning oropharyngeal primary tumour segmentation models without sharing gradient information

Leroy Volmer[1], Ananya Choudhury[2], Aiara Lobo Gomes[2], Andre Dekker[1,2], and Leonard Wee[1,2]

[1]Department of Radiotherapy (MAASTRO), Maastricht University Medical Centre+, Maastricht, The Netherlands
[2]Clinical Data Science, School of Oncology and Reproduction, Maastricht University, Maastricht, The Netherlands

Abstract Federated deep learning is a way of training a deep learning model on vast amounts of privacy-sensitive data without having to exchange the data itself. A vulnerability exposed during federated model training relies on intercepting the gradients during training. In this work, we show that it is feasible to train a model for segmenting an oropharyngeal tumour in a simulated federated manner without any sharing of gradients between institutions. Further, we show that the federally trained model is functionally equivalent to a centrally trained one. In future, we expect geometric similarity performance could be significantly improved by combining multi-modality images as inputs, such as PET and CT.

1 Introduction

Oropharyngeal cancer is one member of a family of rare malignancies that arise from mutations in cells lining the upper aerodigestive tract. Over 50,000 cases are diagnosed in Europe each year, with roughly one in five of these occurring in persons aged under 55 years.
Accurate segmentations of the oropharyngeal gross tumour volume (GTV) are needed to plan and deliver a radiotherapy treatment. This is a time-consuming task being done routinely by experienced radiation oncologists, however deep learning neural networks have recently demonstrated some promising results for automatically segmenting the GTV [1].
Federated learning [2] is a paradigm of working within the limitations of sharing vast amounts of privacy-sensitive medical data to train models, including deep learning neural networks, on rare cancer subjects. An external attack surface has been identified, during a federated model training process, that suggests a method of breaching data privacy that relies on gradient information interception [3]. Being able to train a deep learning model federally without exchanging any gradient information would reduce risk of privacy breaches. Inversion of a model remains a theoretical possibility, but this will be true for any model where the weights are accessible, irrespective of whether it was trained federally or centrally.
In this work, we aim to prove the feasibility of training a deep learning model for oropharyngeal GTV segmentation in a federated learning simulation, but without transmitting any model gradients between cooperating parties. Furthermore, we evaluate the performance of the models in terms of geometric accuracy, and confirm that a federally trained model is functionally equivalent to a centrally trained one.

2 Materials and Methods

Four public datasets - HN1 [4], Montreal [5], OPC [6] and MDA [7] were taken from The Cancer Imaging Archive [8] for training and validation. We only included primary oropharyngeal cancers, resulting in 1223 volumetric CTs with associated primary GTV delineation by radiation oncologists, of which we randomly selected a holdout validation cohort of 20% from each aforementioned dataset. One private institutional dataset named HN3 (n=154) was used entirely as independent test, obtained with ethics authorization from MAASTRO Clinic in The Netherlands. HN3 was demographically the same population as HN1.
CT series and GTV masks were isotropically resampled to 1mm cubes. Hounsfield units were clipped between -1024 and 1024, and the CT intensity rescaled within the range (-1,1). Cubic 144^3 patches were repeatedly sampled for training, such that 75% contained GTV and 25% did not include any part of GTV. To increase robustness, data augmentation was randomly applied to each sampled cube, consisting of cranio-caudal mirror, translation (0/30mm), rotation (-30/30 degrees), shear (-0.1/0.1), gamma intensity scale (0.8/1.2) and Gaussian blur (0/3mm).
The deep learning architecture was based on a squeeze-and-excitation normalization model that has been used for HNC GTV segmentation [1,9]. Succinctly, the model is a 3D U-Net architecture with ResNet elements, with squeeze and excitation normalization blocks following each convolutional block that allows the network to find the ideal normalization for Hounsfield units during training.
Additionally, we included attention gates at each spatial resolution level following every skip connection, aiming to accelerate the localization of the GTV and enhance neuron activations in important areas [10]. Extra up-sampling paths were added to allow low-resolution features to have an impact further along in the network. Lastly, network attention was visualized using Grad-CAM++ [11].
ReLU activation functions were applied throughout, and an Adam optimizer with betas set to 0.9 and 0.99. Weight decay was 1e-4. A batch of 1 was used to reduce GPU memory usage. A compound function of Dice loss and Focal loss was used during training since the GTV represented only a small part of the input CT [12]. False negative predictions are thus penalized less than false positive predictions, therefore we added a weight to over-penalize false negative predictions. Dropout rate was 25% to reduce over-fitting. The learning rate followed a cosine annealing plus warm restart schedule, starting at amplitude 1e-4 decaying to 1e-7 every

10 epochs. Learning rate schedule was the same for all training runs. Starting weights were set with He initialization through a constant seed number for all training runs [13].
Federated deep learning was simulated by placing each dataset in a separate hard disk partition. Four partial models were trained on the data, one in each partition, then only the weights were merged into a single global model using the synchronous federated averaging (FedAvg) [14] algorithm. Averaged weights were used as starting state for the next training epoch. During each epoch of training, each partial model iteratively ran through all of the training samples inside its own partition. There was no exchange of gradient information whatsoever between any of the partial models and between partial and globally averaged model.
We monitored training and convergence dynamics while globally averaging every 1, 5 and 10 epochs, up to a total of 100 epochs. We compared the three "federally-trained" models, "Avg1", "Avg5" and "Avg10", respectively, with a fully centrally trained model with all the data in a single pool for 100 epochs. Only a fixed learning rate was used during the training cycle with FedAvg, to remove the effect of decaying learning rates in the epochs between averaging. For inference, a sliding window method was applied with overlap factor 0.5. No post-inference cleanup processing was applied. The geometric accuracy metric used was Dice Similarity Coefficient (DSC). Statistical significance of DSC between groups was calculated using a two-sided Mann-Whitney-Wilcoxon test including Bonferroni correction.

3 Results

Holdout subjects in HN1 (n=18), OPC (n=101), MDA (n=80) and Montreal (n=48) were used for validation of the trained models. HN3 (n=154) was used as independent test set to evaluate segmentation performance. Median DSC results are summarized in Table 1.

Table 1: Median Dice similarity coefficients (DSC) of predicted versus reference GTV segmentations, as a function of averaging every 1, 5 or 10 epochs. Interquartile range in DSC given in parentheses under median values.

Statistically significant differences (assuming $p<0.05$) in DSC were not detected, neither within datasets across all methods of training, nor when comparing centralized versus any federated averaging method. Among the federated averaging training methods, "Avg1" gave maximum DSC for 3 out of 5 datasets. "Avg10" was marginally better for OPC and MDA. Overall, "Avg1" and the centralized model were functionally equivalent in performance across all datasets.
However, the difference in performance as a function of total size of GTV was statistically significant. Figure 1 shows the DSC of each subject in the validation and test dataset as a dot, and grouped according to GTV $\geq 10cm^3$ versus GTV $< 10cm^3$. Model performance in the smaller GTVs were poorer in terms of median DSC and interquartile spread, and has the overall effect of dragging the median DSC results downwards.

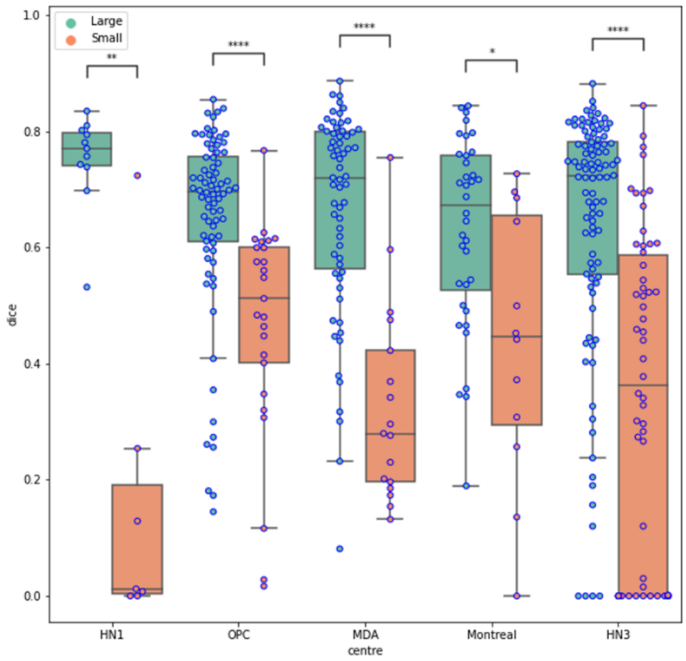

Figure 1: Boxplot showing distribution of Dice similarity coefficient for each subject in the validation datasets as a function of GTV size ($\geq 10cm^3$ in green, $<10cm^3$ in orange) when using the Avg1 trained model. Differences in DSC due to size of GTV was statistically significant.

Examples of automated segmentations produced by model Avg1 in validation subjects are provided in Figure 2. Overall, the model accurately locates the majority of the middle of the GTV, but the extreme outer boundaries of the tumour were not in agreement with the radiation oncologist delineation. Grad-CAM activation maps were partially helpful, such that the vast majority of subjects showed activations near the GTV, but the GTV was not consistently contained within the strongly activation area.

4 Discussion

This study shows that it would be possible to train a GTV segmentation model for oropharyngeal carcinoma in a federated fashion, where we would not need to exchange gradients between institutions. This would mean that there is no opportunity to eavesdrop on gradients, thus removing a potential threat to privacy breach in federated deep learning. Furthermore, with synchronized federated averaging (FedAvg) of partial model weights into a global model every epoch, we showed that we could obtain a federated model that was functionally equivalent to training on all the data centrally. In terms of geometric performance, it is clear that GTVs smaller than 10cm^3 in total volume poses a significant challenge for automated segmentation. Future work would explore whether splitting the deep learning model for large and small GTVs, or considering an ensemble of models, could be feasible options.

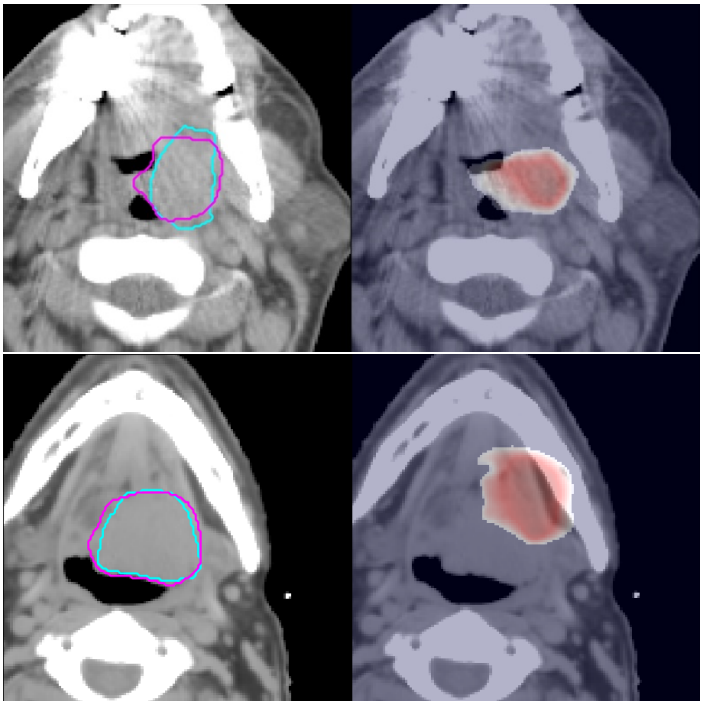

Figure 2: Two examples comparing predicted and reference GTV segmentations. On the left, purple contours are reference delineations of GTV by radiation oncologist and blue contours are inferred by model Avg1. On the right, the red hotspots indicate the highly activating areas using Grad-CAM++. In the background of all images are the original CT image intensities.

There remain a number of issues in a real-world federated deep learning training run that we do not presently have space to address in this report. Inter-observer delineation differences and contouring quality disparities persist between radiotherapy clinics. Our approach for multi-institutional collaboration suggests we can train a deep learning model towards an average global consensus, but we cannot address the underlying data quality issues by federated learning alone.

Secondly, we have only used CT images in this work, which is by far the most common imaging modality in radiotherapy, but other studies [15] show that combining multi-imaging inputs, such as PET, CT and MRI, would should lead to significantly better geometric agreement with radiation oncologists' delineations of GTV.

Third, we surmise that while inversion from updated model weights could be possible for fully-connected neural networks trained on very small sample sizes [16], this kind of model inversion would be significantly harder to execute for a realistic training run with a 3D U-Net on a large sample size, at least in comparison to intercepted training gradients.

In a real-world training run, we may recommend the following as safeguards – (i) that partial model weights from each institution should consist of learning on a reasonably large number of subjects (e.g., 100 subjects or greater per institution), and (ii) that global model weights for each averaging epoch should be aggregated on a dedicated trusted third-party device and then the partial weights should be deleted from that device after running FedAvg. In this way, neither the training institutions nor the researcher that initiated the deep learning run would have access to any partial model weights, only the globally-averaged weights on the total training sample would be available to the training run participants.

Lastly, obviating the need to exchange gradients between training institutions defeats one well-known attack surface, but other security risks persist. In a real world situation, it might still be possible to steal access credentials, execute man-in-the-middle attacks or attempt data re-engineering from a final fully-trained model. Additional privacy-enhancing techniques such as differential privacy and homomorphic encryption may be added to boost security, but one ought to be wary of privacy enhancement technology alone as a single line of protection against potential privacy breaches.

5 Conclusion

It is feasible to train a 3D U-Net for primary oropharyngeal GTV segmentation in federated learning without transmitting model gradients between institutions. The FedAvg algorithm for aggregating multiple partial models into a global model does not significantly impact model performance. The Avg1 model was functionally equivalent in terms of DSC with a deep learning model trained centrally on all patient data at the same time in a single pool.

Abstract
Adaptive Radiotherapy (ART) heavily relies on efficient and accurate target delineation due to the need for real-time adjustments. However, manual contouring hinders ART integration with its variability, labor-intensive, and time-consuming nature. This study introduces a novel template-guided deep learning model for target segmentation. The model built upon a 3D nnUNet featuring three input channels: primary CT image, template CT image, and template mask (GTV, CTV, or PTV). The structure allows "Follow-the-Leader" nature of learning, i.e. the output to dynamically adjust based on the chosen template (the leader), providing segmentations tailored to the template. Additionally, it incorporates stylistic cues from the template leading to accurate segmentation. The approach was tested on a dataset of breast cancer CT images. Patient data (n=114) were randomly split into training (84), validation (15), and test (15). The model achieved Dice similarity coefficients (GTV: 0.74±0.06, CTV: 0.86±0.04, PTV: 0.87±0.03) showcasing its potential for improving ART workflow.

1 Introduction

Online Adaptive Radiotherapy (ART) represents a sophisticated radiotherapy approach wherein the daily treatment plan is adjusted to accommodate the patient's evolving anatomy, such as a shrinking tumor and variations in body weight [1]. These benefits come with the drawback of extended workflows, primarily due to the necessity for online re-contouring. Efficiency is crucial in ART given the real-time nature of this treatment, requiring the patient to be immobilized in the treatment position while awaiting the initiation of treatment [2], [3]. However, the time-consuming task of delineating targets and organs-at-risk (OARs) for all fractions has emerged as a significant bottleneck, impeding the widespread adoption of online ART.

In ART, the GTVs (Gross Tumor Volumes), CTVs (Clinical Target Volumes), and PTVs (Planning Target Volumes) on the treatment day are either manually delineated or auto-deformed from planning CT and validated by radiation oncologists. The definition of these target areas relies on the clinician's expertise, experience, and a comprehensive understanding of the patient's diagnostic imaging, surgical reports, and other relevant data [4], [5]. The quality, efficiency, and repeatability of manual contouring can vary among different radiation oncologists, and the time spent on contouring a patient is influenced by their proficiency. For instance, in clinical practice, manual target delineation for breast cancer cases could range from 30 minutes to several hours.

Atlas-based automatic segmentation algorithms have been extensively employed for target segmentation [6]. Nonetheless, these algorithms encounter challenges when dealing with targets characterized by indistinct boundaries or intricate shapes [7] and frequently yield unsatisfactory results. Consequently, there is a demand for accurate auto-segmentation tools to address the challenges.

Our proposed deep learning (DL) model presents an innovative approach by leveraging template-guided segmentation. The proposed model is based on 3D nnUNet [8] by incorporating three input channels: the input CT image, a template CT image, and a template mask. The template mask encompasses either GTV, CTV, or PTV. The model leverages the knowledge from the template to guide the segmentation in dual aspects. 1) The utilization of templates enables the model to dynamically adapt to various targets, generating precise segmentation based on the type of template selected. In other words, the choice of the template determines the output, allowing the model to generate contours for GTV, CTV, or PTV. For instance, if the GTV template is chosen, the output corresponds to GTV; if the CTV template is selected, the output is CTV, and similarly for PTV. This versatility empowers the model to seamlessly tailor its segmentation output to the specific target of interest, offering a flexible and personalized approach to adaptive radiotherapy. 2) In adaptive radiation therapy, a sequence of images is required to be contoured throughout the treatment course. Typically, some prior CT and contour information is usually available from the initial treatment planning and a few early fractions [9]. Our proposed DL approach is designed in a way to leverage the insights from existing contours as templates to effectively segment the new image. This strategic use of prior information enhances the adaptability of the model, allowing it to learn and apply segmentation patterns in the template to ensure accurate and consistent results throughout the treatment course.

2 Materials and Methods

In this study, we proposed and developed a template-based auto-segmentation scheme for ART. Initially, three 3D nnUNet models were trained exclusively on data corresponding to their specific targets—GTV, CTV, or PTV, each operating with a single-channel setup (i.e., CT image). These three models are used as baseline models for comparison. Further, three distinct 3-channel 'target-specific' models were trained, each dedicated to GTV, CTV, and PTV. These models incorporated CT images, template CT images, and target-specific template masks. The applicability of target-specific models is restricted to the segmentation of their designated targets, namely GTV, CTV, or PTV, lacking versatility for other target types.

Table 1. The table summarizes input requirements and training data for the baseline models, target-specific models, and the proposed model

Models	Input(s)	Training data
Baseline models	• CT image	The three models are trained separately for each target type (GTV, CTV, or PTV) using their specific template.
Target-specific models	• CT image • Template CT image • Specific template mask, limited to GTV, CTV, or PTV, depending on the model	The three models are trained separately for each target type (GTV, CTV, or PTV) using their specific template.
Proposed model	• CT image • Template CT image • Template mask, which can flexibly be GTV, CTV, or PTV depending on the chosen target	The model is trained on pooled template masks of GTV, CTV, and PTV for comprehensive learning and adaptability.

Recognizing the limited adaptability of target-specific models for diverse targets, we introduced the proposed model (Table 1, Figure 1), which trained on pooled of GTV, CTV, and PTV data, offering a more versatile solution. This comprehensive approach aims to overcome the constraints posed by exclusive target-specific models and provides flexibility in choosing templates, addressing the need for a more adaptable and generalized model for adaptive radiotherapy. Overall, seven models as listed in Table 1 are trained in this study for comprehensive models evaluation and comparison.

2.1 Adaptive Output Based on Template Selection

During training, the proposed model learns to adapt its output based on the selected template. The three input channels—CT images, template CT images, and template target masks (GTV, CTV, or PTV)—facilitate joint learning. The model grasps the relationships between these inputs, enabling it to dynamically adjust its segmentation output according to the specific target delineated by the chosen template. This adaptability is achieved through continuous refinement of network weights via supervised learning, ensuring precise target segmentation aligned with the chosen template.

2.2. Stylistic Cue Utilization

Simultaneously, the model gains insights into the stylistic cues present in the template CT and template target mask. This information is incorporated into the learning process, allowing the model to generalize stylistic characteristics and apply them to generate segmentation masks for the input image.

Throughout training, the model refines its weights through continuous updates, minimizing the loss function by comparing predictions with manually contoured masks. Here, the loss function is the sum of cross-entropy and Dice loss (*Eq. 1*). The trained model, with optimized parameters, is then ready for deployment during the testing stage, where it utilizes template guidance to dynamically adapt and generate predicted segmentations.

$$L(G,P) = -\frac{1}{N}\sum_{k=1}^{K}\sum_{n=1}^{N}\left(g_{n,k}\log p_{n,k} + \frac{2\,g_{n,k}\,p_{n,k}}{g_{n,k}^2 + p_{n,k}^2}\right);\ \ g_{n,k} \in G \quad p_{n,k} \in P \qquad \textit{Eq.1}$$

In *Eq. 1*, G denotes the ground truth label, and P is the predicted probabilities for class k and voxel n in the image.

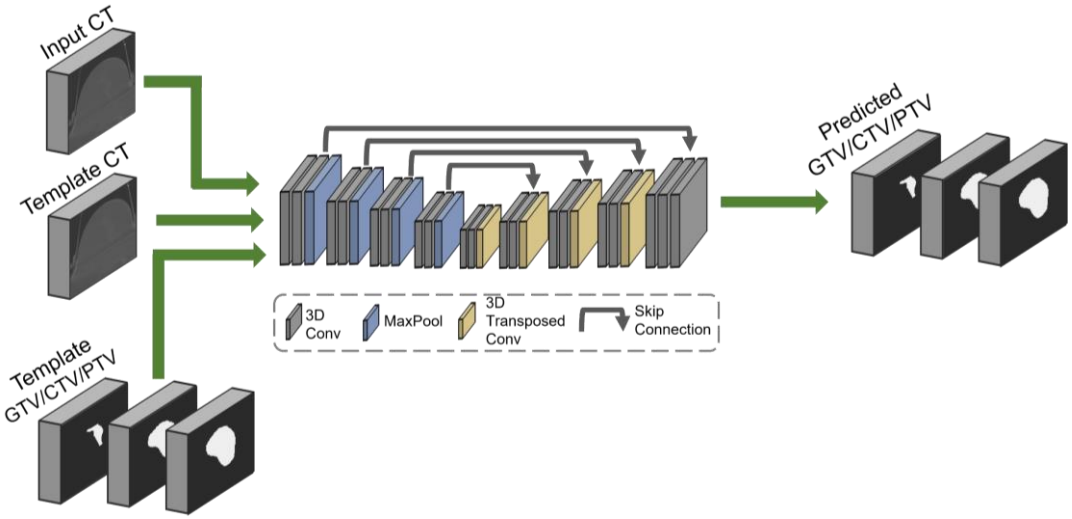

Figure 1. The proposed template-guided model structure. The 3D nnUNet is the model backbone. The model is trained using three input channels including, the CT images of the patient, a template CT image, and the template target mask. The utilization of the input template (GTV, CTV, or PTV) enables the model to dynamically adapt to various targets and stylistic cues provided by the template to predict the output segmentation masks.

2.3 Experimental Data

We utilized our in-house retrospective dataset of 114 post-operative breast SBRT patients in this study. Prior to each fraction, head-first-prone CT scans were acquired on either Airo® Mobile Intraoperative CT (Brainlab AG, Munich, Germany) or Philips Brilliance Big Bore CT (Philips Healthcare, Amsterdam, Netherlands), both with 120 kVp and scanning lengths covering the whole chest region. CT images had slice thickness of 1 mm. To mitigate potential bias arising from high correlation across fractional images for each patient, we deliberately partitioned the data based on patients rather than individual images. The test dataset, comprising 15 patients, remained entirely untouched during experiments, ensuring no overlap with the training set. Out of the total 114 patients, 84 were randomly assigned to the training set, 15 to the validation set, and the remaining 15 to the test. GTV, CTV, and PTV delineation on the CT images was conducted through a meticulous process by expert radiation oncologist from the department of radiation oncology at UT Southwestern Medical Center who had similar levels of expertise. Within each patient's dataset, our training approach for the proposed model involved exhaustive exploration of all possible combinations of fractions for GTV, CTV, and PTV. Given the five fractions per patient, our training dataset for each patient encompassed 20 instances, and in total 5040 (20 instances × 84 patients × 3 targets) training samples. This comprehensive sampling facilitates robust learning.

2.4 Implementation Details

The experiments utilized the PyTorch framework (version 1.8) and Python environment (version 3.8) on a Windows 10 64x system, equipped with an Intel Xeon processor CPU (64 GB RAM) and an NVIDIA GeForce 2080 Ti GPU (12 GB memory). For uniformity, all CT images and corresponding GTV, CTV, and PTV masks were resampled to voxel size of 1.5 mm × 1.5 mm × 1.5 mm. Subsequently, images and masks underwent center cropping to 128 × 128 × 128, focusing on the breast region.

2.5 Network Evaluation

In simulating adaptive radiation therapy, our testing approach replicates the scenario where initial treatment planning and early fractions provide prior CT and contour information. Hence, the input CT image was sourced from fractions 2, 3, 4, and 5, while maintaining fraction 1 as the template. The Dice similarity coefficient (DSC) was used to quantitatively assess the segmentation performance of the model (*Eq.2*). DSC was computed to measure the degree of overlap between the model's output and the ground truth GTV, CTV, and PTV masks. The proposed network was evaluated against the baseline models and the target-specific models.

$$DSC = \frac{2\times|A\cap B|}{|A|+|B|} \qquad Eq.2$$

3 Results

In Table 2, the baseline models provide a reference point, indicating the performance achieved without any specific target adaptation. The target-specific models as described in Table 1, are designed for a particular target type during training, and the proposed model is trained on combined data for all target volumes (GTV, CTV, and PTV). According to Table 2, notable improvements were observed across all target segmentation categories (i.e., GTV, CTV, PTV), for the target-specific models relative to the baseline. The target-specific models demonstrated enhanced performance, with respective DSC of 0.75 (GTV), 0.85 (CTV), and 0.87 (PTV). These values signify a substantial increase in accuracy compared to the baseline model, which yielded coefficients of 0.69 (GTV), 0.81 (CTV), and 0.82 (PTV). The narrower standard deviations associated with the proposed model's results (0.05 for GTV, 0.04 for CTV, and 0.03 for PTV) further highlight its consistency and robustness. The Proposed model maintained competitive performance across GTV, CTV, and PTV with DSC values of 0.74, 0.86, and 0.87 respectively, demonstrating its adaptability and effectiveness in handling various target types.

Table 2. Comparing Dice similarity scores for the proposed model, target-specific model, and the baseline. Values represent mean (standard deviation) across patients.

	GTV	CTV	PTV
Baseline models	0.69 (0.08)	0.81 (0.07)	0.82 (0.05)
Target-specific models	0.75 (0.05)	0.85 (0.04)	0.87 (0.03)
Proposed model	0.74 (0.06)	0.86 (0.04)	0.87 (0.03)

Visual inspection of the segmentation results provides insights into the performance of the proposed model compared to the baseline (Figure 2). To generate the predicted targets in Figure 2, the template—GTV, CTV, and PTV—were individually fed into the proposed model along with the input CT image and the CT template. The proposed model demonstrates a unique capability when aligning with the template; as presented in Figure 2, the model adapts its output based on the selected template (i.e., GTV, CTV, or PTV). Across all targets, the baseline model exhibits a lower accuracy in generating masks compared to the proposed model, signifying the superior segmentation capabilities of the latter. Using the baseline model, significant under-segmentation of the predicted GTV, CTV, and PTV was observed (Figure 2). However, the proposed model utilized the stylistic cues embedded in the template mask and generated segmentation masks that align with the visual characteristics of the specific template leading to improved performance. The results showcases the adaptability of the proposed model to follow the chosen template's characteristics, which has potential for tackling real-time adjustment challenges in adaptive radiotherapy.

4 Discussion

Adaptive Radiotherapy depends significantly on precise and efficient delineation of targets volumes which is

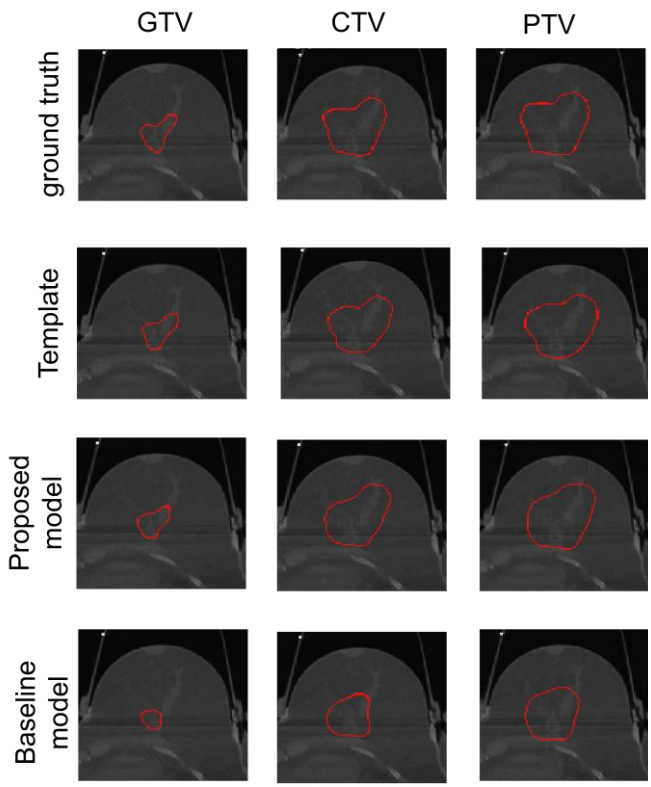

Figure 2. Visual comparison of segmentation results. Each row illustrates the ground truth mask, template, output from the proposed model, and output from the baseline model for GTV, CTV, and PTV, respectively.

essential for prompt adjustments in real-time [10]. This study introduces a solution for automatic target segmentation in ART by integrating DL and template guidance.

The model's dual functionality emerges as a key innovation. The adaptability of the model to generate precise segmentation based on the selected template (GTV, CTV, or PTV) provides a tailored and flexible approach. This adaptability ensures that the model can dynamically adjust to various targets, enhancing its versatility and applicability in different clinical scenarios. The utilization of stylistic cues from the template represents a novel aspect of the model. By capturing and generalizing stylistic intricacies, the model enhances its ability to generate accurate segmentation masks for evolving anatomies. The enhanced performance of the proposed model is attributed to the utilization of stylistic cues embedded in the template mask. By incorporating the template mask during training, the model learns to capture distinctive stylistic features associated with the chosen target (GTV, CTV, or PTV). During inference, when the model encounters a new image, it leverages these learned stylistic cues to generate segmentation masks that align with the visual characteristics of the specific target. This feature holds promise for addressing challenges related to real-time adjustments in adaptive radiotherapy. The ability to leverage prior information from template expedites the contouring process, reducing the time and effort traditionally associated with manual delineation. This efficiency is crucial for the practical implementation of ART in clinical settings.

While the model is demonstrated on breast cancer data, its underlying structure and principles can be expanded to apply to diverse adaptive radiotherapy scenarios. The model's generalizability to different anatomical sites positions it as a versatile tool for broader clinical adoption.

It is essential to consider potential limitations. The model's performance could be influenced by variations in imaging protocols, patient characteristics, and anatomical complexities. Addressing these factors in future studies will contribute to a more comprehensive understanding of the model's robustness.

5 Conclusion

The template-guided deep learning model with an inclusive training scheme presented in this paper showcases a novel paradigm for ART target segmentation. Adapting output based on chosen templates and employing stylistic cues presents a promising solution to the challenges of dynamic anatomical changes in ART workflow.

[4]Department of Applied Mathematics, Technical Medical Centre, University of Twente, Enschede, The Netherlands

Abstract Deep learning-based autosegmentation is conventionally assessed using geometric metrics. However, for clinically relevant quality evaluation, the dosimetric impact and the impact on normal tissue complication probability (NTCP) must be considered. Two distinct dosimetric effects can be distinguished. First, segmentation influences the optimized treatment plan (dosimetric impact on planning, DIP) and second, segmentation influences the dose evaluated in an organ (dosimetric impact on evaluation, DIE). We provide a comprehensive autosegmentation evaluation, considering geometric metrics, the DIP and DIE and the impact on NTCP of 68 head and neck cancer patients on 11 OARs. Mean Dice scores (0.50-0.90) and mean Hausdorff distances (0.74-1.26 mm) of autosegmentation did not correlate with the dosimetric measures. No significant mean dose effect exceeding 2 Gy was observed. The DIE showed larger variations than the DIP. An NTCP difference of ≥1.0 percentage point was found with the DIE for xerostomia. Furthermore, the DIE can be approximated using retrospective clinical dose distributions, reducing the workload of autosegmentation evaluation.

1 Introduction

Deep learning-based autosegmentation has gained prevalent attention by having the potential to improve accuracy, reproducibility and efficiency in segmentation in clinical practice [1]. Many different models are currently being developed, both in research groups and by commercial parties. For a proper comparison of these models and their safe introduction into clinical practice, it is important to understand the clinical impact of errors due to autosegmentation inaccuracies

Typically, autosegmentaion models are evaluated using a geometric analysis on metrics like the Sørensen-Dice similarity coefficient (DSC) or Hausdorff distance (HD). However, it has been shown that geometric autosegmentation discrepancies do not always correspond to clinical impact. [2] Even when clinical contours (CCs) and deep learning contours (DLC) are geometrically comparable, differences can be found when comparing the dose delivered to organs at risk (OARs) between the CC- and DLC-based treatment plans [3]. It is important to note, however, that when evaluating the dosimetric impact of autosegmentation errors, two distinct measures should be distinguished: the dosimetric impact on planning (DIP) and the dosimetric impact on evaluation (DIE). [4] These metrics can be interpreted as the impact of not correcting the DLC on treatment plan optimization and the impact on clinical evaluation of the dose parameters, respectively. While the DIP has been demonstrated to be small in previous studies [3,5], the DIE is, so far, not commonly addressed. The DIP and DIE introduce the task of making new treatment plans for autosegmentation evaluation. The proper assessment of the dosimetric impact on evaluation, however, is crucial since it influences clinical decision making. For example, in the model-based approach [6] to select patients for individualized treatment strategies (i.e. proton therapy or adaptive therapy), the accuracy of dose evaluation parameters resulting from an autosegmentation model is thus clinically relevant.

The aim of this study was to go beyond the use of only geometric metrics for autosegmentation evaluation and perform a comprehensive clinical evaluation of autosegmentation of head and neck DLC OARs. To this end, we compare DLC with CC and evaluate the geometric errors, the dosimetric impact on treatment planning, the dosimetric impact on plan evaluation and NTCP, while clarifying the clinical value of the different measures.

2 Materials and Methods

A total of 68 oropharyngeal cancer patients from a single center treated with primary radiotherapy (70 Gy in 35 fractions) between 2018 and 2022 were included. For all patients, DLC sets of OARs in the head and neck region were available (WorkflowBox 2.0, Mirada Medical Ltd., Oxford, United Kingdom) as well as manually adjusted CC sets. IMPT dose plans for both contour sets were automatically created in RayStation Development 10B (RaySearch Laboratories, Stockholm, Sweden) with a U-Net deep learning model.

A geometric comparison between the DLC and CC was performed for 11 head and neck OARs using the DSC and HD. For all OARs, the mean dose difference was reported as the dosimetric measure of interest. The dose differences were determined using the DIP and the DIE. The DIP was defined as the difference between plans optimized using the CC and DLC, evaluated on the CC. While the DIE was defined as the difference between evaluation on the CC and DLC using the plan optimized on the DLC, see Figure 1. To assess the DIE, an optimized dose distribution on the DLC is required. In a typical retrospective study this might not be available, therefore we also study to which extent the dosimetric impact approximation, the DIA, which is equivalent, but based on the optimized dose using the CC (see Figure 1), can be used as a substitute for the DIE.

NTCP-values for xerostomia and dysphagia, based on the mean dose on the parotid glands and mean dose on the oral cavity and superior pharyngeal constrictor muscle respectively, were chosen as clinically relevant metrics for

autosegmentation evaluation. A difference in mean dose of ≥2.0 Gy or NTCP-value of ≥1.0 percentage point (pp) was defined as clinically relevant by the head and neck radiation oncologist team. Statistical significance was assessed with a Wilcoxon signed-rank test. Correlation between geometric and dosimetric measurements was evaluated using scatter plots and the Spearman's Rank correlation coefficient.

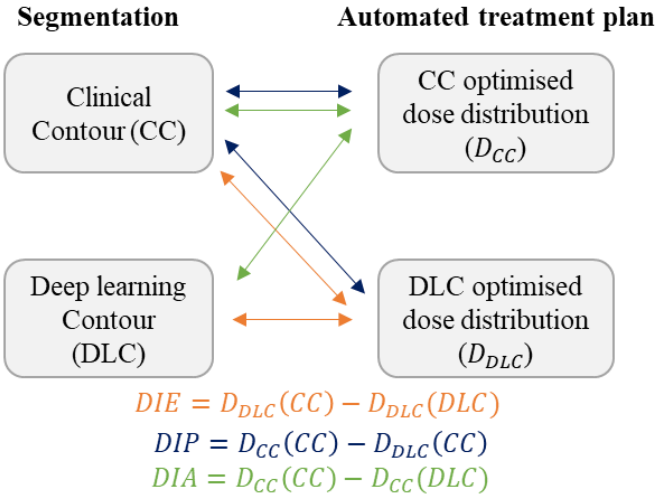

Figure 1: Schematic overview of DIP and DIE evaluation. DIP = dosimetric impact on planning. DIE = dosimetric impact on evaluation. DIA = dosimetric impact approximation.
D_x(y) = Dose optimized using segmentation x, evaluated on segmentation y

3 Results

Geometric evaluation

Geometric evaluation was performed using the DSC and HD. The DSC scores ranged from 0.50-0.90, see Table 1. The HD ranged from 0.74-1.26 mm.

Dosimetric impact on planning vs dosimetric impact on evaluation

The mean dose differences based on the DIP, DIE and DIA can be found in Table 1. A significant difference in mean dose with the DIP analysis was found in 7 out of 11 OARs. However, in none of the OAR structures the mean dose difference was more than 2.0 Gy. For the DIE and DIA analysis, the mean dose differences were generally higher than with the DIP, however, never larger than 2.0 Gy. The OARs portray a predominantly negative dose difference value (i.e. overestimation of dose deposition on DLCs compared to CCs).

Impact on NTCP

The NTCP values for dysphagia and xerostomia using the DIP, DIE, and DIA mean doses can be found in Table 1. A significant difference in NTCP-value ≥1.0pp was found for xerostomia grade II when using the DIE and DIA analysis. The other mean NTCP-value differences were smaller than 1.0pp.

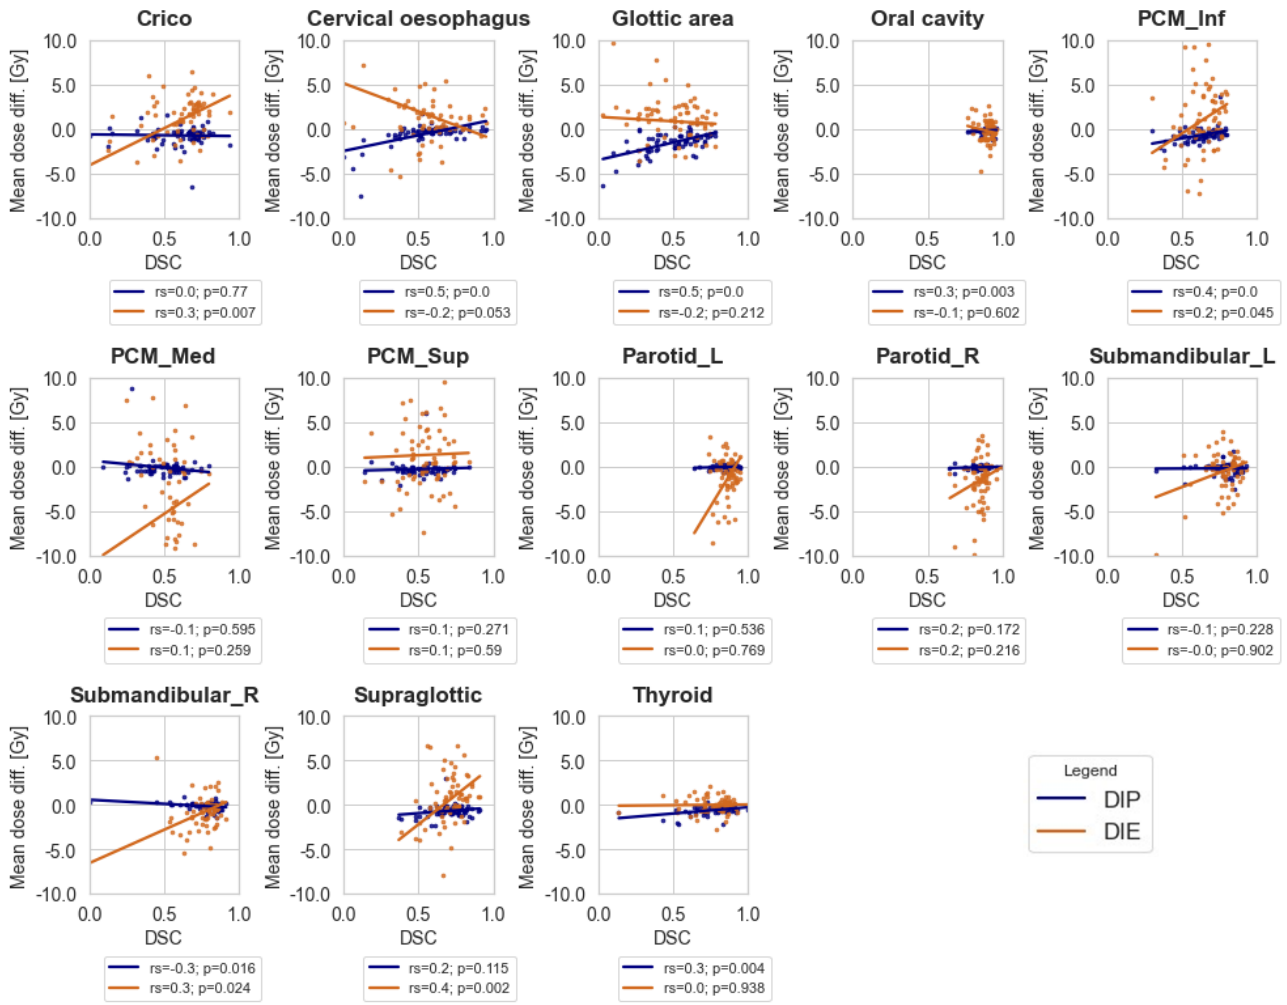

Figure 2: Geometric comparison (DSC) vs mean dose difference (diff.) (CC – DLC) using DIP, DIE and DIA per OAR with Spearman's Rank Correlation coefficient (rs) and corresponding p-value. A correlation coefficient > 0.5 or < - 0.5 with p < 0.05 is seen as a correlation. PCM = pharyngeal constrictor muscle. L = left. R = right. Please note the uneven grid spacing between the

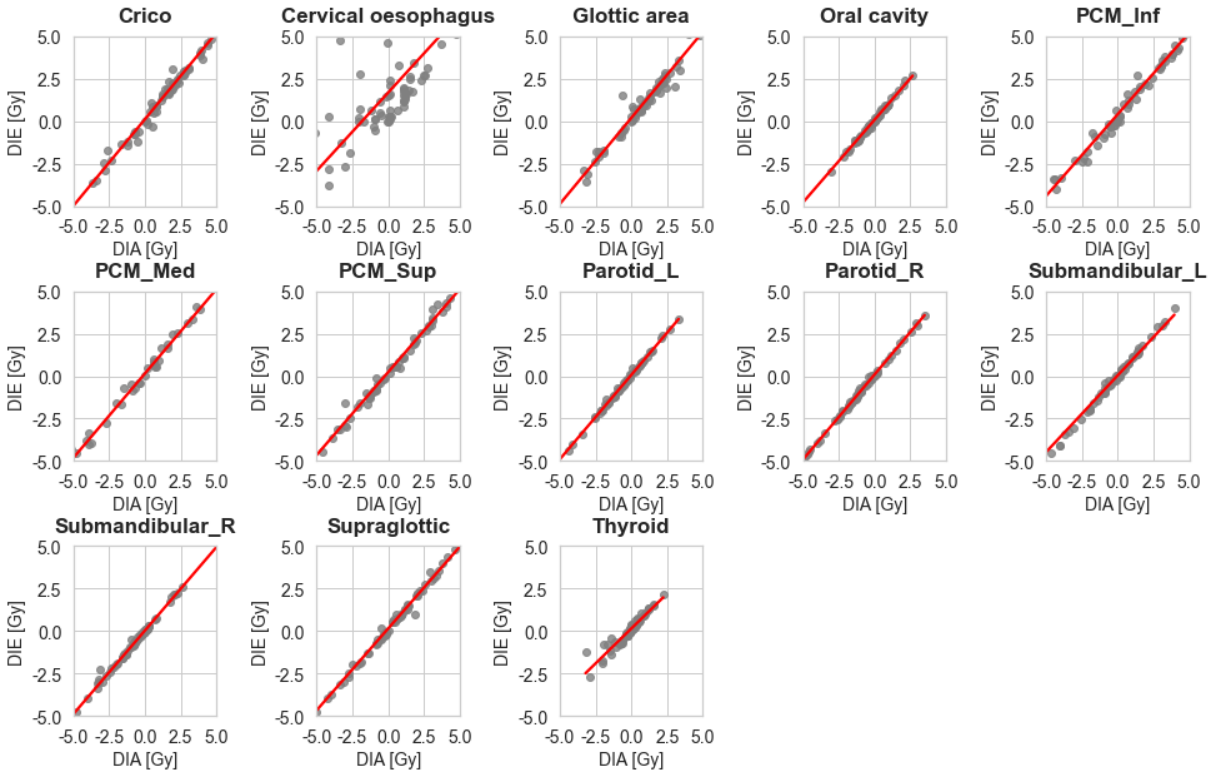

Figure 3: Dosimetric impact on evaluation (DIE) vs dosimetric impact approximation (DIA) mean dose difference (CC-DLC) per OAR.. PCM = pharyngeal constrictor muscle. L = left. R = right.

Measurement comparison
A comparison per OAR between the DIP and DIE relative to the DSC can be found in Figure 2. No significant correlation is found between the mean dose difference and DSC for all OARs.

Segmentation evaluation using retrospective clinical plans
The correlation between the DIE and DIA is shown in scatterplots per OAR in Figure 3. All OARs show a strong correlation.

4 Discussion

The impact of potential autosegmentation inaccuracies on dosimetric measurements in treatment planning (DIP) and treatment plan evaluation (DIE) was limited, with only Grade II xerostomia resulting in a clinically significant difference of 1.0pp. No significant correlation between the DSC and mean dose difference was found (Table 1 and Figure 2). This indicates that the extent to which the DSC is a meaningful metric to evaluate the clinical acceptability of the DLC is limited at best.

Furthermore, analyses of the DIP and DIE show that they are two distinct measures evaluating two different ways in which autosegmentation inaccuracies have a dosimetric impact. On average, the mean dose difference for the impact on plan evaluation (DIE) is larger than the impact on the optimized treatment plan (DIP), the standard deviation for the mean dose difference is larger with the DIE (Table 1) and the correlation with the Dice score is unalike between the DIP and DIE (Figure 2). The dosimetric analysis shows that the autosegmentation quality of this DL model is sufficient for automated treatment planning as the quality is not influenced by it, but that the autosegmentation quality is not satisfactory for treatment plan evaluation purposes. This is also shown in the clinical measurements where an NTCP-value of 1.0pp was seen for grade II xerostomia using the DIE analysis while for the DIP all NTCP values were below 1.0pp.

A possible explanation for the distinct results between the DIP and DIE can be found in the way dose plans are optimized using mean dose criteria. This is possibly less sensitive to the 3D dose distribution: presumably because if an OAR is in the beam's line of sight, the dose fluence coming through that line of sight will be lowered in the optimization. The precise shape of the OAR has only a limited impact on how the dose fluence is modulated. On the other hand: the impact on evaluation can be quite sensitive e.g. to volume changes of the OAR along dose the steep dose gradients. Thus, conceivably leading to larger mean dose difference when using the DIE compared to the DIP.

We also found that there is a strong correlation between the DIE and DIA for all OARs and that the DIA could thus be used as a substitute for the DIE evaluation. This would alleviate the workload for a retrospective dosimetric evaluation on autosegmentation, as no new treatment plan for the DLC has to be created for this analysis.

5 Conclusion

For all OARs the geometric quality of autosegmentation was found to be uncorrelated to the clinical impact measures. This indicates the importance of a comprehensive analysis beyond sole geometric evaluation for autosegmentation. The mean dose and NTCP differences when evaluating the dosimetric impact on treatment plan optimization (DIP) are lower compared to the impact on treatment plan evaluation (DIE). Indicating that both dosimetric measurements are essential in a clinically relevant evaluation of autosegmentation as they encompass distinct but both clinically important aspects of autosegmentation quality. The DIE might be approximated by using the dose differences between the CC and DLC in the retrospective analysis of clinical plans (DIA), reducing the workload of autosegmentation evaluation.

Abstract

Introduction
Recent developments in segmentation focus on enhancing accuracy and efficiency. Convolutional Neural Networks (CNN), especially the UNet architecture, has been applied for segmentation, however lately Vision Transformers ViT models have achieved high accuracy for segmentations. Therefore using a CNN UNet and ViT in ensemble learning could benefit from the different properties, to enhance a models' capabilities of handling variations in organ sizes, while providing high quality segmentations on smaller datasets.

Method and Materials
nnUNet and a ViT model were trained individually to perform segmentation of 8 organs at risk (OAR) in the brain. The dataset included 55 T1 contrast enhanced MRI scans split with 49 used for training and 6 for testing. Ensemble learning was applied to the models from fold 4 to generate the final segmentation. The evaluation compared the predicted segmentations and manual delineations provided by oncologists, using dice score, 1mm normalized surface dice and hausdorff distance 95th percentile.

Results
1mm normalized surface dice medians was in the range of 0.90 to 0.94, the dice in the range of 0.85-0.97 and hausdorff 95th percentile ranged from 1.0 to 2.0 across 8 organs at risk,

Discussion
The results suggest that ensemble learning of different small deep learning models could contribute to increasing accuracy when having a smaller dataset size and class imbalance however additional evaluation on a new dataset is needed.

1 Introduction

With the recent advancement in artificial intelligence, in particular in deep learning, more advanced models are being proposed to obtain highly accurate and clinically acceptable segmentations. Traditionally, this is achieved by increasing a single models' complexity, which creates a reliance on the availability of large datasets as the size of the dataset impacts the performance of the segmentation model.[1] This is a challenge in radiotherapy as data is often limited resulting in a small dataset sizes.

Additionally a challenge called class imbalance also arises, which can induce biases in model performance, when the model struggles to adequately learn the underrepresented class. So a limited dataset size coupled with class imbalance presents obstacles for acquiring a high accuracy and generalizability of segmentation models. To enhance model performance and address these challenges effectively, several techniques could be employed.

Therefore we apply ensemble learning for two distinct, separately trained, deep learning models: a Convolutional Neural Network (CNN) UNet and a Vision Transformer (ViT). We hypothesize that this will reduce the impact of the limited dataset size and class imbalance for multi organ segmentation on MRI scans of patients with brain cancer.

1.1 Related works

Significant advancements have been made in the field of medical image segmentation in recent years, to improve accuracy and efficiency of the models . CNNs have frequently been proposed for segmentation, with UNets as a widely employed architecture. CNN UNets has been successful in delineating organs at risk(OARs) in various areas of the body including in the brain. [2] [3] [4] [5] [6].

More recently ViT models have been used for segmentation. [1]. ViTs have been shown to provide highly accurate segmentations of small structures which have been attributed to their ability to capture global context and relationships within the images. [1] [7] [8]

These notable advancements observed in the individual models, prompted a suggestion to integrate the properties of CNNs and transformers. This could use the diverse model properties for capturing both local and global information, thereby enhancing the models' ability to handle variations in organ sizes [9] [10]. For brain structures such architectures have been employed, to enhance segmentation accuracy of OARs, including for brain structures where DSCs of 0.96 has been achieved for larger organs, however this on significantly larger datasets. [1]. More commonly DSCs of 0.70-0.89 are acquired on smaller datasets. [11] [12]

While advancements in medical image segmentation are evident, challenges such as limited dataset sizes and achieving consistently high segmentation accuracy independent of organ size, remain [13] [14]

2 Materials and Methods

2.1 Data

Patient demographics of the patients included in the study is presented in table 1

Median Age (range)	47.0 (35.5 - 59.5)
Gender	Male: 53 % , Female : 47 %
Tumor type:	glioma , meningioma

Table 1: Patient demographics

The available dataset for this study consists of 55 T1-weighted contrast-enhanced (T1w CE) Magnetic Resonance Imaging (MRI) scans with corresponding manually delineated structures of 8 OARs of patients with brain cancer. The 8 OARs manually delineated include

- Brainstem
- Chiasm
- Hippocampus L/R
- Optic nerves L/R
- Optic tract L/R

49 of the patients were allocated as training data with the remaining 6 patients for test.

2.2 Preprocessing

Initial preprocessing consisted of z-score normalization, to standardize the intensity values across all scans. Subsequently, cropping a central region with boundaries based on the label mask was performed to reduce the computational load.

2.3 Ensemble learning

Ensemble learning was applied to integrate the predictions of two individually trained weak models, to collectively improve quality and generalization via a strong model. This approach allows for fine-tuning of individual models, emphasizing their distinctive strengths of smaller compact models which are well-suited for optimization of the grounds of smaller datasets while enhancing accuracy.
The initial weak model in the ensemble is a UNet architecture using CNN, specifically nnUNet, while the second weak model in the ensemble adopts ViTs trained using an identical dataset to collectively create a strong model which provides final segmentation of the 8 OARs as presented in figure 1.

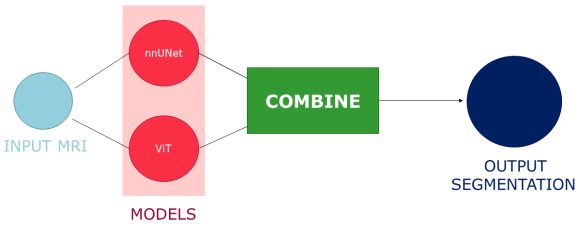

Figure 1: Representation of ensemble learning

2.4 Evaluation

For assessment of the proposed ensemble model, a set of evaluation metrics representing the volumetric and distance accuracy was employed. These metrics encompass the 1mm normalized surface Dice (1NsDSC), Dice score (DSC), and the 95th percentile of the Hausdorff distance (HD95). Using these metrics, we assess the similarity between the predicted segmentations from the ensemble model and the manually delineated OARs provided by an oncologist.

3 Results

3.1 Dice results

The median DSC values ranged from 0.85 to 0.97 across all segmented structures. The lowest median DSC was observed for the right optic tract see figure 2, while the highest obtained median DSC was for the brainstem.

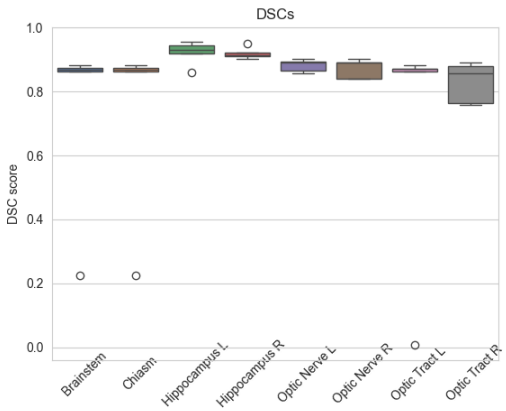

Figure 2: DSCs for the ensemble mode for 8 OARs

3.2 1 mm normalized surface dice results

The 1NsDSC, demonstrated median scores within the range of 0.90 to 0.94, with the lowest medians being for the left hippocampus and the highest being the brainstem

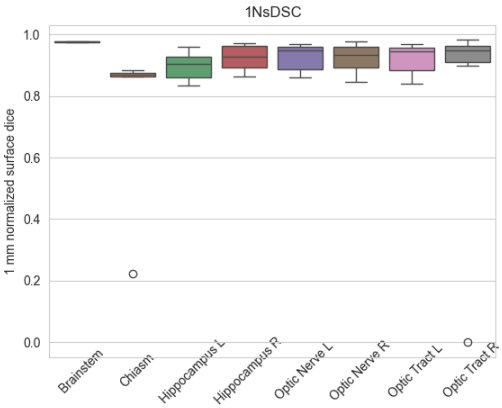

Figure 3: The ensemble models' 1 mm normalized surface dice for 8 OARs

3.3 HD95 distance

The HD95 distance metric, medians ranging from 1.0 to 2.0, with the right hippocampus displaying the lowest HD95 distance and the left optic tract showcasing the highest.

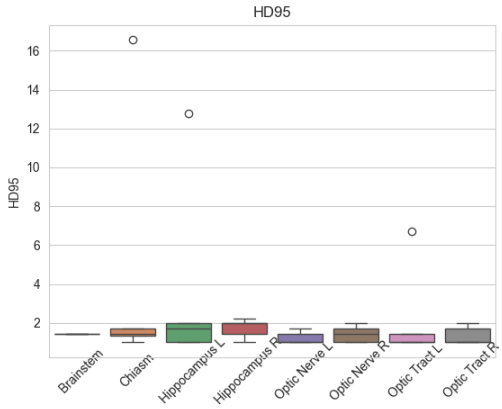

Figure 4: Hausdorff distance 95th percentile for the ensemble model across 8 OARs

4 Discussion

4.1 Results

The ensemble learning approach, combining the strengths of UNet and ViT models suggest a plausible approach when working on smaller datasets. The consistently high DSC and 1NsDSC, coupled low HD95 distances, suggest a high efficacy of the ensemble models' ability to achieve precise segmentations across the diverse set of OARs. Furthermore, these findings indicate a high capacity to localize small anatomical structures in challenging regions, which could indicate that combining various types of deep learning models in such way could contribute to mitigate the class imbalances otherwise present in the dataset.

Assessing the effectiveness of the ensemble approach can be done through a comparative assessment of the ensemble model and the weaker models contributing to the final strong model. Effectiveness is assessed by comparison of the evaluation metrics, specifically the 1NsDSC and HD95, which was used in the evaluation of the ensemble model performance. Examination of the 1NsDSC scores, for the nnUNet, medians lie in the range of 0.77 to 0.89 and 0.85-0.90 for the ViT. Compared to the medians of 0.90-0.94 for the ensemble, it suggests that the ensemble model's ability to define organ boundaries did improve when compared to its individual weak models. For the HD95, the ViT and nnUNet models showed medians in the range of 3.3-1.9 and 4.3-1.0, respectively, whereas the the ensemble model demonstrated distances within the range of 2.0- 1.0. This coupled with the DSC scores results suggest an improvement when utilizing the ensemble to create the final segmentations
The ensemble has notable enhancements in accuracy, as indicated by the evaluation metrics, which suggest a potential of ensemble modeling as a robust strategy for improving medical image segmentation tasks when having small datasets containing class imbalance.

4.2 Model

The decision to employ ensemble learning, combining the strengths of CNN UNet and ViT models, was motivated by their ability distinct features and patterns due to their different architectures. The UNet provided local information, while the ViT ensures a global oversight of the entire image. By using both models, we aimed to exploit the unique capabilities of each model type for more accurate segmentation. Training on the same dataset, the models were provided with a common understanding of the underlying patterns in the dataset which contributed to the consistency of the ensemble model. Meanwhile the likelihood of overfitting can be reduced by distribution of parameters between two models with individualized training sessions.

4.3 Clinical Significance

The consistently high performance across multiple metrics suggests a strong potential for clinical use. Accurate segmentation of OARs is important in treatment planning of patients with brain cancer, and the ensemble models are promising. However, additional clinical qualitative evaluation should be performed.

4.4 Limitations and Future Directions

Result obtained in this study rely on the quality of the training dataset. Future work could explore the impact of dataset variability and the generalization capacity of the models for a larger patient cohort in the test phase. Additionally, the proposed ensemble architecture opens the possibility for additional fine-tuning and optimization on smaller datasets for an enhancement performance on other modalities. Finally, a

clinical assessment to determine the quality of the segmentations in a clinical setting is needed.

5 Conclusion

In conclusion, the ensemble learning approach integrating UNet and ViT models seems promising for the segmentation of OARs in the brain. The obtained results underscore the potential clinical significance of the proposed methodology and contribute to the ongoing discourse on using diverse model architectures for enhanced medical image segmentation. As the field continues to evolve, this work sets the stage for further exploration, refinement, and application in real-world clinical scenarios.

Abstract Large interobserver variations (IOV) are expected when delineating structures on a CT scan, especially small structures with low visibility, like the clinical target volume internal mammary lymph node chain (IMN). A solution to avoiding IOV is deep learning-based auto-segmentation (DL). However, to train a robust and well performing model, a large and high-quality data set is needed. A large data set can become available if using delineations from the daily clinical practice, however these can be prone to large IOV. A data set created specifically for the purpose of training a DL model allows for obtaining a lower IOV, however this also entails a small cohort, as it is time-consuming to create. The aim of this study was to investigate the difference in output, when training a model in three different scenarios: a large clinical delineated data set (with 700/78 patients for training/testing, from the Danish Breast Cancer Group (DBCG) RT Nation Study), a clinical but curated dataset (with 328/36 patients for training/testing, from the DBCG RT Nation Study) and a smaller, but dedicated data set created by delineation experts (with 123/14 patients for training/testing, consensus delineations created by delineation experts). The model performance was estimated based on the performance metrics dice similarity coefficient (DSC), Hausdorff 95th percentile (HD95) and mean surface distance (MSD). Models were tested in test sets from their own cohort, and afterwards also compared in the dedicated data test set. The difference between model output was finally estimated by measuring the mean width and cranial caudal length of the model output for the models. When testing the model output between the clinical models and the dedicated models in their own test set, the two clinical models had a poorer performance, than the dedicated models, but not all metrics showed statistically significance. When testing the models in the dedicated data, the dedicated model showed a slightly better performance, along with fewer segmentation outliers. As a way of taking advantage of the strength from both types of data set, it could be an option to use a large clinical data set as a baseline model, and then finetune with smaller sized cohorts with dedicated delineations.

1 Introduction

Yearly more than 4700 women are diagnosed with breast cancer in Denmark[1]. Most patients are operated and more than 80% of these are treated with post-operative adjuvant radiotherapy[2]. Node positive breast cancer patients are treated with internal mammary lymph node (IMN) irradiation to improve overall survival[3,4]. Constraints to organs at risk (OAR), such as the heart, lung and contralateral breast, often call for a clinical compromise during treatment planning. The radiation treatment plans are optimized based upon manual structure delineations on CT scans. The IMN target is difficult to see on CT scans[5], which may introduce interobserver variation (IOV), despite strict national and international delineation guidelines[5,6]. Recently, DL has been studied as a way of mitigating IOV. For OAR, DL has been shown to work well [7], but for target structures there are still challenges. In order to achieve a good performance with DL models, large data sets of high quality are generally needed. But, achieving both high quantity and high quality in these data sets is a challenge, as delineation is time-consuming.

In the radiotherapy community, the data sets for DL models are often achieved through data farming - a single expert or a small group delineates a dedicated data set, to minimize the IOV. This is only feasible for small data sets due to the limit on clinicians' time, and thus hampers the size of the cohort. This further decreases the generalizability of the model, as the limited size training data set lacks diversity. One solution to obtaining large data sets could be to use the clinical delineations retrospectively. This will not only allow for larger data sets, but also include a variation of patient anatomy, setup scenarios and CT scanners for increased generalizability. Clinical delineations reflect daily high workload and a larger variation in delineation quality is therefore expected compared to dedicated data sets created by a single or group of experts strictly following the same delineation guidelines. The Danish Breast Cancer Group (DBCG) has established the DBCG RT Nation database, containing CT scans and structure sets from more than 7500 Danish high-risk breast cancer patients, who received radiotherapy in 2008-2016[8]. In addition, for a small subset of the DBCG RT Nation data set dedicated edited delineation of target structures has been generated by the DBCG following a target delineation consensus workshop.

The primary aim of this study was to investigate the difference in model performance when training a DL based model for the IMN target structure on clinical delineations vs dedicated delineations.

2 Materials and Methods

The study included left-sided breast cancer patients, treated in 2015-2016 from the DBCG RT Nation study, as this was the period after implementation of national delineation guidelines[5,6]. In total 778 patients were included (data_CLIN). The patients were treated with adjuvant loco-regional radiotherapy at the seven radiotherapy centers in Denmark, generating a variance in scanner and set-up protocols in the data. Depending on tumor location, it is clinical practice to delineate the IMN to intercostal room (IC) 3 or IC 4.

The full CT scans and IMN delineations were used as input in a 3D full-resolution nnUNet [9], and the data set was randomly split into a training set (90%) and test set (10%). Five-fold cross validation was used with default parameters and the number of epochs was varied depending on cohort size, to avoid overfitting. Before training of the two models, the DICOM files were converted into NIfTI files with the Python package dcmrtstruct2nii [10]. Three different models were trained. The first model was trained on the full cohort of 778 clinical IMN delineations (model_CLIN), with no data curation. The model was trained with 800 epochs. For the second model, the data was crudely curated to only encompass IMN delineations extending to IC 3, to lower the variance in the data set occurring due to differences in inclusion of IC 3 and IC 4 (data_CURATED_CLIN). The model was trained with 600 epochs (model_CURATED_CLIN). The third model was trained on a smaller, but dedicated data set (data_DED). The data_DED was created from the data_CLIN. Of the 778 left-sided breast cancer patients, 143 were used to create the data_DED. The patients were chosen to be equally distributed from the seven radiotherapy centers in Denmark and equally distributed between lumpectomy or mastectomy. A national target delineation workshop was held in October 2022 by the DBCG and the Danish Comprehensive Cancer Center, where 21 participants from all RT centres in Denmark discussed the national delineation guidelines [5,6]. Following the workshop days, the participants were asked to correct the 143 clinical delineations (6-7 each), so they followed the national delineation guidelines. The model_DED was trained with 300 epochs. Because the dedicated data set was relatively small, as an extra robustness test, the training and test set split was performed arbitrarily additionally two times with the data_DED. This allowed for an extra two versions of model_DED (model_DED_second_split and model_DED_third_split) and two extra dedicated test sets, to test the performance of model_CLIN and model_CURATED_CLIN. To estimate and compare the IOV in the five training cohorts, the mean width and cranial caudal length were calculated for all delineations in the training cohort. The width was calculated by measuring the longest distance between each coordinate set, and subsequently the mean width was calculated by averaging over all slices. The cranial caudal distance was measured from the most cranial slice to the most caudal slice. The measurements were conducted on the NIfTI masks.

The performance of the five models was first evaluated in their own test-set with the performance metrics: the dice similarity coefficient (DSC), the Hausdorff distance 95th percentile (HD95) and the mean surface distance (MSD). The statistical significance was tested with the Mann-Whitney U-test, assuming statistical significance level at $p<0.05$. As the variation in model training data might be reflected in the testing data as well, the model_CLIN and model_CURATED_CLIN was tested in the three different data_DED test sets, to estimate the performance of all three in a low IOV data set. In addition, the mean width and the cranial caudal length of the three model_DED, model_CLIN and model_CURATED_CLIN segmentations in the model_DED test sets were measured and compared. The statistical significance was tested with the Wilcoxon signed-rank test, assuming statistical significance level at $p<0.05$.

	DSC (mean) range	HD95 [mm] (Mean) range	MSD [mm] (mean) range
Model_CLIN (own test set, n = 78)	0.65 *,+, # (0.46 – 0.80)	11 *, # (2.30 – 125.6)	2.55 *,+,# (0.59 – 19.8)
Model_CLIN (dedicated test set first split , n = 14)	0.71 (0.57– 0.84)	6.54 (1.95–25.8)	1.37 (0.42– 3.49)

Table 1. The performance of model_CLIN, model_CURATED_CLIN and model_DED in their respective test set and in the three dedicated test set splits (n=14). The performance metrics are the dice similarity coefficient (DSC), the Hausdorff 95th percentile (HD95) and the mean surface distance (MSD). Statistical significance between clinical models tested in their own test and model_DED is denoted with * for the first split, + for the second split and # for the third split. Statistical significance between clinical models tested in the dedicated test sets and model_DED tested in the corresponding split is denoted ¤. The third test is used as example in both figure 1 and 2.

3 Results

A total of 778 delineations were available from 2015-2016, leaving 700 for training the model_CLIN and 78 for testing the model_CLIN. During curation of the IMN delineations a total of 442 delineations were excluded, leaving 328 for training the model_CLIN_CURATED and 36 for testing the model_CLIN_CURATED. In the data_DED six delineations were excluded, due to the IMN extending to IC 2 or IC 4, leaving 123 for training the model_DED and 14 for testing the model_DED. In the training cohort, the data_CLIN had a mean width = 14.4 mm and a mean cranial caudal length of 108.2mm, the data_CURATED_CLIN had a mean width = 13.5mm and a mean cranial caudal length of 102.1mm and the data_DED (first/second/third) with a mean width = 14.5 mm/14.4mm/14.4mm and mean cranial caudal length of 107.8mm/108.1mm/108.0mm, figure 1.

Statistically significant difference was found for all except the difference in cranial caudal length between data_CLIN and data_DED and cranial caudal length and width between data_CLIN and data_DED_second_split and data_DED_third_split.

In their respective test sets, the two clinical models generally had poorer performance (mean DSC 0.65-0.66, HD95 11-11.8, MSD 2.55-3.00) than the three model_DED (mean DSC 0.71-0.74, HD95 5.3-7.58 MSD 0.96-1.41), however not all metrics showed statistical significance, table 1.

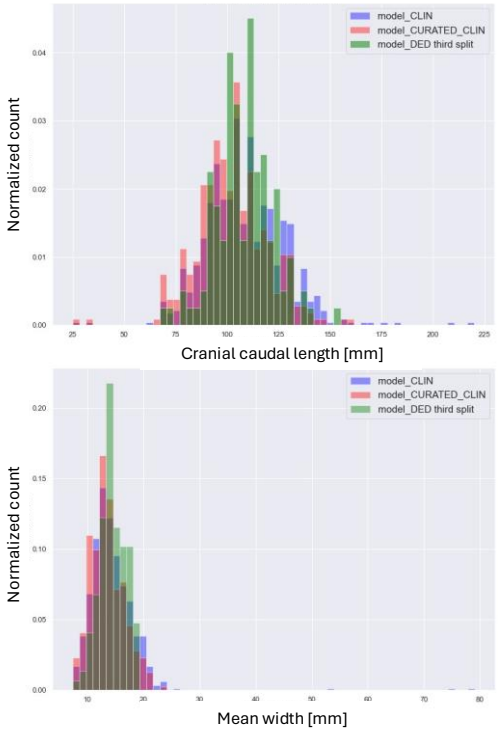

Figure 1: (top) The cranial caudal length of the delineations in the training cohort of the model_CLIN(blue), model_CURATED_CLIN (orange) and the third split of model_DED (green). (bottom) the mean width of the delineations in the training cohortsThe counts are normalized.

The difference between the performance of the two clinical models tested in the three dedicated test sets and the model_DED varied with the different training/test splits, table 1. A large range in both HD95 and MSD was seen in the two clinical models (MSD range 0.42-7.97 and 0.39-6.16) when tested on the dedicated test sets, along with an overall better performance of the three model_DED (MSD range 0.54-2.44), but not all were statistically significant, table 1.

The mean width of the CTVn_IMN with the model_CLIN in the third dedicated test set was 12.9mm and the mean cranial caudal length was 115.7mm and the mean width with the model_CURATED_CLIN was 12.3mm and the cranial caudal length was 104.7mm. The mean width of the CTVn_IMN with the model_DED_third_split in the third dedicated test set split was 137.7mm and mean cranial caudal length was 112.1mm. The difference in cranial caudal length was found statistically significant between model_DED_third_split and model_CURATED_CLIN and the width was found statistically significant between both clinical models and the model_DED_third_split, figure 2 and table 2.

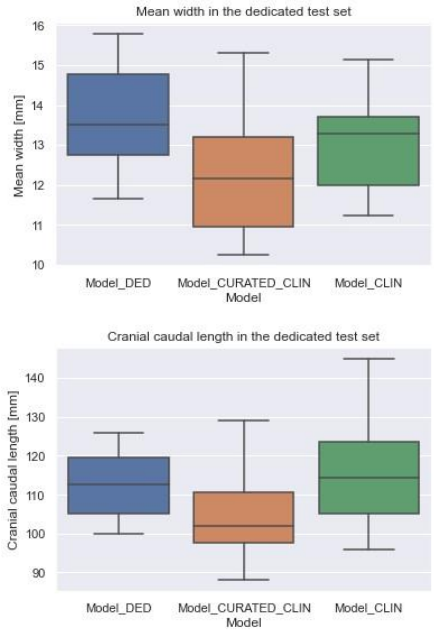

Figure 2: (top) The mean width in model output of the third split with model_DED (blue), model_CURATED_CLIN (orange) and model_CLIN (green) in the dedicated test - set. (Bottom) the cranial caudal length of the segmentations.

	Cranial caudal length [mm] (mean) range	Width [mm] (mean) range
Model_CLIN (dedicated test set first split, n = 14)	119.4 (102.0-150.0)	12.9 (11.0-14.8)
Model_CLIN (dedicated test set second split, n = 14)	113.3 (97.5-132.0)	13.3 * (11.0-16.0)
Model_CLIN (dedicated test set third split, n = 14)	115.7 (96.0-145.0)	12.9 * (11.2-15.1)
Model_CURATED_CLIN (dedicated test set first split, n = 14)	110.0 (86.3-144.0)	12.4 * (10.8-14.7)
Model_CURATED_CLIN (dedicated test set second split, n = 14)	101.3 * (85.0-129.0)	13.3 * (11.1-17.0)
Model_CURATED_CLIN (dedicated test set third split, , n = 14)	104.7 * (88.0-129.0)	12.3 * (10.2-15.3)
Model_DED (dedicated test set first split, n = 14)	115.1 (94.0-130.0)	13.4 (11.6-16.1)
Model_DED_second_split (dedicated test set second split, n = 14)	112.5 (92.5-136.0)	14.2 (12.2-16.7)
Model_DED_third_split (dedicated test set third split, n = 14)	112.1 (100.0-126.0)	13.7 (11.6-15.8)

4 Discussion

In this study, we have investigated the difference in performance when using a clinical cohort, a curated clinical cohort, and a dedicated cohort to train DL-based auto-segmentation models for the left-sided CTVn_IMN. The differences among the three model predictions were minor and dependent on test set choice. However, for geometrical shape metrics, statistically significant differences were seen between the clinical models and the three versions of model_DED. The optimal balance between high-quality delineations and a large cohort is difficult, and both factors contribute to the performance of a DL model. Normal practice in the radiotherapy community is data farming, by creation of a dedicated data set, which limits the cohort size. Studies have investigated how low it is reasonable to go in size of data set without losing the precision of the DL

model. In Henderson et al, it was shown that for OAR in head and neck cancer increasing the data set beyond 250 scans gave very little improvement in model performance[11]. However, in a recent study from our group, we showed that for heart segmentation, smaller training cohorts increased the risk of outlier segmentations, when testing it in a set with larger variety in anatomy[12].
In this present study, there is a difference in model performance metrics among the three models, however there is not a consistent statistically significant difference between the models. It is worth noting that the test sets with dedicated delineations were small (n=14) and therefore does not represent a large variety of patient anatomies. Two additionally splits of the train/test set was performed with data_DED as an extra robustness test. The three different data_DED test sets led to different results of performance for model_CLIN and model_CURATED_CLIN, showcasing the impact of the specific patients included in the test set for such a small number of patients[12]. It would be expected that a larger number of patients in the test set would give a better estimate of the robustness of the models. However, despite the small test sets, there is still evidence of generally poorer performance and larger spread in the range of performance metrics in the clinical models than in the dedicated models, table 1. As a way of taking advantage of the strength from both types of data set, it could be an option to use a large clinical data set as a baseline model, which can then be finetuned with smaller sized cohorts with dedicated delineations. This would give both the variety available for generalizability from the clinic, and the low IOV and high precision delineations from dedicated data generation. If this approach is proven feasible, it might also be a way to tackle the problems arising when the delineation guidelines are updated and there will be a need for an update of the DL model. The dedicated delineations were created by delineation experts from seven institutions and based on editing existing delineations used in the clinic. The choice of correcting clinical delineations instead of delineation from scratch aimed to lower the delineation burden on busy clinicians. However, presenting delineators with an existing delineation imposes a risk of creating a bias as compared to delineating from scratch. The variety of expert delineators also introduce some IOV. Nevertheless, it is expected that the delineations created in the dedicated process, are as precise as possible on a national scale. Only a quantitative comparison has been conducted on these models. For a performance check, a qualitative investigation with expert assessments would be needed, as studies have shown, that the quantitative metrics not always correlate with clinical acceptance[13].

5 Conclusion

Training of a model on a clinical data set, showed on average a good performance, showcasing the benefits of using a large data set. Furthermore, a model trained on a large clinical data set performed better than a model trained on a curated clinical data set. However, the models trained on a dedicated data set showed a slightly improved performance, along with fewer segmentation outliers as compared to the models trained on clinical delineations. A combination of both models may be a way to utilize the best of both worlds.

Abstract In order to optimize the radiotherapy treatment and reduce toxicities, organs-at-risk (OARs) and clinical target volume (CTV) must be segmented. DL techniques have great potential to accomplish this task taking into account also segmentation variability. Thanks to the availability of a large single-institute data sample together with numerous multi-centric data, a reliable CTV segmentation model is feasible and possible to be validated. A preprocessing, aimed to uniform all the images, followed by a 3D-Unet able to segment both right and left CTV was implemented. The metrics used to evaluate the performance are the Dice similarity coefficient (DSC), the Hausdorff distance (HD) and its 95th percentile variant (HD_95). The segmentation model achieved high performance on the validation set (DSC: 0.901; HD: 20.9 mm; HD_95: 9.6 mm). Moreover, the model predicts contours more extended than clinical ones along the cranio-caudal axis in both directions. The same metrics applied on a large multicentric dataset showed an overall agreement and model transferability for all but one (Institute 9) center considered.

1 Introduction

A largely applied approach in the treatment of breast cancer consists in the sequence of breast-conserving surgery followed by radiotherapy. To optimize the radiotherapy treatment, organs-at-risk (OARs) and clinical target volume (CTV) must be segmented. This is a highly time-consuming task done nowadays manually and prone to large inter and intra-observer variability [1]. Thus, the interest toward automatic tools supporting OARs/CTV segmentation is rapidly increasing, although also if just few studies dealt with CTV breast segmentation using large cohorts [2]. Atlas-based methods were first considered [3], but Deep Learning (DL) based methods (e.g., ResNet, U-net, nnUnet) are preferred to train/test reliable models [4–7], particularly for soft tissue-based regions. This may help in optimizing and reducing the clinical workload in the radiotherapy workflow, also if particular attention must be given to reach high segmentation precision considering the direct influence on treatment planning. Moreover, in order to improve the consistency between manual and automatic segmentation, inter-observer variability has to be taken into account, task not reached by ATLAS based method, but by DL models. Very importantly, the inter-observer (and inter-Institute) variability in breast CTV segmentation is large [8, 9] and, to our knowledge, this issue has been considered just by few works [10] into the development of DL tools for auto-segmentation. Futhermore, the multi-institute external validation of a DL model on the CTV auto-segmentation was not described before.

The aim of this work is to create for the first time an advanced in-house DL 3D model able to automatically segment right and left CTV breast together thanks to the availability of a large patients' cohort treated all in a single institute (611 patients). Moreover, the model has been internally and externally validated on a multicentric cohort of 8 institutes (including Institute 3, the same center on which training was performed) on 978 patients.

2 Materials and Methods

The dataset (3D CT images) consists of 611 patients, who underwent breast-conserving surgery followed by radiotherapy (RT), of which 20% was used for model validation. Patients collected are respectively 332 for right-sided breast cancer (BC) and 279 for left-sided BC. The images were acquired through different scanners and thus have variable 3D size

and resolution. CTV delineation was performed by different clinicians in the period 2017-2021. All patients signed an informed consent for treatment and permission for publication of disease-related information following the Helsinki Declaration. The institutional ethics committee approved the retrospective revision of patient outcomes and a prospective study of the quality of life of BCa patients treated with hypofractionation, registered to ClinicalTrials.gov (NCT03077191).

A pre-processing phase was firstly accomplished, aiming to make image format optimal to train a neural network (es. crop, resize, scaling). All images were re-sampled in order to have uniform images of 512*512*256 voxels (voxel space: 1*1*1.5 mm^3). To help in the CTV side identification (right or left) and to reduce the input parameters without reducing the voxel resolution, an automatic cropping of the left/right quadrant was applied, resulting in final images' dimension of 256*256*256 voxels. To do this, the xy coordinates of the body ROI center were computed for each slice along the cranio caudal axis. The median value of these coordinates were used as the lower left/right (depending on the side) corner of the crop rectangle for every slice with the addition of a fixed extra shift of 25 pixels, including more tissue in the image fed to the neural network. Moreover, to make the network properly working and to enhance the glandular and fat tissue intensity difference, a minimum of -200 HU and maximum of 100 HU were chosen and then scaled to be between 0 and 1.

Then, all images (i.e., with left/right BC) were used to train a global model. A 3D Unet, enriched with dropout and residual units, from the MONAI library (`https://zenodo.org/records/8436376`, v1.3). All procedures were implemented in-house and included in a library called libsrdl in mAItre, using python 3.10.9. The best parameters of the Unet were obtained after an hyperparameter optimization done through "optuna" [11]. Other architectures were tested (e.g. DynUnet, SegResNetDS), obtaining performances comparable or lower. Regions with rescaled intensity value of zero were removed to focus on the valid body area. Data augmentation (random flip on x, rotation, translation, scaling, Gaussian sharpening) was performed.

The segmentation performance of the validation dataset was addressed through Dice Similarity Coefficient (DSC), Intersection over Union (IOU), the Hausdorff distance (HD) and its 95th percentile variant (HD_95) metrics. Each 3D segmentation prediction was cropped in the cranio-caudal direction, a posteriori, to match the clinical segmentation, due to their expected large inter-observer variability. Finally, the predicted segmentation was co-registered back to the original image dimension needed in future for clinical purpose.

As external validation dataset, planning CTs from the MIKAPOCo (Multi Institutional Knowledge-based Approach to Plan Optimization for the Community, AIRC Grant IG23150, 248/2021) study were used, which includes 10 centers (eight of which were here analyzed). Within the MIKAPOCo activities already accomplished, plan prediction models were developed aiming to quantify inter-institute variability in plan prediction, suggesting high transferability for both right and left breast scenario [12]. Patients considered are respectively 526 for right-sided BC and 452 for left-sided BC, with a minimum number of patient per center of 54. Of these, 81 patients from

Institute 3 are here used as internal validation set within the MIKAPOCo dataset, not overlapping with the training set.
The preprocessing applied to the external validation dataset is the same applied to the training set and the global model was applied to the images for prediction. From the generated CTV prediction, quantitative features were extracted to assess the contours quality. The metrics chosen to compare between centers are DSC, HD, HD_95 and the difference of the volumes volumes difference (VD) of CTVs segmented by radiation oncologists and the predicted ones.
Considering that the model trained could also seldom segment the controlateral breast, patients with Hausdorff Distance values greater than 50 mm were not considered in this first stage. Follow-up studies will implement a post-processing pipeline where just the main continuum volume predicted will be considered, getting read of both cranio caudal and controlateral misprediction.

3 Results

The best 3D model obtained was able to reach, after 178 epochs, high metrics performance on model validation (DSC: 0.901; HD: 20.9 mm; HD_95: 9.6 mm, see Figure 1, 2), similar to what reached in [9]. Our network, however, is a 3D model and the predictions are smoother between slices, as it should be, well mimicking clinical practice. The predicted segmentation well matches the clinicians' contours on the skin and chest side, while it is more uncertain, as expected, on the lateral and cranio-caudal side (see Fig. 3). The cranio-caudal direction is also uncertain given the different strategies used in that regard by clinicians. In particular, the median absolute difference between predicted and observed segmentation is respectively 4.5 mm (IQR: 1.5-9.0) and 10.5 mm (IQR: 4.5-21.0) in caudal and cranial. They have thus a larger prediction along the cranio-caudal axis in both directions. This variability is also confirmed by running the same model with different random seeds for the dropout layer. Moreover, the predicted segmentation is found fully larger than the clinicians contouring (17 ml).
Finally, we performed prediction on the internal validation dataset (Institute 3) withing the MIKAPOCo set, obtaining on average values similar to model validation (DSC: 0.900, HD: 21.1 mm, HD_95: 9.5 mm; both sides, see black lines in Fig. 4). By using the Mann-Whitney test (with $p < 0.05$), Institute 10 and 7 right, Institute 4 and 9 left are different from Institute 3 for two out of three metrics. Considering that Institute 4 has better performances than Institute 3, it is possible to consider it still compatible. Our model tends to predict CTVs larger than the radiation oncologists' ones, mainly in the cranio caudal side. For what regards the lateral side, it depends on the center behaviour: Institute 4 (right side), 5 and 9 have predictions typically larger than clinical CTV, Institute 2 and 3 are smaller, while the other centers are statistically in line with clinical volumes. Institutes 1, 10 and 7 are in line with clinical volumes. Comparing volume differences to the one of Institute 3, all institutes but 2 and 10 have smaller differences (Mann-Whitney $p < 0.05$).

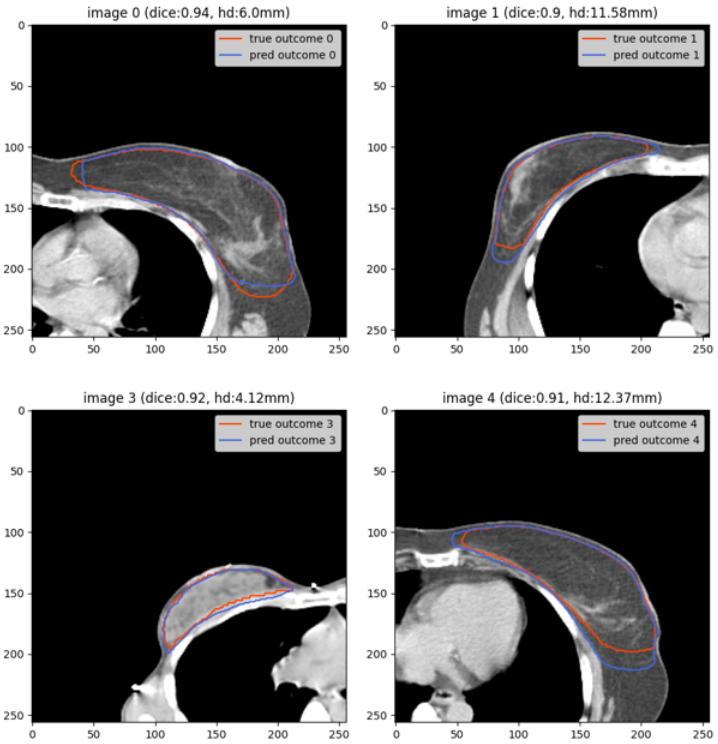

Figure 3: Four randomly chosen patients CT right and left examples taken at the mean cranio-caudal slices from Institute 3. The clinical CTV delineation (red) is superimposed with the observed predicted (blue) segmentation ROI. On top of the images, the DSC and HD_95 value for that specific patient is shown.

4 Discussion

The issue of clinical segmentation done manually with a extensive effort by clinicians is still open, particularly for what regards the CTV segmentation. Thanks to the availability of DL techniques this task started to be feasible automatically. The large dataset both collected in a single institute and multicentric data allowed us to train a reliable 3D neural network and validate it both internally and externally. Our model's performances are in line with the results obtained by previous papers [1, 13]. However, our dataset is larger than the data used by [13] and a 3D model was considered differently from [1]. Moreover, for the first time it is presented a validation done on multiple institutes showing the model consistency. All institutes, indeed, are in line with the training institute, with the exception of Institute 9 that seems to have a different approach in contouring (smaller clinical CTV, [12]). From this, contours of all centers could be included in a next benchmark model, with the exception of Institute 9. Important to note that, for all centers, outliers found with a DSCs below 0.7 have silicone implants, with the exception of only one patient from Institute 1 with a very small CTV (DSC = 0.61).

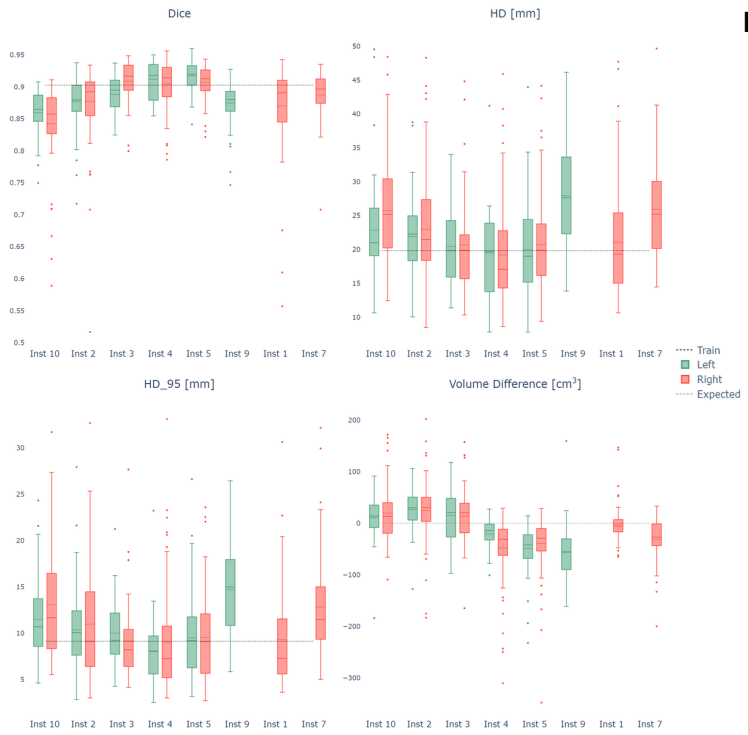

Figure 4: DSC, HD, HD_95 and VD (divided by the side of the CTV) trend across different institutes, being Institute 3 the training one. VD negative means larger CTV prediction. Box plots are shown with median (solid line) and mean values (dashed lines). Outliers are shown with dots. Black line shows the best metric values obtained for validation and gray line the median expected VD (zero).

5 Conclusion

We have constructed a 3D Unet for CTV segmentation trained on 611 patients of a single institute. The training performance was accessed through model validation metrics, obtaining DSC: 0.901 and HD_95: 9.6 mm. Moreover, the model was internally and externally validated. The internal validation confirms the results obtained in the training. The metrics used for comparison showed an overall agreement and model transferability for all centers, with the exception of Institute 9. Institutes 10, 7, 1 showed a larger variability in some metrics, though globally comparable with the internal validation set. Our model tends to predict contours larger than the radiation oncologists' ones in the cranio caudal side, while for the lateral side, it depends on the center: Institute 9 is the most discrepant one, with clinical contours definitely smaller than the other centers. A quality score assigned by radiation onclogists could also assess the impact of the predicted CTVs on the clinical workflow, giving an indication of how much editing is required in order to make the contours clinically acceptable. Considering that the presence of few patients with silicone implants generate most of the outliers present in our results, an increase the model performance is expected with their exclusion.

Abstract

While Deep Learning (DL) auto-segmentation has the potential to improve segmentation efficiency, manual verification and adjustment of the predictions are still required. To ensure an efficient segmentation workflow, auto-segmentation should be supplemented with appropriate quality assurance. In this work, we consider DL auto-segmentation of the mesorectum clinical target volume (CTV). To identify regions of the prediction likely requiring correction, uncertainty maps based on Monte Carlo dropout were generated and compared to segmentation performance. Interpreting network uncertainty is often complicated due to various sources of uncertainty interacting non-trivially both globally and on a local level. Therefore, we extended existing approaches in two aspects. First, network predictions were compared with both independent manual segmentations and manual corrections of the prediction. We hypothesized that the corrections only edit clinically relevant errors, reducing uncertainty due to less inter-observer variation. Second, we compared network uncertainty with network performance both globally and locally. On a global level, we investigated the correlation between mean network uncertainty and global network performance metrics. To study the correlation between two local metrics, we compared the width of the local uncertainty envelope with the length of the local editing vector. Using the uncertainty envelope width as a binary classifier, we achieved a median AUC of 0.8 in identifying regions that were manually corrected with edits of 2 mm or larger. For small edits, the median AUC to classify inconsistencies compared to the independent segmentations was significantly lower at 0.68. Assuming only truly relevant errors were manually adjusted, this demonstrates the capability of MC dropout uncertainty maps to capture relevant regions requiring corrections.

1 Introduction

Online Adaptive Radiation Therapy (OART) adjusts the dose distribution of each fraction to the anatomy of the day to account for anatomical changes throughout the treatment. This workflow potentially enables the use of smaller treatment margins and lower doses for healthy tissue. However, OART can lead to very long treatment times per fraction. The primary reason for this lies in the segmentation process, which needs to be performed for each treatment fraction and demands the presence of a clinician during treatment. As segmentation represents the primary bottleneck in the widespread clinical introduction of OART, automation of the workflow becomes crucial [1].

Deep learning (DL) for automatic segmentation represents a promising technique to improve both the consistency and speed of segmentation. However, these segmentation models are not perfect yet, therefore the need for manual adjustments reduces the time saved in clinical practice.

For an efficient segmentation workflow under time pressure, auto-segmentation should be supplemented with appropriate quality assurance. Uncertainty estimates can help to quantify the level of confidence in the DL model's prediction. These estimates can potentially guide the correction process of the DL-based contours by identifying the areas that need adjustments. Nevertheless, the interpretation of the predictive uncertainty is complex since it incorporates various sources of uncertainty interacting non-trivially, such as model-specific uncertainty and data-inherent uncertainty [2]. Moreover, probabilistic models suffer from miscalibration which can limit their use [3].

Typically, clinically used ground truth segmentations are employed for DL predictions and hence for uncertainty maps. Inter-observer variation in segmentation, however, is known to be present and therefore not all mismatches between a prediction and a clinical ground truth will be relevant. Moreover, the actual key question is whether the uncertainty maps can highlight the regions of an auto-segmentation that would be manually adjusted. Since the adjustments are biased by the prediction, we hypothesize that fewer sources of uncertainty are present in the edits and only truly relevant errors are addressed in the corrections.

To validate our hypothesis, we analyzed the correlation between uncertainty estimates and manual corrections performed on automatically predicted contours, as well as inconsistencies with manual contours performed independently of the DL model in clinical practice. We performed our analysis both at global and local levels. To the best of our knowledge, this study represents the first attempt to perform such analysis at a local level using corrected contours, aiming to progress towards the integration of uncertainty estimates into the OART workflow.

2 Materials and Methods

2.1 Data and Model

We included 16 patients treated in our institute on the Unity MR-Linac [Elekta AB, Stockholm, Sweden] for rectal cancer. The patients were treated with 5 x 5 Gy with an adapt-to-shape procedure. The dataset includes in total 79 MRI scans with a voxel size of 1.2 x 0.57 x 0.57 mm^3. *Clinical* contours of the mesorectum CTV were delineated online by a clinician before treatment, without access to the DL network.

We employed a nnU-Net framework [4], previously trained in our institute to segment the mesorectum CTV on MRI scans of a separate training set [5]. The model works on a 2D level and achieves a median Dice score of 0.89. *Predicted* contours were generated using this model, and a clinician manually *corrected* the predictions. The

predictions were found to be clinically acceptable only after correction.

2.2 Uncertainty Maps

The Monte Carlo (MC) dropout technique [6] was applied to generate uncertainty maps at inference, using a dropout rate of 0.2. At test-time, $T = 25$ random samples of the softmax output of the network were generated. The probability p_n for each voxel n to belong to the CTV was then computed as the average of the T samples using Equation 1.

$$p_n = \frac{1}{T}\sum_{t=1}^{T} p_{n,t} \qquad 1$$

Probability maps were converted into uncertainty maps by using Equation 2,

$$H_n = -[p_n\, log(p_n) + (1-p_n)\, log(1-p_n)]\frac{1}{log\, 2} \qquad 2$$

where the normalized entropy $H_n \in [0,1]$ is employed as a measure of uncertainty.

2.3 Global Analysis

We first investigated the global relationship between the uncertainty estimates and the segmentation performance of the network. The mean uncertainty ($\bar{H}$) was computed to define the global level of uncertainty of each CTV contour as in Equation 3:

$$\bar{H} = \frac{1}{N}\sum_{n=1}^{N} H_n \qquad 3$$

where N represents the number of voxels in the volume of interest.

To evaluate the segmentation performance, the *predicted* contours were compared with the *clinical* contours and the manual *corrections* using the following global metrics: Dice similarity coefficient (DSC), 95th percentile Hausdorff distance (95th HD), Surface Dice similarity score (SDSC) at 3 mm and added path length (APL).

The correlation between H_n and each performance metric was examined for both the *clinical* and *corrected* contours and quantified with the Pearson correlation coefficient *R*.

2.4 Local Analysis

A local interpretation of the correlation between uncertainty and contours was based on the hypothesis that the uncertain area is larger where the errors, and consequently edits, are bigger. The local analysis was performed per slice (2D) since the model used was 2D and clinicians tend to adjust contours per slice.

A threshold T was set to extract an uncertainty envelope from the uncertainty map. Specifically, pixels with an uncertainty value above the specified threshold were included in the envelope creating a mask:

$$\begin{cases} if\ H_n \geq T \rightarrow 1 \\ if\ H_n < T \rightarrow 0 \end{cases}$$

Subsequently, the width of the uncertainty envelope was calculated using the Bidirectional Local Distance (BLD) at every point of the *predicted* contour [7].

While the envelope width was used as a measure of local uncertainty, for the delineations we chose the length of the editing vector. When comparing the *predicted* contours with the *clinical* contours, this length correlates to the local inconsistency between the two contours. Conversely, when comparing *predictions* with *corrections*, the length can be interpreted as the local edit. The BLD was again employed to compute the length of the editing vector in both cases.

At this stage, for each predicted point of the CTV, three values were available: the width of the envelope, the length of the editing vector for the *clinical* contour, and the length of the editing vector for the *corrected* contour. A threshold, denoted as λ, was applied to the editing vector's length to convert the length values into binary form. In other words, choosing λ = 2 mm implies that we study only all errors larger than 2 mm. Subsequently, each envelope width value served as a binary classifier for the length.

The performance of the classifier was evaluated per slice using the Area Under the ROC Curve (AUC). Then, the AUC values of the slices were averaged per scan. The analysis was repeated for different combinations of T and λ, considering both *clinical* and *corrected* contours. Finally, we studied the calibration of the model by selecting the scan-optimal T, i.e. the uncertainty threshold that optimizes the AUC for a specific scan. This is crucial as distinct thresholds may be optimal for different scans [3].

3 Results

Figure 1 shows the outcomes of the global analysis. Each subplot displays the relationship between $\bar{H}$ and one of the four selected performance metrics, with *corrections* represented by blue dots and *clinical* contours represented by orange dots. Major differences in terms of segmentation performance emerge between *corrections* and *clinical* contours. Notably, the APL metric shows the highest correlation (R_{Corr}=0.76, R_{Clin}=0.81), while the DSC exhibits the smallest Pearson coefficient (R_{Corr}=-0.32, R_{Clin}=-0.37). However, no substantial differences in correlation between *corrections* and *clinical* contours were identified.

Figure 2 illustrates the AUC-based performance of the uncertainty estimates employed as a binary classifier for segmentation edits, utilizing three different thresholds (2 mm, 6 mm, and 12 mm). Each subplot, accordingly, shows the performance of the classifier for edits or inconsistencies larger than the specified threshold. Each boxplot illustrates the distribution of the AUC values across the 79 scans for a specific combination of T and λ. The blue boxplots pertain to edits based on the *corrected* contours, while the orange boxplots relate to errors associated with the *clinical* contour. No editing thresholds λ smaller than 2 mm and higher than

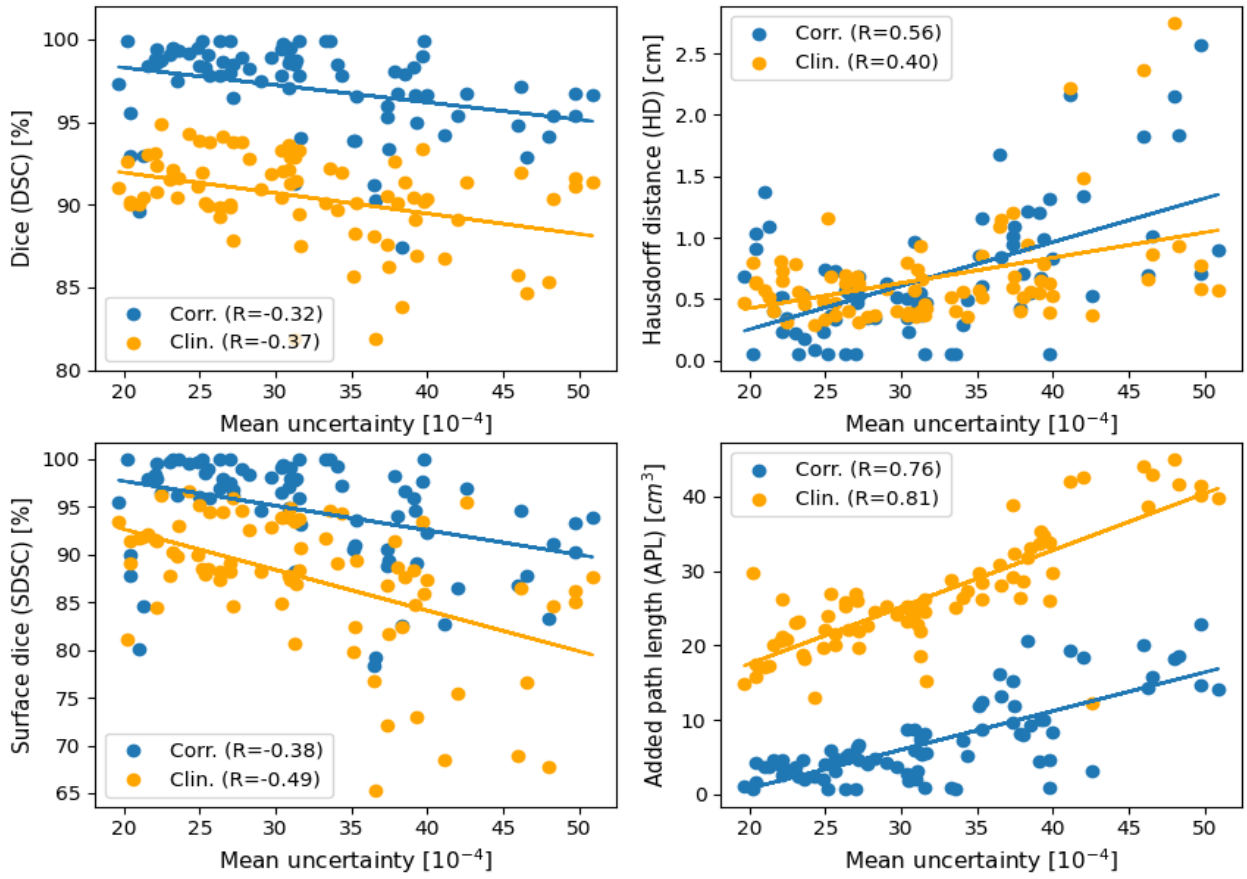

Figure 1 Global correlation between mean uncertainty $\overline{H}$ and network performance metrics.

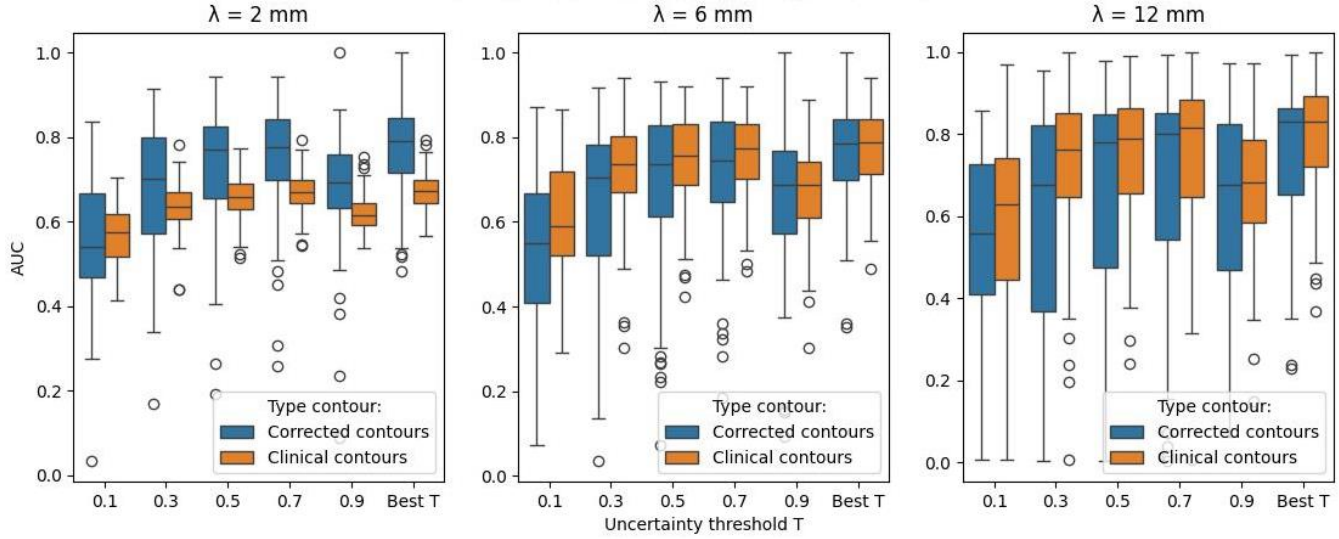

Figure 2 AUC-based performance of the local uncertainty metric used as a binary classifier for edits larger than λ.

12 mm were used due to a decrease in the number of scans with edits that were binary classifiable for values of λ outside this range.

What stands out in Figure 2 is the influence of the uncertainty threshold *T* on the performance. The AUC exhibits an increase until *T*=0.7, followed by a subsequent decrease. This trend remains consistent while varying λ and holds for both *corrected* and *clinical* contours. For minor edits (λ=2mm), the classifier performed better on the *corrected* contours compared to the *clinical* contours, whereas results are comparable at medium and large λ values. Additionally, the variability of the performance increases when increasing the editing threshold λ. The final boxplots in each subplot, labelled '*Best T*,' present the performance of the classifier when utilizing patient-specific T. Selecting the optimal T for each patient enables to obtain a median AUC value above 0.8 for *corrected* contours and around 0.68 for *clinical* contours at λ=2mm.

4 Discussion

This study aimed to study the differences between *clinical* and *corrected* contours in the context of uncertainty application. Conventional analyses typically only investigate how well uncertainty estimates correlate with

segmentation quality on a global level [8]. Our approach also involved local investigation. Specifically, we examined the correlation between network uncertainty and the amount of editing on the *predicted* contours in order to build a binary classifier for edits.

The results of the global analysis show no significant differences in the correlation with uncertainty between *corrections* and *clinical* contours. The geometric similarity improves when comparing *predictions* to *corrections*, as opposed to *clinical* contours. This suggests that *corrections* are biased towards the *prediction*, which may be due to reduced inter-observer variability in the *corrections*. Possibly, only the truly relevant edits are addressed in the *corrections*, while less critical errors may be ignored. Furthermore, there is a clear correlation increase as the examination moves from volumetric measures, such as the volumetric Dice score, to more local metrics, like the APL. This emphasizes the potential of a local analysis of the correlation.

When studying the local association, the predictive value of local uncertainty is stronger in the *corrected* contours compared to the *clinical* ones for small edits (λ=2mm). This demonstrates that uncertainty can capture the relevant edits that are prevalent in the *corrections* but may be intertwined with less significant errors in the *clinical* contours. Conversely, for higher editing thresholds, the classifier performance is comparable for both types of contours. Larger errors are more likely to be relevant and thus considered in both *corrections* and *clinical* delineations.

Additionally, employing extreme uncertainty thresholds, such as T=0.1 and T=0.9, leads to poorer performance of the binary classifier. Intermediate values seem to be more favourable for this analysis. Performance is further improved by utilizing patient-specific thresholds ('*Best T*'), involving the selection of the threshold that maximizes the correlation between editing vectors and uncertainty envelopes for each patient. However, it is noteworthy that the distribution of AUC using patient-specific T is very similar to the one at T=0.7, indicating that the model is properly calibrated [3].

Our work exhibits some limitations. First, the dataset used included a limited number of scans. Moreover, the *clinical* contours were made under time pressure and may be biased by different non-DL models. Additionally, the computation of both local metrics, namely envelope width and edit length, relied on BLD which may yield suboptimal results for intricate contour shapes. Finally, the use of a 2D network posed challenges in extending the analysis to the sagittal plane since the model works on an axial level.

5 Conclusion

In this study, we explored the correlation between uncertainty estimates and both manual *corrections* and inconsistencies with the *clinical* contours. Our novel methodology offers a local analysis, resulting in an uncertainty-based binary classifier that predicts which region requires editing. We obtained a median AUC of around 0.8 to identify manual edits of 2 mm or larger. The findings highlight that for small edits, the uncertainty maps did correlate with manual *corrections* but only weakly to inconsistencies with the *clinical* contours. Assuming only truly relevant mistakes were manually adjusted, this demonstrates the capability of the uncertainty maps to capture these errors.

Despite the limitations, the study contributes to taking OART a step further by leveraging the uncertainty estimates to help clinicians to more efficiently evaluate and correct DL auto-segmentation. However, future work is still needed to assess the relevance and predictability of edits, further enhancing the potential to reduce the physician's workload and save time in OART through uncertainty-guided segmentation corrections.

Virtual patient-specific quality assurance: a prospective two-year analysis

Alon Witztum[1], Phillip Wall[2], Emily Hirata[1] and Gilmer Valdes[1]

[1]Department of Radiation Oncology, University of California – San Francisco, California, USA
[2]Department of Radiation Oncology, Washington University in St Louis, Missouri, USA

Abstract In modern radiation oncology clinics, patient-specific quality assurance (QA) has been shown to have questionable utility in relation to the disproportionate amount of resources it demands. Predictive machine learning models can be designed to indicate the likelihood a treatment plan will fail QA based on its complexity, which can maximize efficiency by focusing resources less on "simple" plans and more on "complex" plans. Our implementation of this method – Virtual QA (VQA) – has been integrated into a clinical workflow to run prospectively alongside regular QA operations for over two years, storing a predicted QA result alongside the measured result for every treatment plan. Results from this study show VQA can reduce the number of QA measurements by approximately two-thirds, with a specificity of 100% and sensitivity of 67% in identifying plans with an absolute QA result greater than or equal to 4%. The model maintained a mean absolute error of 0.97% and a maximum absolute error of 2.99%. The area under the ROC curve for VQA to predict QA results that fail at a 3% threshold is 0.77, and at a 4% threshold it is 0.94.

1 Introduction

Measurement-based patient-specific quality assurance (QA), despite being both labor and resource intensive, has long been the most popular method to QA patient plans, posing challenges in a clinical setting where timeliness and efficiency are crucial. As far back as 2012, patient-specific quality assurance was identified as being the least effective at identifying treatment plan issues [1]. Since the seminal paper described the use of machine learning (ML) to predict patient-specific QA results via plan complexity in 2016 [2], several academic institutions have reinforced the viability and accuracy of such ML models [3].

In 2021 our group developed a machine learning based clinical decision support system which was deployed as a web-platform, Virtual QA (VQA), at the University of California, San Francisco (UCSF). VQA provides clinicians with a predicted QA result without the need to deliver the treatment plan. VQA was deployed to demonstrate the first long-term prospective validation of a patient-specific QA prediction model. With the initial publication describing the platform and initial clinical implementation, we also reported initial results from the first three-month period [4]. We now present the results of our long-term study, with a dataset covering 26 months of prospective validation. This work aims to provide a comprehensive analysis and evaluation of the long-term effectiveness and reliability of the VQA model in a clinical setting.

2 Materials and Methods

Patient specific QA data was extracted for 3798 unique VMAT treatment plans delivered between February 1st 2021 and April 10th 2023. The data includes treatment plans delivered on one Truebeam STx and three matched Truebeams (Varian, a Siemens Healthineers Company, Palo Alto, CA).

Patient-specific QA at our institution pairs a 3D independent dose recalculation performed by Mobius3D (Varian, a Siemens Healthineers Company, Palo Alto, CA) with a single-point ion chamber measurement within the Mobius solid water verification phantom (Figure 1). This phantom has seven inserts for ion chamber placement (positions A-G). Treatment plans were all created in the RayStation (Raysearch Laboratories, Sweden) treatment planning system (TPS). A Python script was developed in the TPS to automatically create QA plans on the Mobius phantom and send the dose at each ion chamber insert position to Research electronic data capture (REDCap), an online HIPAA-compliant research database.

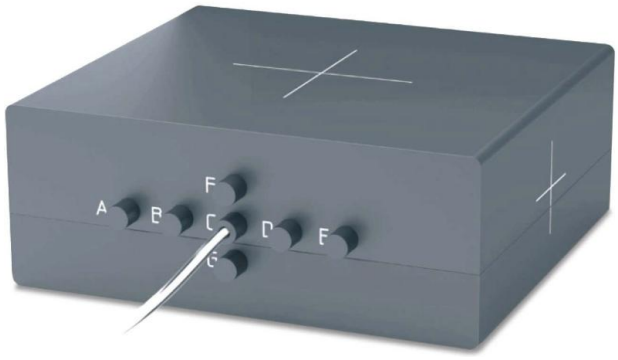

Figure 1: Mobius solid water phantom with seven ion chamber inserts labelled A-G. Reproduced from www.varian.com.

Following the recommendations of AAPM Task Group 218 [5], the QA team are instructed to use one of the seven ion chamber positions that meets the following high-dose-low-gradient conditions: 1) dose greater than 80% of the prescription dose, 2) standard deviation of less than 5% across the chamber volume. If there is no such point, the isocenter is shifted in the QA plan so that the high-dose-low-gradient region can be measured in one of the seven ion chamber positions. The QA team record the ion chamber dose in REDCap, which automatically calculates the percent difference between the TPS dose and the measured ion chamber dose (QA result). The QA team also record the percent difference predicted by the deployed VQA system (VQA prediction).

VQA utilizes an XGBoost machine learning (ML) model which was trained on 579 clinical treatment plans and tuned to predict QA results of VMAT plans. The ML model incorporates 30 classes of complexity features (details of which can be found in established literature [2, 4]) as input for the model. Model tuning was performed using a grid search over learning rate and tree depth hyperparameters and evaluated with 10-fold cross-validation. Further details on the platform are available [4].

For the 3798 VMAT plans extracted, the percent difference between the TPS dose and the measured QA dose (QA result), this percent difference predicted by VQA (VQA prediction), and the difference between these two results (VQA error) were extracted. Initial data cleaning involved remeasurement of the poorest predicted (absolute VQA error > 3%) treatment plans in order to eliminate setup errors and poor ion chamber position choice as the cause of the disagreement. The mean absolute error (MAE), maximum absolute error, and ROC curves of the VQA model are reported.

3 Results

In the initial three-month prospective validation, the machine learning model had a mean absolute error of 1.08% ± 0.77% and maximum absolute error of 2.98% [4]. Of the 3798 unique treatment plans, 87 plans (2.3%) initially fell outside of the expected 3% maximum absolute error and were remeasured. After remeasurement, all 87 plans improved, with the mean absolute error of all plans remaining around 1% (1.02% prior to remeasurement, 0.97% after remeasurement), but the maximum absolute error falling from 8.65% to 2.99%. The distribution of VQA errors is shown in Figure 2 with an average and standard deviation of 0.02% ± 1.20%.

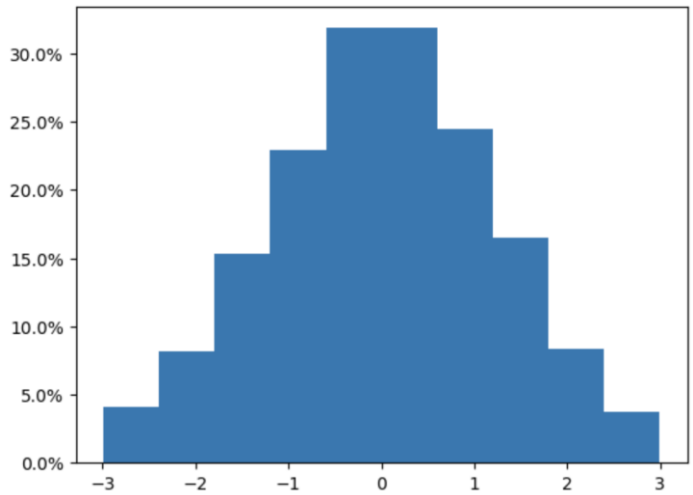

Figure 2: Distribution of VQA Error, the difference between the VQA prediction and the QA result.

The distribution of the QA results is shown in Figure 3 with an average and standard deviation of 0.62% ± 1.26%. There were 11 QA results with an absolute percent dose difference greater than or equal to 4% and 108 with an absolute percent dose difference greater than or equal to 3%.

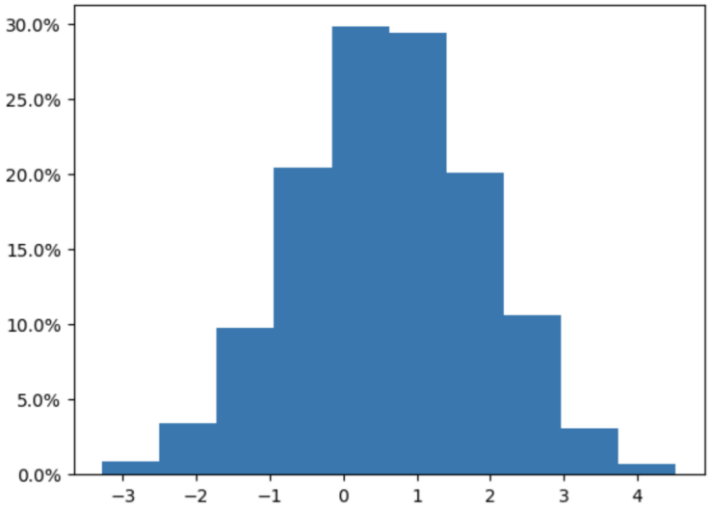

Figure 3: Distribution of QA measurement results

Considering QA results of above 3% or 4% absolute percent difference as 'failing', the VQA prediction model has an AUC of 0.77 or 0.94 as seen in Figure 4.

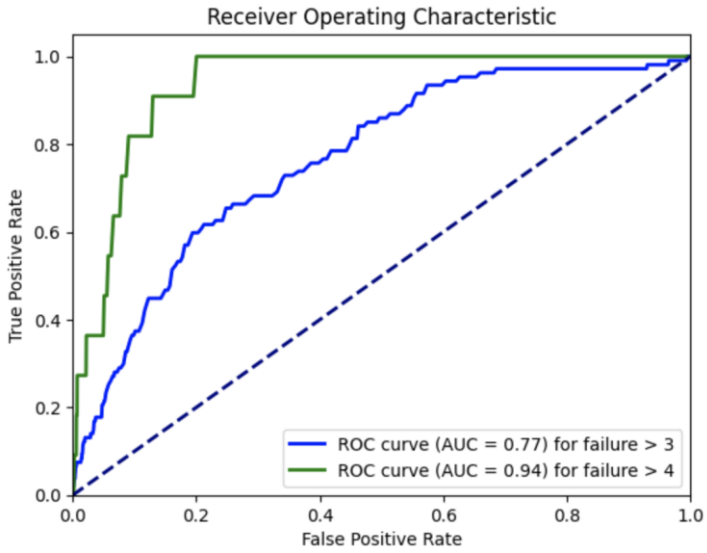

Figure 4: ROC curves and AUC values for VQA model using 3% and 4% as clinical QA failure thresholds.

For this prospective study, a threshold of 1% on the VQA prediction was chosen, meaning that if the absolute percent difference predicted by VQA was less than or equal to 1%, a QA measurement would not be required. Applying this retrospectively to the 3798 plans, 2529 (66.6%) would not need to be measured. Of those 2529, 33 had a QA result greater than or equal to 3%. Of the 1269 (33.4%) plans that still required measurement, 75 had a QA result greater than or equal to 3%, of which 11 were greater than or equal to 4%. This data is summarized in Table 1 below.

	Pass QA	Fail QA		Pass QA	Fail QA
Pass VQA	2496 (66%)	33 (0.01%)		2529 (67%)	0 (0%)
Fail VQA	1194 (31%)	75 (0.02%)		1258 (33%)	11 (<0.01%)

Table 1: Truth tables showing number of measurements needed and saved by using a 1% threshold on the VQA model and a 3% threshold on the QA result (left) and a 4% threshold on the QA result (right).

4 Discussion

Our continued brute-force approach to patient-specific QA, requiring the same time-consuming approach for every single plan remains an ineffective use of physicist time [1]. Fewer than 0.03% of plans (108) 'fail' QA with a 3% threshold, and even fewer (11, <0.01%) 'fail' with a 4% threshold. The VQA machine learning model can predict QA results, and therefore identify treatment plans that are more likely to fail QA. By applying a simple threshold of 1% below which a QA measurement is no longer required, we can reduce our QA load by approximately two thirds. By building an ML model that predicts a continuous numeric QA result, rather than a pass/fail classification model, we also allow for a customizable threshold that can be adjusted based on risk tolerance and periodic data analysis.

An unfortunate limitation of QA prediction models is the lack of gold standard data due to the uncertainties introduced through set-up as well as poor measurement point selection. This is demonstrated by the fact that in all 87 remeasured plans, the VQA Error was reduced. An additional limitation is the small number of treatment plans that actually 'fail' with a 3% or 4% threshold, giving machine learning models few data points in the region of the most interest. This limitation is another reason why prediction of a continuous numeric QA result is preferred over a classification system.

A barrier to removal of measurement-based patient-specific QA is that it is often used as an end-to-end test to test data transfer and data integrity. This is especially true of clinics that operate in a multi-vendor environment. As part of setting up a comprehensive QA program, these needs should also be addressed. An efficient patient-specific QA pipeline could feasibly involve three components: 1) independent dose recalculation, 2) VQA prediction model, 3) computerized data integrity checks. None of these three components require delivery of the treatment plan prior to treatment, making it also an attractive option for online adaptive radiotherapy.

5 Conclusion

A machine learning based clinical decision support system has been successfully deployed and integrated into the clinical workflow. While at this time, QA measurements are continuing on all treatment plans, VQA has been shown to maintain the accuracy quoted during initial testing and validation.

Abstract Convolutional neural networks (CNNs) are at the forefront in medical imaging diagnosis and prognostics. Typically, networks contain millions of parameters and are predominantly designed for the ImageNet database, which consists of millions of images across 1000 categories. In contrast, medical imaging tasks usually involve fewer categories and a smaller number of training images. In this study, we introduce an innovative method for automatic model size reduction in CNNs that preserves performance in computer vision classification tasks.

1 Introduction

The application of deep learning models in medicine has brought transformative changes to healthcare [1,2]. Larger models have demonstrated remarkable capabilities, including superior generalization and prediction performance [3,4], heightened ability to capture intricate patterns in complex data [5-8], and increased versatility across various applications [9]. These advancements have been instrumental in pushing the boundaries of machine learning—ranging from radiological images to genomics—identifying patterns and features that are often imperceptible to human experts [10]. However, this scaling up of model sizes introduces several challenges. One such challenge is that training models with numerous parameters on small datasets can result in overfitting, where the model performs well on the training data but fails to generalize effectively to new, unseen data [11]. This limitation is particularly significant in healthcare, where large datasets are often either not readily available or are costly to acquire [12,13]. Additionally, large models require substantial computational resources, which may be prohibitively expensive and have a significant environmental impact due to energy consumption [14,15]. Another important constraint is memory usage, which is determined by the number of mathematical operations the hardware can perform. With fewer parameters, the memory requirements are lessened, making it possible for instance to handle larger images resolutions (e.g. CT-scans) and to run models for training or inference on less powerful hardware. This is a crucial consideration, especially in environments where high computational resources are not readily available or are cost prohibitive. Additionally, the complexity of these models often makes them "black boxes," thereby raising concerns about interpretability and trust in clinical settings. These challenges amplify the need for more efficient, interpretable, and adaptable deep learning solutions tailored for medical applications.

The idea of reducing the size of deep learning models while maintaining similar performance is not new in the realm of machine learning and it has been extensively researched [15, 16]. Currently, there are three primary strategies for achieving less computationally intensive models. The first approach involves the manual design of adaptive architectures, such as MobileNet [17] and EfficientNet [18]. These CNN architectures were specifically engineered to achieve nearly equivalent performance using only a fraction of the computational resources required by their full-sized counterparts. However, the use of these models is restricted to some specific computer vision tasks and require a thorough testing and tweaking of their size configurations to find an optimal balance between performance and computational efficiency. The second approach, known as Magnitude Pruning, seeks to simplify network architectures by setting smaller parameters in absolute value to zero based on specific heuristics [15,16,19]. The biggest limitation of Magnitude pruning is the fact that the size of the parameter is not indicative of its impact into the loss function and as such results in suboptimal solutions. Moreover, it is also important to note that these methods do not automatically lead to faster inference times or more efficient memory usage. This is primarily because modern hardware is optimized for dense matrix operations, and the sparsity introduced by pruning tends to disrupt these operations, reducing their efficiency. In simpler terms, the hardware still computes the zeroed or pruned parameters, meaning the reduction in the number of parameters doesn't translate to proportional gains in computational speed or memory efficiency. While pruning may reduce storage requirements, the practical benefits in terms of computational efficiency, inference time, and memory usage are often limited. Additionally, some pruning techniques require complex mask matrices or indices to remember which connections have been pruned, adding an extra layer of computational overhead. Moreover, magnitude pruning techniques are prone to underperformance, which may require cessation of the pruning process, hindering researchers from reaching their original objectives. Ultimately, the ability of these ad hoc techniques to generalize across various tasks or datasets is not assured, making them an unreliable solution for model simplification and computational efficiency. Lastly, the third strategy is Second-order pruning techniques [20] which utilize information from the loss function but are computationally expensive due to the

need to calculate second-order derivatives, like the Hessian matrix, making them impractical for large models.

We propose a novel methodology to reduce CNN model size while maintaining near-equivalent performance in a computer vision classification task. Our core algorithm introduces sparse regularization into nonlinear functions, solving a long-standing constrained optimization problem without any prior knowledge of the regularization strength. Unlike existing regularization methods that require trial-and-error based cross-validation to find the regularization strength, we automatically identify a set of network architectures based on dataset-specific regularization constraints.

2 Materials and Methods

We solve the optimization problem:

$$\hat{\boldsymbol{\omega}} = \text{argmin}_{\boldsymbol{\omega}} \mathbb{E}_{\boldsymbol{x},y}(L[y, f(\boldsymbol{x};\boldsymbol{\omega})]) \quad \text{s.t. } P(\boldsymbol{\omega}) \leq t$$

where L is a loss function, f is a non-linear function (e.g. CNN), and P(w) is a general constraint function that monotonically increases with |w| so that:

$$\frac{\partial P(\boldsymbol{w})}{\partial |w|} \geq 0.$$

For instance, $P(\omega) = \Sigma|\omega|$ for Lasso (L1) and $P(\omega) = \Sigma\omega^2$ for Ridge regression (L2).

In our approach, we impose varying values to the constraint function $P(w)$ and solved through sparse regularization (L1). By solving the optimization problem for each specified value of regularization strength, we systematically generate a series of different model architectures. Each architecture is then analyzed to assess its performance and structural characteristics. During this analysis, we identify and remove filters within the architecture where all the weights have become zero. Effectively, these weights no longer contribute to the model, and their elimination helps to reduce the complexity of the network. After pruning these non-contributive elements, we redefine the architecture to include only the remaining, or 'surviving,' convolutional channels. This structured pruning and restructuring process is a critical step towards achieving a more efficient architecture that retains the necessary parameters for accurate predictions while discarding the redundancies that do not contribute to the model's performance. The result is a set of streamlined CNN architectures, each corresponding to a particular regularization strength, optimized for both performance and efficiency.

3 Results

Our initial experiment compared the performance of our algorithm with three magnitude-based pruning techniques using L1-regularization on the pre-trained ResNET-50 architecture within the MURA dataset. This dataset comprises 14,863 studies from 12,173 unique patients, totaling 40,561 multi-view radiographic images. The images encompass seven types of standard upper extremity radiographic studies: elbow, finger, forearm, hand, humerus, shoulder, and wrist. Each study was categorized into binary classifications, with '1' denoting a normal result (target variable) and '0' indicating an abnormal finding. The classification problem presented a class balance of 50/50 percent.

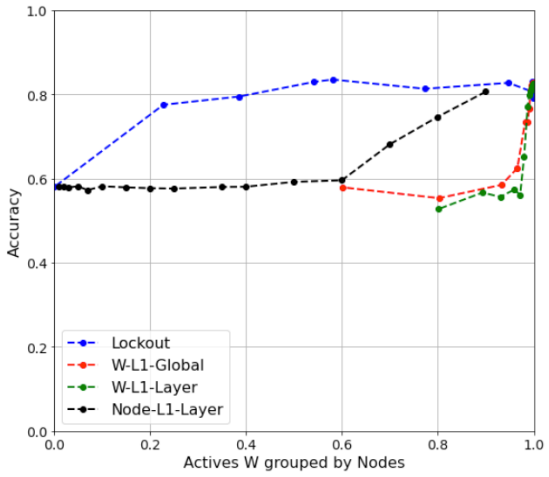

Figure 1: Obtained performance for different model compression rates when using Lockout algorithm (blue) vs magnitude-based pruning techniques (black, red and green curves).

The results, depicted in Figure 1, show our algorithm achieving state-of-the-art performance with a substantially reduced model size. Our approach significantly outperforms standard pruning techniques by reducing the number of active neurons required during the learning process while maintaining near-equivalent performance. This important reduction on the model size translates to fewer operations, lower inference time, and decreased memory consumption (Table 1).

Model	Parameters	Nodes	Inference (s)	Mult-adds (G)	Weights size (mb)	Total size (mb)
Full	25512130	26560	7.72	246	94	10583
Compressed	1627741	8774	4.75	71	6	7390

Table 1: Comparison of computational resources employed for the full ResNet50 architecture vs our compressed network.

An additional significant finding of our study is the clear interpretability gained from examining sparsity patterns across the convolutional network layers automatically induced by our algorithm. Illustrated in Figure 2 is the stratified architecture that emerges under our algorithm's optimization, charting a course from the original model size (depicted in blue) to a reduced model retaining only 20% of the nodes (visualized in black). The visualization reveals a

discernible trend: the encoder portion of the network largely retains its structure, indicating its critical role in performance, whereas the algorithm preferentially prunes channels closer to the output layer.

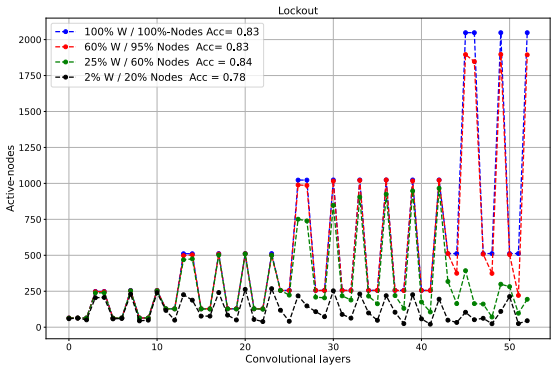

Figure 2: Number of CNN filters employed by convolutional layers for different model compression rates.

This result suggests that in a wide range of scenarios, modern computer vision architectures may be over-parameterized, particularly for tasks beyond the scope of large-scale datasets like ImageNet. Such extensive parameterization, while beneficial for broad datasets (lottery hypothesis), appears excessive for the more specialized requirements of clinical settings. Our findings confirm that a leaner architecture could be equally or more effective in a clinical context, where the data often differ markedly from the vast and varied examples found in large datasets.

Domain specific transfer learning

To test the general character and transferability of the architectures automatically designed by the algorithm we conducted experiments in a similar classification task but using a different dataset. Thus, we used two streamlined architectures, obtained to classify normal versus abnormal activity in multi-view radiograph MURA images, as starting point (pre-trained models) for training a binary classifier on the ChexPert X-ray dataset [22]. The new dataset consists of 24,316 chest radiographs from 65,240 patients labeled for 14 diseases as negative, positive or uncertain. Each study was labeled as either 1 or 0 which represents finding (target-variable) or non-finding activity. The class imbalance in this dataset is 90/10.

As detailed in Fig 3, our two selected compact models small-1 (black) and small-2 (yellow) with 20% and 50% of the nodes respectively achieve equivalent performance to a large model, as the full ResNet50 architecture, both in terms of accuracy and required calculation time (epochs) for an early stopping solution, when trained on the new dataset.

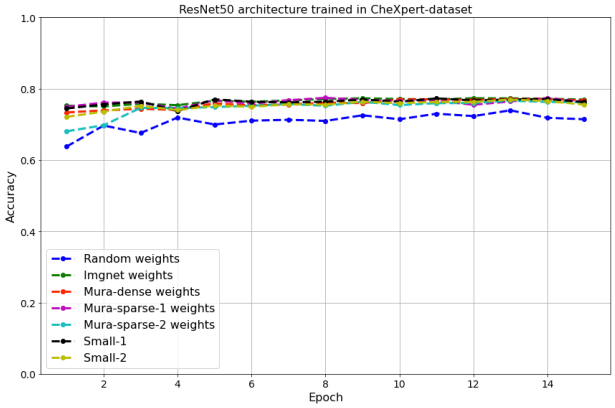

Figure 3: Performance achieved by the leaner architectures obtained (small-1, small-2) in the Mura dataset with respect to the full architecture (ResNet50).

4 Discussion

This study presents a significant advance in the field of deep learning for medical imaging, addressing the common challenge of model over-parameterization without compromising diagnostic accuracy. Our methodology directly confronts the trade-off between model size and performance, offering a solution that caters to the resource-constrained environments typical in healthcare settings. The induced sparsity within the CNNs not only reduces the computational load but also enhances model interpretability—a crucial aspect in clinical decision-making.

Our approach diverges from traditional pruning by incorporating sparse regularization directly into the learning process, thereby optimizing the network architecture intrinsically and eliminating the need for post-hoc adjustments. This automated process allows for a seamless determination of the most efficient architecture for a given dataset, which is particularly beneficial in the medical domain where data diversity and volume may vary substantially.

Moreover, the application of our streamlined models to the ChexPert dataset demonstrates the versatility and transferability of our methodology. The ability of the derived architectures to maintain high performance on a different dataset underscores the potential of our algorithm to serve as a foundation for developing robust, generalizable medical imaging tools.

Our findings also contribute to the ongoing discourse on the necessity of vast parameterization for deep learning models. While larger models have their merits, our results suggest that smaller, more efficient architectures can achieve comparable or superior performance, especially in domain-specific tasks. This aligns with the "lottery ticket hypothesis," which posits that certain subnetworks are inherently well-suited for a given task and once identified, can operate independently of the original, larger network.

5 Conclusion

In conclusion, our novel methodology for CNN model reduction successfully addresses several challenges in medical imaging: the need for large datasets, high computational resources, and model interpretability. By introducing sparse regularization into the training process, we automatically derive compact yet effective network architectures that demonstrate near-equivalent performance to their full-sized counterparts. Our results not only advocate for a paradigm shift toward more computationally efficient models in healthcare but also pave the way for further research into model optimization techniques that do not sacrifice accuracy for efficiency.

The implications of this work are far-reaching, with the potential to democratize access to advanced medical imaging diagnostics across varied clinical environments. Future studies could explore the application of our methodology across other domains of medical imaging and further validate the transferability of the optimized architectures to different tasks and datasets. As deep learning continues to permeate medical technology, our research offers a sustainable, efficient path forward, ensuring high-quality care without the burden of excessive computational demands.

Abstract
Short-term Prostate Specific Antigen (PSA) trajectory has been shown to be prognostic of future biochemical recurrence (BCR), which in turn could be related to too low radiotherapy dose in certain anatomy. PSA follow-up is often irregular and sparse, presenting challenges in population-based studies. We implement Gaussian Process (GP) regression to inform voxel-based analysis aiming at investigating the effect of dose on BCR. Routinely collected PSA data was modelled using GP regression. Interpolated PSA in 6 steps from 0 – 3 years was used as outcome in voxel-based analysis to find regions with significant association of PSA and dose. For this, we used dose distributions mapped to a common reference anatomy, and Spearman's rank test for voxel-wise statistics in a cohort of 219 patients with prostate cancer treated with conformal hypo-fractionated radiotherapy. GP informed voxel-wise analysis was successfully implemented, and revealed a significant correlation between dose and follow-up PSA data at all tested time-points. The identified region identified became larger between 0 – 18 months follow-up, and then shrank. Regardless of the changes over time, dose in the seminal vesicles was consistently identified as significantly correlated with PSA.

1 Introduction

Voxel-based analysis is an established methodology becoming a standard for spatial modeling of outcomes after radiotherapy. It has been used in different anatomical regions for different outcomes[1–5]. This technique has been recently used to show an association between radiotherapy dose and biochemical recurrence (BCR) in prostate cancer patients treated with curative intent radiotherapy, identifying a region in the seminal vesicles where lower dose resulted in worse disease control[6].

BCR, which will occur in one in three men with prostate cancer, is detected via rises in Prostate Specific Antigen (PSA). Current routine follow-up for prostate radiotherapy consists of six-monthly PSA monitoring. Despite regular collection of data, BCR is typically detected via rises in PSA of ≥2ng/ml above nadir (the lowest concentration), which is a patient-defined PSA threshold that can only be defined after the event (NHS NICE guidelines[7]). Further, data is often recorded irregularly and sparsely. This means that recurrence can go undetected between PSA tests for some patients, and more intense follow-up or intervention can be delayed by months.

Studies indicate routinely collected short-term follow-up PSA data utilized differently could offer additional prognostic value, with PSA dynamics acting as a surrogate end-point for future BCR. Several authors suggest close following of PSA can allow for more targeted follow-up and early intervention with salvage treatment[8–13].

In this work, we aim to identify associations between radiotherapy dose and dynamic short-term follow-up PSA data. The main challenge is the way to effectively deal with irregular time-series data. We present a methodology based on Gaussian Process (GP) regression, a common technique for dealing with irregular longitudinal data, to interpolate regularly sampled PSA values. These are then used to inform voxel-based analysis to associate follow-up PSA at determined time-points with planned radiotherapy dose in prostate cancer patient, and follow the evolution of association over time.

2 Materials and Methods

Planning Computed Tomography's (CTs), dose distributions and clinical information, including repeat post-radiotherapy PSA measurements, were collected for prostate cancer patients treated with conformal hypo-fractionated radiotherapy (50 Gy in 16 fractions) between 2005 and 2007 at a single academic centre. Institutional approval had been granted to use this data (research ethics committee reference: 17/NW/0060).

To consider short-term PSA information, only patients with 3-years PSA follow-up, who did not experience BCR within this period, were included. Three years was chosen as a pragmatic and appropriate balance between the small number of patients who are expected to recur within this time period, and the number of patients with sufficient PSA data available[8,9]. All patients had at least two readings during this period.

Modelling PSA data

Log-transformed PSA trajectories were modelled using Gaussian Process regression (MagmaClustR, R (version 4.0.2) in RStudio (desktop version 1.3.1073)). To ensure at least 3-years of data was available for all patients, the first PSA reading > 3-years follow-up was included.

A population-based model was created using the whole cohort of data. The posterior mean for each patient was then sampled at regular time-points (0.5 years) between 0 and 3-years, for use in voxel-based analysis. The posterior mean and 95 % confidence band was plotted for all models and patients and visually inspected to assure a good fit for the data.

To test the robustness of results, individually informed models, where a separate GP model was created for each patient, were also created and analysis repeated and results compared visually.

Dose Mapping

CTs were deformably registered to an arbitrarily chosen reference patient and dose distributions mapped to the same anatomy (in-house software). A region of interest forming a sphere of approximately 10cm radius, centered on the centre of the reference prostate, was chosen for analysis to remove regions where spurious results could occur due to differences in radiotherapy plans depending on patient anatomy[6].

For dose mapping, dose distributions of all patients were flipped in the left-right direction and included in analysis twice[3–5]. Target Registration Error[14] analysis was performed to account for registration uncertainty, and dose distributions blurred using a 3D Gaussian filter of width corresponding to the standard deviation if variation in each cardinal direction of landmarks set at the seminal vesicles and apex (≤0.9cm). All mapped dose distributions were visually inspected.

Voxel-Based Analysis

To assess the correlation between planned radiotherapy dose and post-radiotherapy GP informed PSA at each 6-monthly time-point (0 – 3 years), a Spearman's rank test was performed for each voxel of the dose distribution in the region of interest (in-house software). Correlation coefficients (ρ) for each voxel were collected to create ρ-maps.

To correct for multiple comparisons, and to determine regions of significant correlation, permutation testing was performed (n=1000). PSA values were randomly permuted and the voxel-wise tests performed, recording extreme ρ-statistics for each permutation[2]. From the distribution of extreme ρ-statistics, ρ value corresponding to p≤0.05 were identified and iso-ρ levels plotted on the observed ρ-map to identify the region with significant correlation between dose and PSA at each time-point. Each PSA time-point was analyzed separately.

3 Results

PSA data

Figure 1 illustrates the characteristics of the collected PSA data. The median number of PSA measurements collected within the 3-year period was six [2 - 27], collected an average of 1.2 years apart [0.4 - 4.4], for an average of 6.8 years [3.4 - 10.3].

All PSA data was successfully modelled, and interpolated PSA values used as input for voxel-based analysis. GP informed PSA at 0 months follow-up was, on average, within 0.16 ng/ml of the recorded PSA at 0 months ([0.03 – 1.7 ng/ml], standard deviation 3.1 ng/ml). An example GP sampled posterior mean (0 - 3 years) for one patient is shown in Figure 2.

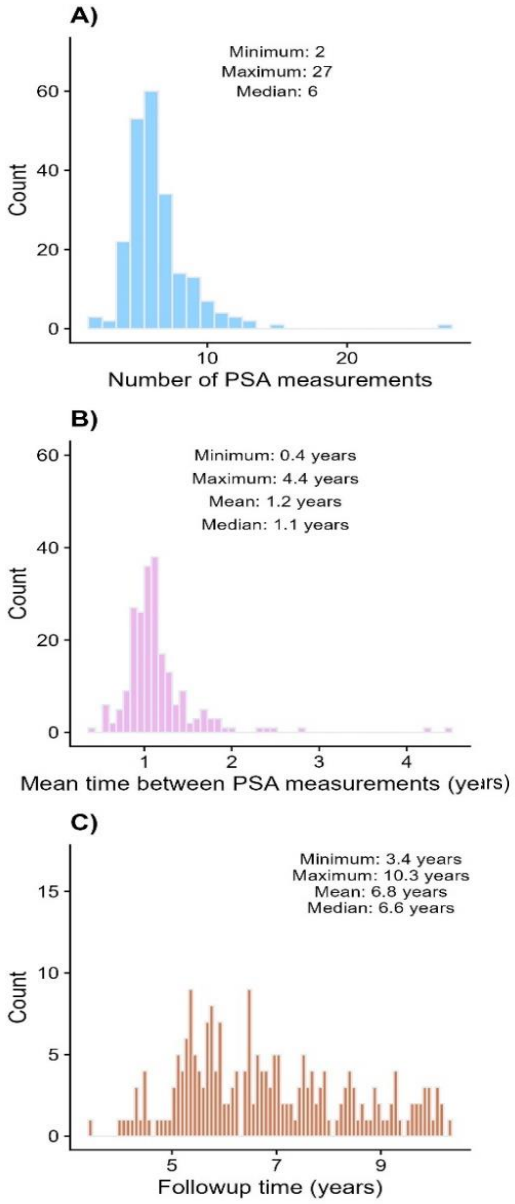

Figure 1: Histograms displaying the distribution of PSA collection across all patients (n=219). Data was highly irregular and, in some cases, sparse. PSA was recorded between 2 and 27 times, on average at 1.2 year intervals, for between 3.4 and 10.3 years.

Voxel-Based Analysis

Figure 3 shows regions of significant correlation between planned radiotherapy dose and PSA at 6-montly intervals between 0 and 48-month follow-up, using A) population-based and B) individually-based GPs ($p \leq 0.05$). For both methods, a large region, indicated by the red overlay, superior to the prostate, covering the seminal vesicles, was detected for all time-points up to 36-months. These regions indicate where a dose and GP informed PSA were negatively correlated, i.e. lower dose correlated with higher PSA.

The region is seen to change between time-points. It appears to grow larger between the beginning of follow-up and 18 months, and then become smaller and eventually disappear at 48 months follow-up. This could indicate that PSA within 18-months of follow-up is most informative of potential treatment failure. Results are consistent between GP methods.

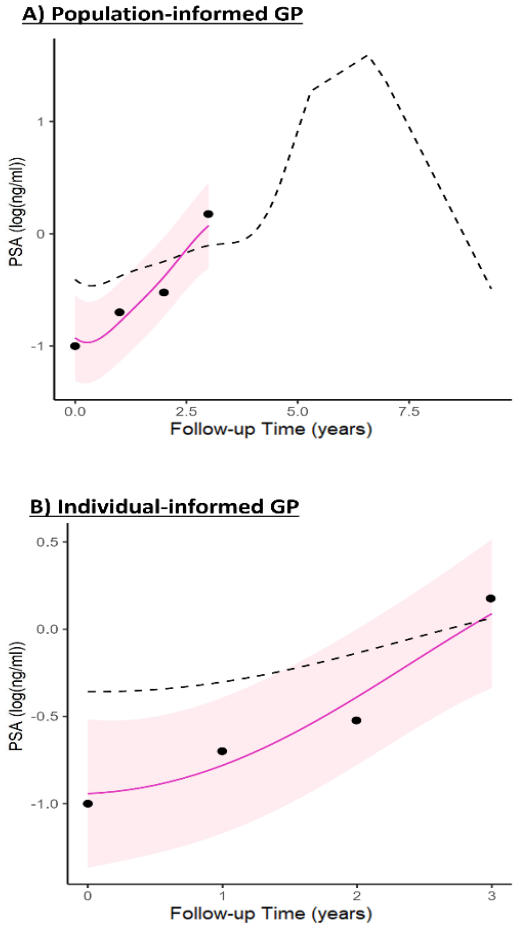

Figure 2: An example population-based (A) and individually-based (B) GP for one patient. Black dotted line represents the mean of each model respectively informed GP model. The pink line shows the posterior mean and 95 % confidence interval for this patient. Note the different scales. Note that the model extends over the 3-year time-period, as the first PSA measurement after 3-years was included to ensure adequate data.

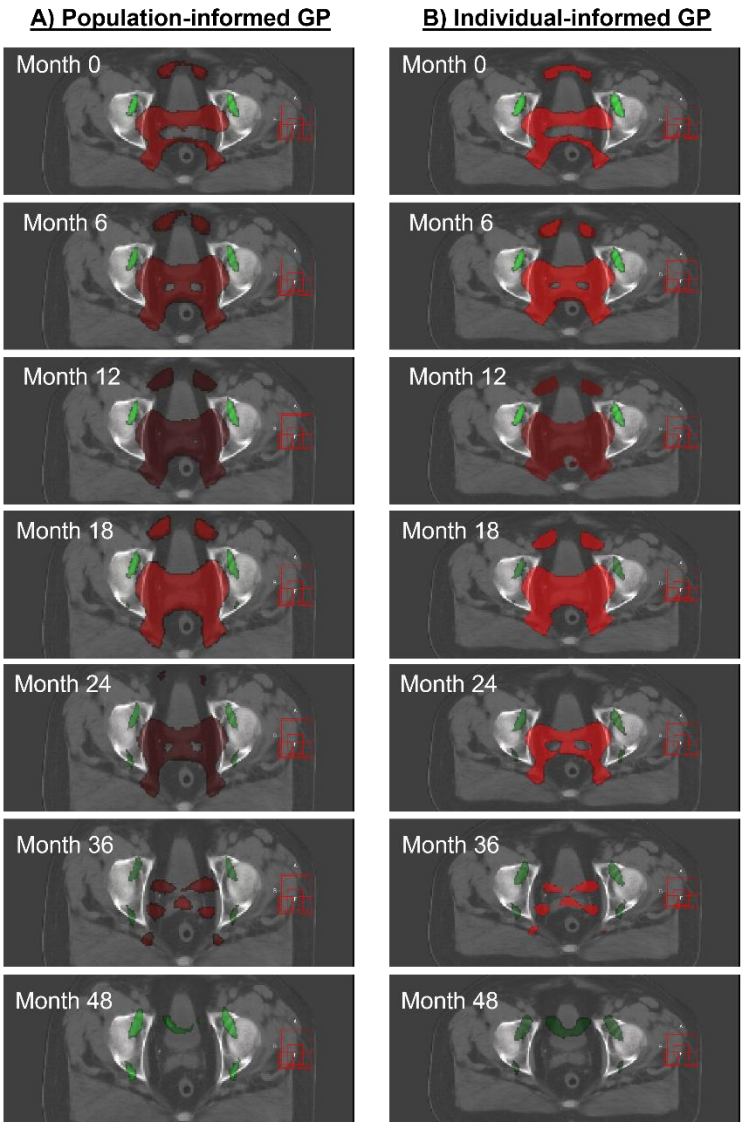

Figure 3: Regions of significant association between planned radiotherapy dose and A) population-based and B) individually-based GP informed follow-up PSA at 6 month intervals between 0- and 48-month post-radiotherapy follow-up. The red and green overlays indicate regions where dose was negatively or positively associated with dose, respectively. Results were consistent across both population- and individually-based GP models.

4 Discussion

Our results demonstrate that irregular and sparse time-series data can be successfully incorporated into GP informed voxel-based analysis to inform outcome models for prostate cancer patients treated with radiotherapy.

We used both population- and individually-based GP models and found similar results after IBDM. The combination of GP and voxel-wise analysis allows the association between dose and irregular time series PSA data to be explored for the first time.

As reported, our results were consistent across population- and individually-based GP models. A simulation study where the ground truth is known, may be a good method to determine which approach is more reliable. The posterior

sampled means of the two methods were, on average, within 0.2 ng/ml ([0.04 – 7.2 ng/ml], standard deviation 2.9 ng/ml), which is not of a magnitude that would change clinical management of a patient. It should be investigated whether the two methods create models that lie within a common confidence bound, however. The robustness of these results could further be tested using a "leave one out" population-based model, where the model is used to predict PSA in unseen data at each available time-point for a direct comparison with measurement.

The identified region varies at across time, with the largest region occurring at 12–18 months into follow-up, before disappearing at 48 months. This could indicate a time window of 0 – 36 months to consider meaningful value from PSA measurements during follow-up, and could be related to recovery after hormone treatment. This should be investigated further, accounting for the time between the end of radiotherapy and beginning of follow-up, which was irregular in our data ([0.01–3.0 years], mean 0.8 years, standard deviation 0.4 years).

Regardless of the changes over time, dose in the seminal vesicles and their surrounding is consistently identified as significantly correlated with PSA, with association growing up until 18 months follow-up. This supports recent work that uses voxel-based analysis to identify a region in the seminal vesicles where radiotherapy dose was significantly associated with BCR[6]. The large size of the region is likely due to spatial correlation of the dose distributions.

We use short-term post-radiotherapy PSA as a surrogate for treatment failure. Both PSA at defined time-points within follow-up, and PSA dynamics have been associated with the prediction of treatment failure for prostate cancer patients[8,10,13,15]. Our results suggest that radiotherapy dose could be influencing follow-up PSA. It should further be explored whether our results can be related to treatment outcome. Once validated in other external datasets, these results could be used to create a tool to re-stratify patients after radiotherapy, allowing for more informed follow-up schedules, earlier intervention, and refined target volumes.

We consider absolute PSA values at defined time-points. Recent work demonstrates how short-term PSA dynamic information can be characterized as one of three typical trajectories using clustering techniques. This work further indicates significant association between short-term PSA trajectory and future BCR, allowing for potential re-stratification during early follow-up[13]. It would be interesting to repeat our analysis using cluster specific prediction curves[16], to associate radiotherapy planned dose with each typical PSA trajectory.

5 Conclusion

We present a method to successfully incorporate sparse time series data into GP informed voxel-based analysis to inform outcome models for prostate cancer patients treated with radiotherapy. Population and individual GP were implemented showing good agreement in inference of PSA and in the VBA.

Voxel-wise causal inference to detect location and dose-response of organs at risk in lung cancer

Marcel van Herk, Azadeh Abravan, Alan McWilliam, Eliana Vasquez Osorio

Division of Cancer Sciences, University of Manchester, UK
The Christie NHS Foundation Trust, Manchester, UK

Abstract. Dose correlations between neighbouring organs complicate NTCP modeling. Sometimes even the dose-sensitive region and NTCP function are unknown. We propose a novel voxel-wise NTCP modelling approach based on instrumental variable analysis, a causal inference technique, to address this problem and apply it to lung cancer patients. Our instrumental variable is the random perturbation of the delivered dose due to an action threshold during historical image-guided radiotherapy (IGRT). We test many NTCP models and perform Cox regression per voxel between ΔNTCP due to perturbation and hazard of death. The largest AIC-significant voxel cluster over all parameters defines region and NTCP model. In a cohort of 609 stage III patients, a dose-response was found in a location close to the sinoatrial node in the heart, with an integrated Gaussian dose-response with D_{50} of 20+/-1Gy and γ of 2+/-0.5Gy. This is the first time voxel-wise causal inference is used in radiotherapy research.

1 Introduction

Estimating dose-effect relationships poses challenges due to various issues. First, it is not clearly known which part of an organ at risk (OAR), such as the heart, is most sensitive [1]. Second, overall survival is often confounded, the outcome not only dependent on the disease itself but also on the toxicity of normal tissues, e.g. the heart in lung radiotherapy (RT) [2]. Such toxicity is often under-reported. The main factors driving dose to OARs are tumour size and location. Through these variables, OAR dose is indirectly associated to cancer survival independent of toxicity (**Figure 1**). To estimate a dose-effect relationship for toxicity we must, therefore, carefully correct for such associations.

Causal inference is the process of determining the causal effect of a particular exposure that is component of a larger system, to a given outcome. We aim, for the first time, to combine a form of causal inference used for natural experiments, an instrumental variable method, with a voxel-wise proportional hazard analysis to allow direct estimation of voxel-wise dose-effect relationships. We detect the most significant dose-sensitive heart region and model its normal tissue complication probability (NTCP) relationship for hazard of death in lung cancer patients.

2 Materials and Methods

As usual, dose distributions were first mapped to a template patient using deformable registration (Niftyreg). Here we mapped both the planned dose distribution and an estimate of the delivered dose distribution based on historic IGRT data with an action threshold of 5mm. The causal directed acyclic diagram (DAG) that represents our method per voxel that incorporates NTCP modeling is shown in **Figure 1**. A change of NTCP due to residual setup error is calculated for an assumed dose-effect relationship and fitted to time-dependent survival data using Cox regression. However, if performed voxel-wise, the change in dose due to residual setup affects only a small number of voxels depending on the steepness of the NTCP function and dose gradients (**Figure 2**).

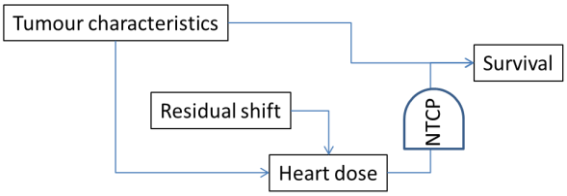

Figure 1: Adapted causal Directed Acyclic Graph (DAG) representing our voxel-wise assumptions and incorporating NTCP modeling. 'Residual shift' is the instrumental variable affecting heart dose randomly. Tumour characteristics affect survival but also voxel dose, because patients with more advanced tumours tend to receive higher doses everywhere. Therefore the planned voxel dose cannot be used directly to estimate NTCP from survival data. Instead the change in NTCP is estimated from random perturbations in dose (here due to the use of image guidance with an action threshold).

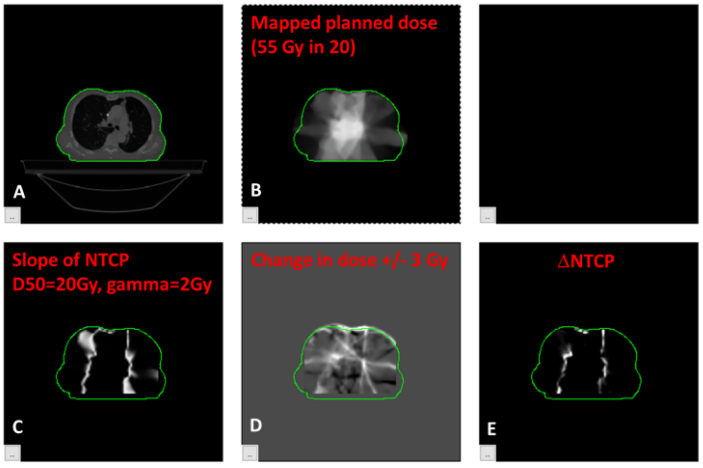

Figure 2: Visualisation of image processing in voxel-wise causal inference. The dose distribution of each patient in the cohort (B) is mapped to a template patient (A) using deformable registration. The slope of an NTCP curve is highest for doses that are close to D_{50}. Effectively, the ΔNTCP is the product of the derivative of the NTCP function (C), bright where high, and the perturbation in dose due to the use of an action threshold (D). As a result, ΔNTCP (E) only differs from zero (black) in few voxels, making its average signal small even if analysing hundreds of patients. For this reason the resolution must be matched to the unknown scale of anatomical structures.

For this reason, the dose resolution is reduced, and the cluster size of significant voxels with a change in Akaike Information Criterion (AIC) over a preset threshold is used as test variable. AIC summarizes the relative quality of a statistical model, and a reduction of 2 points or more indicates a model has better discrimination. The pipeline is illustrated in **Figure 3**. We limited the analysis to the heart in the template patient with 2cm margin, at a voxel size of 2.3x2.3x3 mm^3. This means that for each parameters combination about 300,000 voxel-wise Cox regressions are performed. We used an efficient multithreaded implementation as described in [3]. A previously studied cohort of 609 patients with stage III lung cancer treated with 55Gy in 20 fractions was analysed [4].

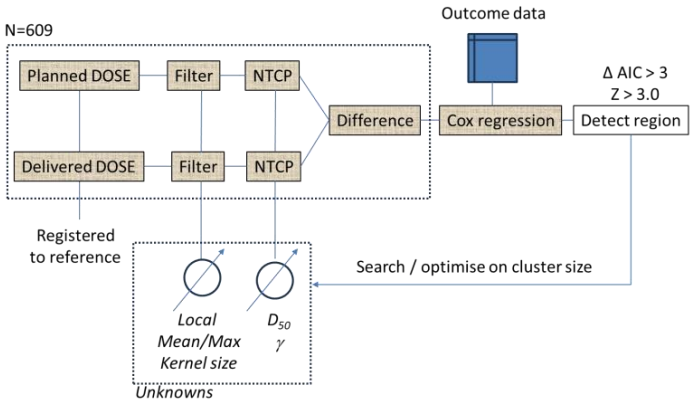

Figure 3: Pipeline for voxel-wise causal inference. Shaded boxes are applied voxel-wise. Unknown parameters are the type of the local filter used to reduce the resolution of the dose distributions and the shape parameters (D_{50} and γ) of the NTCP model. The Cox regression utilizes time-dependent survival from start of radiotherapy of 609 lung cancer patients. An exhaustive search over about 2000 parameter combinations was performed based on the cluster size of significant voxels at a pre-set significance level.

3 Results

Residual setup errors ranged from -5 to 5 mm and were not correlated with age, tumour size, performance status or comorbidities [4]. The combination of applying a single integrated normal dose response-model for planned and delivered dose distributions and performing a univariable Cox regression between their difference and survival for 300,000 voxels took 45-200s on an Intel i7-9700 CPU, depending on the convergence of regressions, which was poor for some parameter combinations. Note that we cached the filtered dose distributions of all patients in memory to improve performance.

We arbitrarily used an AIC reduction of 3 and Z-value over 3 to define significant voxels. The largest clusters were found using a local maximum filter with a kernel size of 10x10x10 mm.

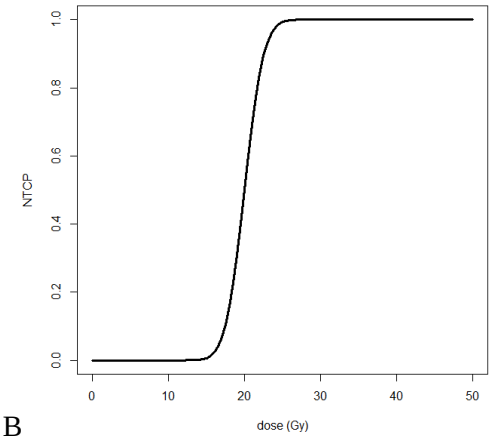

Figure 4: A) Detected heart region at a dose-response of (20Gy, 2Gy) in red. The template patient has a pacemaker and the detected region is located at the end of one lead. Contours illustrate the current heart sparing regions in our rapid-learning trial. The detected significant voxels are near to it but cover less volume. B) Estimated NTCP curve.

Use of a 7x7x7 mm or 12x12x12 mm reduced the number of significant voxels by about a factor 2. Use of a local mean filter reduced the number of the significant voxels over 5 times. The ultimate detected region is close to the sinoatrial node and has its steepest dose response at 20Gy (**Figure 4**).

4 Discussion

This is the first application of voxel-wise causal inference based on instrumental variables that directly integrates NTCP modeling. We were able to pinpoint both a sensitive location in the heart and define its dose-response. By adopting causal inference methods with an instrumental variable, confounding is implicitly dealt with.

There are several limitations to this method. First we rely on an instrumental variable that may not always be available. Moreover, by nature, many voxels will not have a detectable impact on outcome simply by having a dose in an incorrect range or having too small dose perturbations.

To deal with this, we had to lower the resolution of the analysis and found that filter parameter choice was very sensitive. It is likely that with much larger cohorts than our 609 patients, we may need less filtering. Running 6 billion Cox regressions took about 48 hours. To explore the resulting data, a specific browser was developed but exploring the 6-dimensional solution space remains time consuming. For this reason, the browser detects the largest cluster for each tested dose level given a D_{50} and γ.

Our results are in agreement with the published voxel-based-analysis literature for dose sensitive regions of the heart. The region defined here however is smaller and may be more targeted at the clinically relevant region driving early mortality. Once our methodology and results are validated they can help refine ongoing clinical trials of targeted heart sparing for patients with lung cancer treated with radiotherapy.

5 Conclusion

This is the first application of voxel-wise causal inference in radiotherapy outcome modeling and we were able to pinpoint a sensitive location close to the sinoatrial node in the heart as well as its dose-response.

Abstract

To assess clinical/dosimetric predictors of late hematological toxicity in a prospective multi-institute cohort study of prostate cancer (PCa) patients undergoing pelvic-nodes irradiation (PNI).

Clinical, dosimetric and blood test data were prospectively collected, including lymphocytes count (ALC) at different time points. DVHs with irradiated volumes of the body and of four pelvic bones were extracted: ilium (BMILEO), lumbosacral spine (BMLS), lower pelvis (BMPELVIS) and whole pelvis (BMTOT). Current analysis focused on 2-year CTCAE v4.03 grade≥2 (G2+) lymphopenia (ALC<800/μL). Mann–Whitney U tests selected DVH parameters that better discriminate patients with/without toxicity. Twenty-four clinical/dosimetric covariates were considered as potential predictors, including best-selected DVH parameters. Acute CTCAE v4.03 grade≥3 (G3+) lymphopenia was also separately considered as a potential predictor. After data pre-processing, a multi-variable logistic regression model was identified. Bootstrap-based internal validation was finally performed.

Forty-six out of 499 patients (9.2%) experienced Late G2+ lymphopenia. ALC at baseline [HR=0.997, 95% CI 0.996-0.998, p<0.0001], smoke (yes/no) [HR=2.9, 95% CI 1.25-6.76, p=0.013] and BMLS-V≥24Gy (cc) [HR=1.006, 95% CI 1.002-1.011, p=0.003] were retained for the model. When acute G3+ lymphopenia (yes/no) was considered, it was included in the model [HR=4.517, 95% CI 1.954-10.441, p=0.0004]. Performances were moderately high and internal validation confirmed the robustness of the results.

Two-year lymphopenia after PNI for PCa is not negligible and mostly modulated by baseline ALC. Multivariate analysis showed BMLS-V24 as the most prominent dosimetry predictor with baseline ALC and smoking. An independent role of acute G3+ lymphopenia was also ascertained.

1 Introduction

The interest in quantifying hematological toxicity (HT), with a special focus on severe dropout of blood counts, after radiotherapy (RT) without chemotherapy is high, aiming to estimate the impact of the "RT-induced" symptoms [1, 2, 3, 4, 5].

In particular, as the reduction of lymphocytes relates to the immune response, stimulating cytokine secretion and helping anti-tumor immunity [6], lymphopenia could translate into detrimental effects of anti-cancer therapies [7]. Clearly these effects mainly depend on the delivered dose, on the anatomical location and on the extent of the Planning Target Volume (PTV). Effects are expected to occur acutely by the direct killing of the circulating lymphocytes and the incidental irradiation of BM, as primary site of hematopoiesis [8]. A situation at high risk of moderate/severe RT-induced lymphopenia concerns the irradiation of large volumes of the pelvic region; more than half of the active BM is located at this level [9] and consequently not negligible effects especially occur in case of pelvic nodes irradiation (PNI), mostly for bladder and prostate cancer (PCa) [4].

In this scenario, a multi-centric study was started in 2012 (IHU-WPRT TOX [1, 2, 10, 11, 12]) to assess predictors of intestinal, hematological and urinary toxicity after PNI for PCa, delivered with intensity-modulated radiotherapy (IMRT). Data were mature for current study, with the aim of 1) quantifying dose-volume relationships between BM structures and 2-year moderate/severe lymphopenia; 2) developing predictive models of 2-year lymphopenia combining BM (and possibly Body) dosimetry information with clinical predictors.

2 Materials and Methods

In September 2012 a national multi-centric institutional review board-approved study was activated at San Raffaele Scientific Institute, Milan, to evaluate clinical/dosimetric predictors of intestinal, hematological and urinary toxicity in WPRT (ClinicalTrials.gov identifier NCT2803086).

Eight hundred eighty-seven PCa patients were enrolled up to the end of 2021, irradiated with radical or post-surgery IMRT, including PNI, and followed for 5-years: the trial involved 14 clinical centers, the coordinating Institute included. Details on aims, patient characteristics, planning and volumes, dose/fractionation, delivery and methodology

of the study were previously reported [1, 2, 10, 11, 12] as well as preliminary results regarding the single institute pilot study on HT [1, 2].

Four pelvic bone volumes were prospectively contoured: ilium (BMILEO), lumbosacral spine (BMLS), lower pelvis (BMPELVIS) and whole pelvis (BMTOT) [13].

Full planning data (planning CT, RT-Plan, RT-Dose, RT-Structure DICOM files) of the PNI part of the treatment were collected to incorporate dosimetric predictors into the analysis at a later stage.

Dose-volume histograms (DVHs) of bones and body were extracted in absolute values (cc) in the range 0-70Gy with a 1Gy pitch.

The cranial extent (mm) from the L5 vertebrae lower edge to the PTVLN upper extremity was automatically computed through a proper script in Python as the vertical distance obtained by the combination of the baseline CT image and the contoured structures. To achieve this, L5 vertebras were previously delineated with TotalSegmentator [14].

The PTVLN volume (cc) was retrieved, along with the cranial extent, to evaluate the impact of spatial extension of irradiated volumes - target and organs at risk (OARs) - on late HT.

Blood tests, including lymphocytes counts (ALC), were collected at various intervals over 5 years to analyze late grade≥2 (G2+) lymphopenia, being ALC at 2 years (or 30 months if missing) after RT conclusion<800/µL (CTCAE v4.03) [15].

Patients with available 3D planning, baseline clinical data and with complete baseline, RT mid- and/or endpoint, 3 or 6 months, 1 year or 18 months, 2 years or 30 months blood tests were included.

Mann–Whitney U tests were preliminarily performed to assess the DVH regions of each BM and Body structure that better discriminated patients with/without toxicity (corresponding to p-values<0.05). The selected volumes were then checked for Pearson's pairwise correlation. When Pearson's correlation coefficient was deemed to be sufficiently high (ρ>0.7) the volume with the lowest p-value at the Mann–Whitney U test was kept as the best DVH predictor.

Twenty-four clinical/dosimetric covariates were considered as potential predictors, including best-selected DVH parameters. In addiction, acute CTCAE v4.03 grade≥3 (G3+) lymphopenia (ALC at its lowest value between mid and end RT<500/µL) was separately considered as a potential predictor.

Preprocessing and training used the information available for the included patients while 1000 bootstrap replicates were generated for internal validation. Univariate logistic regression assessed the effect of each covariate on the binary outcome of toxicity. For those variables with a significance level p<0.3, pairwise Spearman correlation was measured. In case of high-level correlation (ρ>0.7) between two variables maintained at univariable, the one with the lowest p-value was considered.

The training phase tuned a backward stepwise multiple logistic regression, aimed to identifying feature subsets that maximize the average precision (AP) as the primary selected performance indicator. The AP consists in the area under the precision-recall curve (AUPR) which, when maximized, assures the best tradeoff between high precision and high recall for different thresholds, particularly suitable when the classes are very imbalanced.

During the internal validation procedure, bootstrap resampling determined the robustness of the model by iteratively resampling the training population with replacement [16]. The chosen performance indicators (average precision and ROC curve AUC) were then corrected for optimism.

Raw data manipulation and analysis were performed with an in-house Python 3.7.9 code: medicalAI library in mAItre (Medical Artificial Intelligence Toolkit for REsearch).

3 Results

In current analyses, 499 patients respecting the selection criteria were included. Forty-six patients (9.2%)

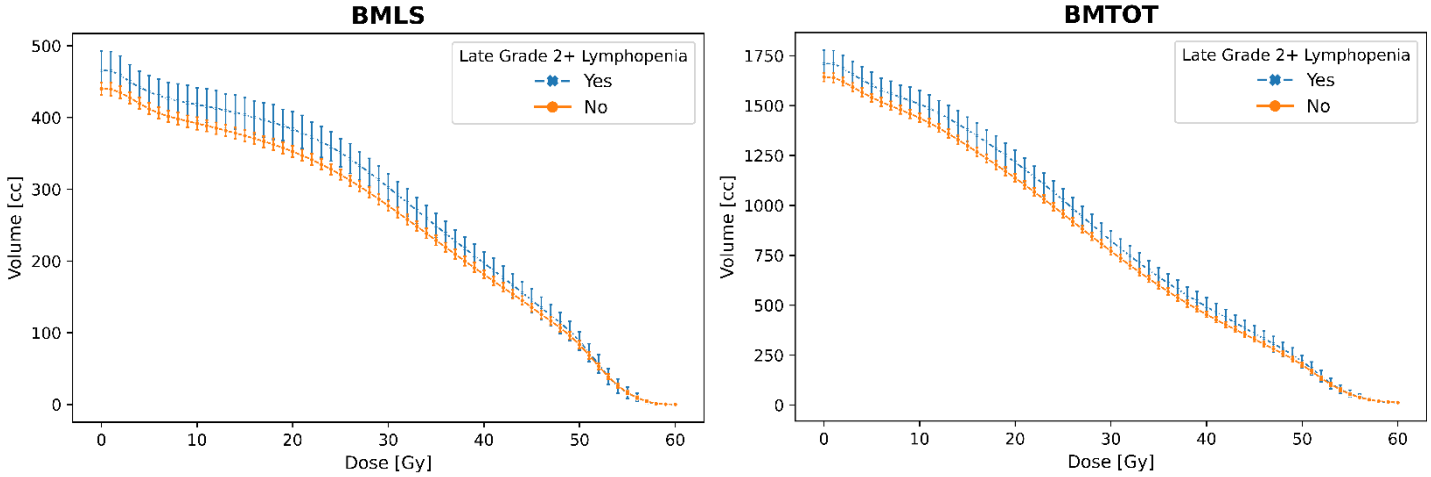

Figure 1: Mean absolute DVHs of BMLS (left) and BMTOT (right) for patients with and without late G2+ lymphopenia with 95% confidence intervals. Significant differences (p-values<0.05) at the Mann–Whitney test were found in the ranges V0-V36Gy for BMLS and V0-V5Gy and V10-V29Gy for BMTOT.

experienced late G2+ lymphopenia. DVHs of structures were stratified by the presence of the endpoint and significant differences (p-values<0.05) at the Mann–Whitney test were found in the ranges V0-V36Gy, V15-V24Gy, V0-V5Gy and V10-V29Gy, V20-V32Gy and V38-V43Gy for BMLS, BMPELVIS, BMTOT and BODY respectively (Figure 1). The latters were compared pairwise to measure the strength of their inter-correlation. Of them, BMLS-V24 was finally selected as the best independent DVH variable so that eleven features were found to be eligible to enter the training phase.

The variables which the backward sequential feature selection retained for late G2+ lymphopenia were: ALC at baseline (μL^{-1}) [OR=0.997, 95% CI 0.996-0.998, $p<6.1*10^{-11}$], smoke (yes/no) [OR=2.840, 95% CI 1.254-6.432, p=0.01] and BMLS-V≥24Gy (cc) [OR=1.006, 95% CI 1.002-1.011, p=0.002]. The ROC and PR AUC (hereinafter referred to as the "apparent" performance) were 0.865 and 0.415, respectively, suggesting that the model was performing well in distinguishing between classes overall, with modest precision in the positive class. The McFadden's pseudo-R-squared (0.259) and LLR p-value (p<0.0001) assessed the goodness of fit.

In Figure 2, the resulting 2-year risk of G2+ lymphopenia is shown against ALC at baseline, stratified by Smoke and dichotomized BMLS-V24 (above/below the Youden optimal cutoff value of 307cc).

During the internal validation stage, the "apparent" performance in the original sample was corrected for the mean "optimism" across the bootstrap replicates, resulting in a more realistic performance of 0.859 and 0.379 for ROC and PR AUC, respectively.

When acute G3+ lymphopenia (yes/no) was added among the possible predictors it was retained in addition to the previous three variables: ALC at baseline (μL^{-1}) [OR=0.997, 95% CI 0.997-0.998, $p=5*10^{-9}$], smoke (yes/no) [OR=2.902, 95% CI 1.246-6.761, p= 0.014], the fraction of lumbosacral volume receiving≥24Gy (cc) [OR=1.006, 95% CI 1.002-1.011, $p=3.5*10^{-3}$] and acute G3+ lymphopenia [OR=4.517, 95% CI 1.954-10.441, $p=4.2*10^{-4}$].

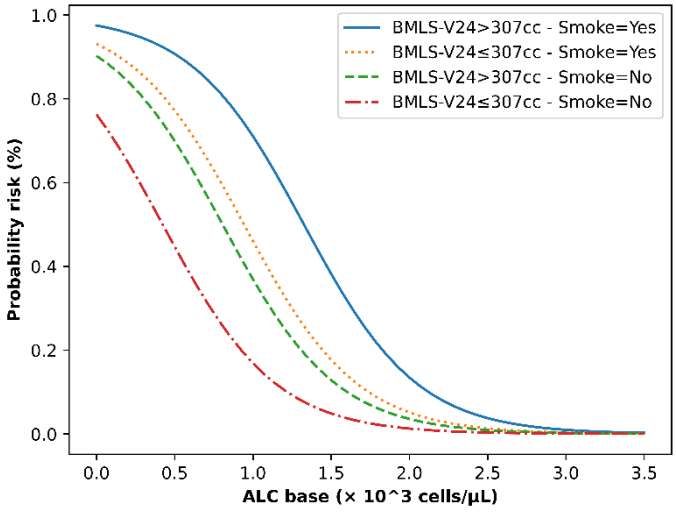

Figure 2: Probability risk (%) for 2-year G2+ lymphopenia at increasing levels of ALC at baseline, stratified by Smoke and dichotomized BMLS-V24 (above/below the Youden optimal cutoff value of 307cc.

In this case, the performance on the original dataset for ROC and PR AUC slightly improved with a value of 0.878 and 0.489, respectively, as well as McFadden's pseudo-R-squared (0.308) and LLR p-value (p<0.0001).

The internal validation statistics (ROC AUC=0.870, PR AUC=0.446) accounted for the natural decrease in performance in the bootstrap sample compared to the original sample.

DVH constraints to reduce late G2+ lymphopenia were determined for BMLS (V24<307cc) and BMTOT (V10<1520cc, V20<1250cc, V30<850cc) via the Youden index (J) method: the optimal cut-points simultaneously maximized sensitivity and specificity for toxicity classification.

4 Discussion

To our knowledge, current study for the first time shows that, in a large multi-centric patients' cohort treated with IMRT, moderate/severe lymphopenia still affects patients 2 years after RT with a G2+ rate of 9.2% (G3+=0.8%) against a baseline (pre-RT) rate of 1.8%. On the other hand, the rates of acute G2+ and G3+ lymphopenia (86.8% and 39.5% respectively) were in line with other investigations [5] and with our previous single institution reports [1, 2].

A second major outcome is the quantification of the dose-volume effect of pelvic BM and sub-structures. Interestingly, the lumbosacral BM showed the strongest association with late lymphopenia and its corresponding DVH surrogate value (V24Gy) was retained in the resulting multi-variable models. Our results suggest that, along with an expected large risk reduction when limiting the cranial PTV limit, sparing BM may translate in a minor but still significant risk mitigation even for patients' sub-groups with similar cranial limit.

A significant association between the whole pelvic BM and the risk of late lymphopenia was also found, leading to suggest the following DVH constraints: V10<1520cc, V20<1250cc and V30<850cc.

The presence of two clinical predictors corroborates the evidence that G2+ lymphopenia is largely modulated by the baseline patient situation, being baseline ALC the strongest predictor. The smoking effect seems to suggest a likely relevant negative role in micro-circulation modifications.

The final model was also slightly improved when considering acute G3+ lymphopenia as a potential predictor of 2-year lymphopenia, suggesting a quite intuitive relationship between the entity of ALC in the acute phase and recovery ability and speed.

The information that patients with lower baseline ALC value and/or smoking have a much higher risk of experiencing persistent G2+ lymphopenia could help the clinician during treatment planning. Considerations could

also be made on the real expected benefit in including PNI, maybe small or questionable for a not negligible fraction of patients, especially in the post-operative setting [17]. On the other hand, the detrimental effect of persistent lymphopenia in terms of decreased QoL and/or anti-tumor effect for PCa is not clear yet.

As pelvic BM is not usually included in the planning optimization phase, there could be substantial improvements in reducing the risk of 2-year lymphopenia thanks to refined planning strategies [3] or considering, when feasible and justified, the use of protons [18]. The choice of the cranial limit of the fields could also significantly impact this risk and could be discussed by clinicians when considering the cost-benefit of the therapy, especially in patients with low ALC and/or smokers.

5 Conclusion

The risk of 2-year lymphopenia after PNI for PCa is not negligible and mainly depended on pre-RT ALC, smoking and pelvic BM DVH, with evidence of a major impact of the cranial extension of PTVLN including a larger portion of lumbar vertebrae in the irradiated volume.

The knowledge of the risk factors is important for the radiation oncologist in the treatment decision phase and its optimization. There should be a large room to improve the sparing of pelvic BM without detriment to other OARs and/or PTV coverage, at least in patients with unfavorable clinical factors (i.e.: baseline ALC, smoking).

Inter-patient registration methods for voxel-based analysis in lung cancer

Chloe Min Seo Choi[1], Jue Jiang[1], Maria Thor[1], Joseph Deasy[1] and Harini Veeraraghavan[1]

[1]Department of Medical Physics, Memorial Sloan Kettering Cancer Center, New York, United States

Abstract Accurate registration between patients is crucial for reliable radiotherapy outcomes prediction that utilizes voxel-based analysis (VBA). We compared three registration methods, including: 1) an iterative non-deep learning intensity-based B-spline deformable image registration method available in open-source Elastix called SyN, 2) a published deep learning method called patient-specific anatomy and shape context (PACS), and 3) an enhanced version, called PACS-tumor aware, which specifically considers relevant structures that may change, e.g., tumors. The algorithms were tested on a dataset of 3D planning CT images from 240 patients with lung cancer. Our analysis showed that PACS-tumor demonstrated minimal differences in tumor volume (1.08%) and GTV dose (0.05Gy) between non-deformed and deformed moving images, preserving tumors effectively. Additionally, it exhibited robust registration accuracy and consistency across patients of different sizes. In conclusion, PACS-tumor is a well-performing method for inter-patient registration in VBA for lung cancer patients.

1 Introduction

Voxel-based analysis (VBA) has emerged as an important tool to understand the radiation therapy (RT) dose-response relationship for various toxicities after RT for cancer [1-4]. VBA refers to pixel- or voxel-based methods that examine how doses are distributed locally, moving beyond traditional organ-focused approaches using Dose Volume Histograms (DVH). Unlike typically used DVH-based approaches, which offer a 2D aggregation of the 3D dose distribution, VBA incorporates the complete dose distribution. This could allow the identification of specific spatial dose-response relationships.

The success of VBA relies heavily on accurate image registration. This involves aligning individual patients' images onto a common reference anatomy. To date, numerous registration algorithms have been utilized for inter-patient registration. Of these, Symmetric normalization (SyN), which is an iterative optimization-based deformable image registration (DIR) method [5], has been the most widely used DIR approach for inter-patient registration [6, 7]. More recently, deep-learning (DL)-based approaches have been developed, with one example being Transmorph, which has a hybrid Transformer-ConvNet architecture [8]. Moreover, we previously developed a Patient-specific Anatomic Context and Shape prior model (PACS), which uses 3D convolutional long short-term memory networks [9]. Using this approach, large differences in anatomy are handled by computing a spatially and temporally varying dense deformation field by incrementally refining registrations between patients.

However, registration accuracy is impacted by the anatomic variabilities between patients such as various sizes of the heart and other organs due to factors such as gender, race as well as the presence of tumors, which are arbitrarily distributed within the chest. Hence, VBA depends on the selection of canonical reference patients to whom all the other patients are aligned to perform the analysis. So far, the selection of such a patient has been performed by using a patient with median lung or heart volume without considering the impact of the presence of tumors. In fact, patient scans with tumors can adversely impact the accuracy of the analysis due to the difficulty of aligning patient scans without causing unrealistic stretching of the normal tissues as well as erosion of tumors.

Tumor erosion on the aligned moving image occurs when tumors are absent on the target or fixed image, leading to physically unrealistic stretching of normal tissues. The spatial locations of tumors on the fixed image contribute to this issue. In previous studies, patients with unsuccessful reregistration were excluded from the analysis, aiming to mitigate inaccuracies [10, 11]. However, excluding patients is problematic because it creates an inaccurate representation of the general population.

To address this issue, we introduce a novel registration model, "PACS-tumor," designed to prevent inadequate tumor warping while still yielding satisfactory registration outcomes. The aim of this study was to compare the accuracy of different registration methods to assess how the choice of model affects inte-rpatient registration for VBA analysis. Additionally, we explore the potential demographic bias inherent in these methods.

2 Materials and Methods

This retrospective study was approved by the local institutional review board at the Memorial Sloan Kettering Cancer Center. The dataset included 240 locally advanced non-small cell lung cancer (LA-NSCLC) patients treated with intensity-modulated RT to 60 Gy in 2 Gy fractions. Each patient had a treatment planning CT (pCT) with associated gross tumor volume (GTV) and organ-at-risks (OARs) including the heart, esophagus, normal lungs, and cardiac substructures (Inferior Vena Cava (IVC), left and right ventricle (LV, RV), left and right atrium (LA, RA), pulmonary artery (PA), superior vena cava (SVC)).

For each patient, the pCT was re-sampled to a 1x1x3mm resolution. The pCT was thereafter cropped in the z-axis to extract a 3D volume that includes the visible lung regions with an additional 5 slices kept above and below the visi-

ble lung region to have a uniform field of view of all the patient scans. A reference patient with a population median lung volume was chosen as the initial reference anatomy. To ensure pCT alignments, all pCTs were affinely pre-registered to the reference patient before applying any DIR. Air and table occurring outside the body were excluded by first extracting the body region using automatic thresholding of the CT density followed by morphological processing. The largest connected component was extracted, and the image volume was cropped with a 30-pixel extension around the body region to focus deformable image registration towards relevant parts of the image that contain the body and the organs.

Three registration configurations were compared: 1) SyN, 2) PACS [9], and 3) novel PACS-tumor model, which also input tumor conditioning in addition to bi-directional tumor rigidity, thereby preserving tumor volumes and preventing unrealistic stretching of the adjacent normal tissues.

To calculate the registration accuracy, the Dice similarity coefficient (DSC) between the OARs of the aligned patients and the canonical patient was computed. DSC is defined by $DSC = (2 \times |X \cap Y|) / (|X| + |Y|)$ where DSC=0 means no overlap and DSC=1 means perfect overlap between the moving and reference. We also computed the difference in the Planned Tumor Dose (ΔPTD) between undeformed and deformed moving images. The smaller the difference, the better the algorithm's ability in preserving the tumor and its associated dose. Next, to estimate the potential impact of registration quality on VBA, the number of patients with lung segmentation DSC scores ≤ 0.7 was computed, which would indicate poor registration. Furthermore, the tumor volume change (ΔT) was calculated and defined by $(|V_{def}-V_m| / |V_m|) \times 100$ where V_{def} and V_m indicate tumor volume after and before DIR respectively.

We further investigated the algorithm's robustness to patient size variations to mitigate potential population bias arising from the reference patient selection. Here, we observed the correlation between the DSC of the heart and lungs and the patient's body size. The body size was determined by calculating the volume of voxels corresponding to the body region in a single CT slice (slice number 60).

3 Results

Standard PACS showed (Figure 1a) physically unrealistic tissue stretching in locations containing tumors whereas PACS-tumor effectively preserved tumors while also avoiding unrealistic tissue stretching (Figure 1b). The DSC scores measuring registration accuracy for the thoracic OAR is shown in Table 1. The overall DSC was the highest for PACS followed by PACS-tumor and SyN. PACS and PACS-tumor produced comparable accuracies. Registration quality indicated by lung DSC ≤ 0.7, showed that PACS resulted in the least number of excluded patients followed by PACS-tumor (Table. 2). SyN resulted in an exclusion of the greatest number of patients.

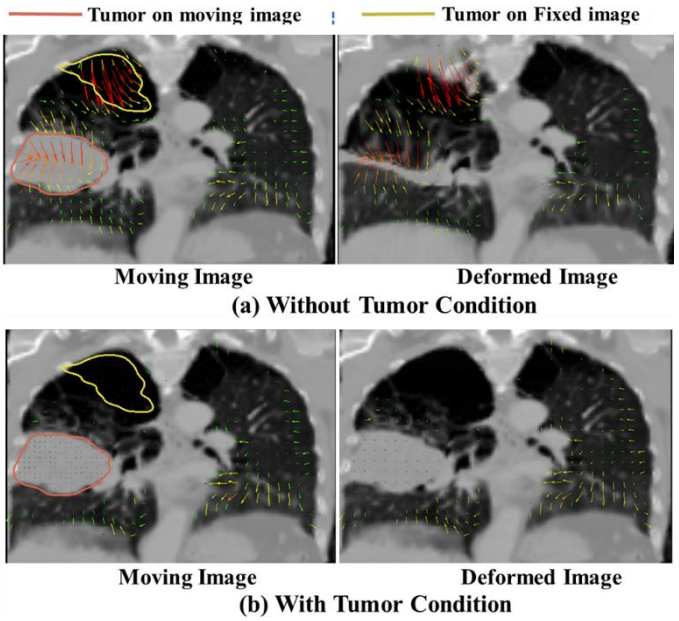

Figure 1: Rationale for tumor conditioning. Large deformations and physically unrealistic stretching of normal tissue in the regions occupied by tumors occurring without tumor conditioning (a) is avoided when using tumor conditioning (b).

	SyN	PACS	PACS-tumor
Heart	0.67	$0.77^{*\dagger}$	$0.74^{\dagger}$
Esophagus	0.18	$0.24^{*\dagger}$	$0.20^{\dagger}$
Lungs	0.71	$0.87^{*\dagger}$	$0.81^{\dagger}$
IVC	0.25	$0.29^{\dagger}$	$0.29^{\dagger}$
LV	0.31	$0.44^{*\dagger}$	$0.41^{\dagger}$
LA	0.38	$0.41^{\dagger}$	$0.41^{\dagger}$
RA	0.26	$0.34^{*\dagger}$	$0.32^{\dagger}$
RV	0.22	$0.28^{*\dagger}$	$0.25^{\dagger}$
PA	0.29	$0.34^{*\dagger}$	$0.32^{\dagger}$
SVC	0.16	$0.26^{*\dagger}$	$0.19^{\dagger}$

Table 1: DSC scores of the OARs for registration methods measured for multiple structures. IVC: inferior vena cava; LV: left ventricle; LA: Left atrium; RA: right atrium; RV: right ventricle, PA: pulmonary artery; SVC: superior vena cava. †: significantly greater than SyN ($p<0.05$), *: significantly greater than PACS-tumor ($p<0.05$)

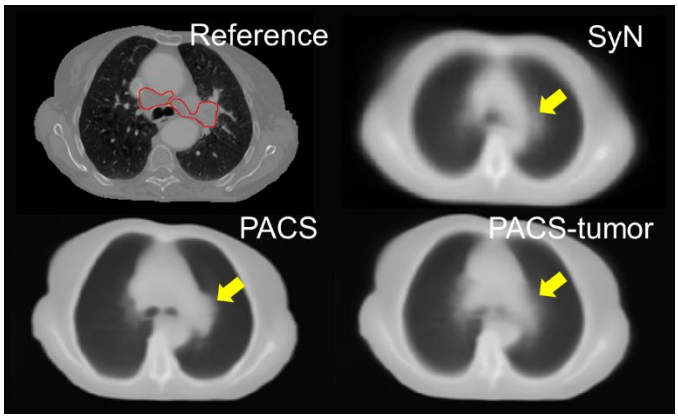

Figure 2: Voxel-wise averages of the patients' anatomical images using different methods. The initial image depicts the reference patient with the GTV outlined in red.

PACS-tumor preserved tumor volumes to the highest degree as shown by the lowest tumor loss ΔT metrics (Table 2). PACS on the other hand was thest least effective in preserving tumor volumes, indicating the importance of tumor conditioning used in PACS-tumor. SyN method achieved minimal ΔPTD and ΔT, suggesting that overall deformation was negligible. This was also visually confirmed as in Figure 2. The tumor in the canonical reference patient was located in the medial region. The voxel-wise average of the PACS and PACS-tumor show better inter-patient agreement compared with SyN. In the tumor region, however, PACS methods induced warping of surrounding tissues whereas the extent of warping is much less with PACS-tumor. SyN shows large inter-patient discrepancies everywhere.

	Excluded cases (Lung DSC ≤ 0.7)	Tumor dose difference, ΔPTD (Gy)	Tumor volume difference, ΔT (%)
SyN	89	0.004	3.40
PACS	7	7.59	46.69
PACS-tumor	19	0.05	1.08

Table 2: Suitability for VBA. Number of excluded patients (heart and lung DSC < 0.7), tumor dose preservation ΔPTD (Gy), and tumor volume difference ΔT (%) by various methods measured.

In the analysis of the impact of patient size on registration accuracy, we found that the overall trend across all patients did not show a significant impact of size on registration accuracy. However, larger patients had notably lower DSC values for both algorithms (Figure 2). Overall, the registration models showed similar trends.

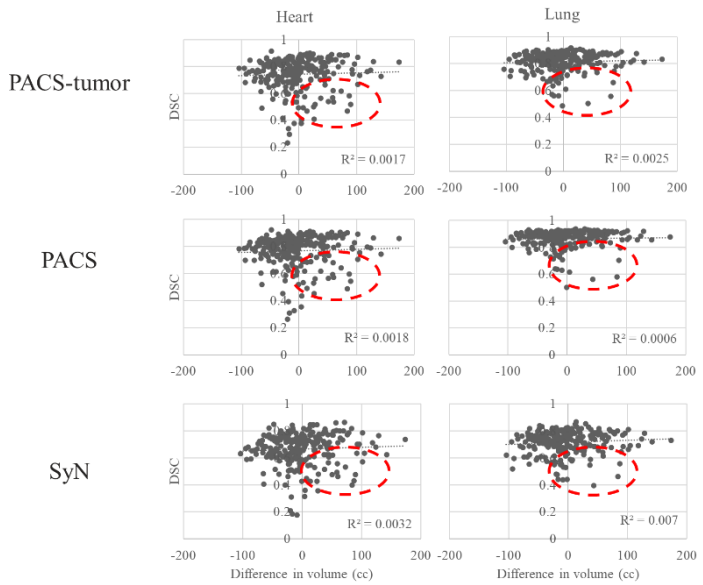

Table 2: Figure 2: Correlation between patient size and the DSC accuracy.

4 Discussion

To our knowledge, no previous studies have investigated how the choice of registration tool affects VBA in RT. This study emphasizes the importance of considering both registration accuracy and dose preservation when selecting an algorithm. Our analysis revealed that PACS-tumor demonstrated superior accuracy in preserving conditioned structures, preventing unrealistic anatomy deformations in locations with tumors, especially in comparison to the PACS registration methods.

Although PACS achieved slightly higher accuracy in terms of OAR, it unrealistically warped tumor volumes to mimic the reference patient's tumor anatomy, resulting in large variations in tumor shrinkage and subsequent dose. This is critical for VBA, as deformed dose mapping is a central analysis component. SyN, on the other hand, was the least accurate method, which resulted in the largest number of excluded patients due to poor registration. Notably, iterative registration methods are frequently used in VBA analysis as they are relatively easier to apply without requiring training on task-specific datasets. However, poor registration quality and the need to exclude patients can also diminish the utility of these analysis methods.

Considering population bias, a slight trend in patient size was observed in which patients with larger body sizes than the reference presented worse registration outcomes. While the trend may be slight, it highlights the importance of investigating the influence of patient size on registration accuracy and fairness.

There are some limitations of this study. This study did not include the downstream impact on VBA and its subsequent prediction. This will be the end goal of future studies. Furthermore, this study used a female median patient as a reference, analysis with a male reference patient will be conducted to observe gender-related differences. Additionally, exploring alternative strategies to balance accuracy and inclusivity, such as patient-specific optimization or hybrid approaches, could prove beneficial.

5 Conclusion

This study has demonstrated that the success of inter-patient VBA is strongly dependent on the algorithm. The novel PACS-tumor model showed significantly better performance in preserving tumor anatomy while maintaining robust registration accuracy across patients of varying sizes. This promising performance suggests its potential application in VBA workflows.

Abstract Progressive anatomical changes are often observed in head and neck cancer patients over the course of radiotherapy. To create proton therapy treatment plans that are robust against these changes, these potential anatomical changes must be known in advance.
In this work we present a novel methodology for developing statistical population models that capture progressive anatomical changes and their variability. The models are continuous in time, and can be built from a population of patients with a varying number and frequency of images over treatment. The statistical population models are based on principal component analysis of the progressive anatomical changes, and can generate scenarios of many potential anatomical changes. In this work two principal components were used to generate nine scenarios of potential anatomical change. The evaluation found, for some patients, one scenario that matched their progressive anatomical changes better than by just considering the average change.

1 Introduction

Inter-fractional anatomical changes during proton therapy can lead to uncertainties in the delivered dose distribution. These uncertainties may reduce the efficacy of treatment, typically increasing dose to some organs at risk and/or reducing dose to the tumour. In an attempt to mitigate for inter-fraction changes, proton therapy treatment plans are optimized on uncertainty scenarios considering rigid shifts and range uncertainty of the protons. However, more complex non-rigid anatomical changes are commonly observed during treatment, such as weight loss and tumour shrinkage or growth. These changes are often progressive over treatment resulting in systematic errors in the delivered dose.

Ideally, a patient would be administered a treatment plan which is robust against predictable anatomical changes. To achieve this, a patient's potential anatomical changes need to be known in advance.

Statistical population models have been explored for this purpose[1-4]. However, most models presented in the literature do not explicitly model progressive changes and therefore, cannot efficiently represent the potential anatomical changes. The models in the literature which do explicitly model progressive changes require imaging at the same time points during treatment, which is not always available.

We present a novel methodology for building statistical population models of progressive anatomical changes. The models can predict trajectories of potential anatomical changes over the course of treatment, and do not require imaging on consistent days in the population for training.

2 Materials and Methods

2.1 Datasets

Datasets from three institutions were used for this study, as shown in Table 1, together with details of how the datasets were split between training and testing.

Dataset	Training	Testing
1	46	5
2	27	1
3	0	14

Table 1 – Table showing the split of patients provided from three institutions. The number of patients which were included for training and testing the population models are shown.

All patients were treated with photon radiotherapy. Each patient had a planning CT (pCT) and a number of CBCTs (5-26), over the course of treatment. The staging, tumour location and prescription doses varied across the patients in all three datasets. To make the population more anatomically consistent, images were flipped so that all patients had the same tumour laterality. The degree of anatomical changes, and hence the need for replanning, varied across the 3 datasets: in Dataset 2 no patients were replanned; in Dataset 3 all patients were replanned; and in Dataset 1 some patients were replanned but most were not.

The statistical population models were built from the training datasets using the following steps: 1) inter-patient correspondence was determined to spatially align all patients into a model space. 2) Intra-patient registrations were used to estimate the anatomical changes of each patient over the course of treatment. 3) Patient specific models were fit to capture the progressive anatomical changes. 4) Statistical population models were then built from the patient specific models. The statistical population models aim to capture the average progressive anatomical changes and the variability in these changes as seen in the training set.

2.2 Inter-Patient Correspondence

To build population models the data from individual patients must be mapped into a common model space so they are spatially aligned. A groupwise registration between the pCTs from Dataset 3 was used to build an anatomical atlas and define the model space.

Inter-Patient correspondence was achieved by aligning all patients to the anatomical atlas. A rigid, affine and deformable registration were performed in turn, and the resulting transformations were composed to calculate $T_{M\to p}$. The transformation $T_{M\to p}$ maps each point in the model space, M, to the corresponding point in the patient space, p, and can be used to resample the patient's images into the model space using pull interpolation. All registrations in this work were performed using NiftyReg[6]. The deformable registrations were parameterized by stationary velocity fields, v, using a regular grid of control points defining a B-Spline Free-Form-Deformation (FFD). Therefore, the registrations produced diffeomorphic transformations that ensured topology was preserved, provided both the forward ($T_{M\to p}$) and inverse ($T_{p\to M}$) transformations, and gave a rigorous framework for building the population models[7,8].

2.3 Intra-Patient Correspondence

For each patient, all CBCT images were rigidly aligned to the patient's pCT, and then transformation $T_{M\to p}$ was used to resample all images into the model space. The anatomical changes were then estimated by registering the pCT to each CBCT in the model space. Each intra-patient registration resulted in a transformation, $\tilde{T}_{reg,p,t\to 0}$, which maps from the CBCT image at time point t to the pCT image for a patient p, in model space, and is parametrized by the stationary velocity field $\tilde{v}_{reg,p,t\to 0}$.

2.4 Patient Specific Models

The patient specific models (SMs) aim to estimate $\tilde{v}_{reg,p,t\to 0}$ for any time point t in treatment, $t = 1 \dots T$. A cubic B-Spline was fit to each parameter of $\tilde{v}_{reg,p,t\to 0}$ i.e. to the *x, y, z* components of each FFD control point, over time. Four SM control points were placed equidistantly over time for each parameter, so that the B-Spline was defined between the first CBCT scan and day 35, i.e. $T = 35$. The B-Spline function was fit using a linear least squares solution. The SMs are defined by a grid of control points, $C_{SM,p}$, which define B-Splines in both the spatial and temporal dimensions. Therefore, the SMs provide very compact models of the anatomical changes over space and time. The SM can be used to estimate $\tilde{v}_{SM,p,t\to 0}$, the SM velocity field, and $\tilde{T}_{SM,p,t\to 0}$, the corresponding SM transformation, for patient p at any timepoint t between the first and last CBCT scans.

2.5 Statistical Population Models

To create the statistical population model (PM) principal component analysis was performed on $C_{SM,p}$ from all training patients. The resulting eigenvalues, λ, and principal components, w, are used to generate potential representations of C_{PM},

$$C_{PM} = \bar{C} + \sum_{i=1}^{N} a_i \sqrt{\lambda_i} w_i$$

where $\bar{C}$ is the average of $C_{SM,p}$ over all training patients, a_i defines the number of standard deviations taken in the ith principal component, and N is the number of principal components used in the model. In this work, we set $N = 2$ and used the PM to generate nine different instances of C_{PM} with $a_1,\ a_2 \in \{-1, 0, +1\}$. The nine potential anatomical changes can then be generated for any timepoint t up to day 35, by calculating $\tilde{v}_{PM,t\to 0}$ and $\tilde{T}_{PM,t\to 0}$ from C_{PM}.

2.6 Transporting Transformations

To apply $\tilde{T}_{PM,t\to 0}$ or $\tilde{T}_{SM,t\to 0}$ to a patient, the transformation needs to be transported from model space to patient space. This is done using conjugate action,

$$T_{t\to 0} = T_{M\to p}(\tilde{T}_{t\to 0}(T_{p\to M}))\,,$$

where $T_{t\to 0}$ is the transported model transformation of patient p. This is shown schematically in Figure 1.

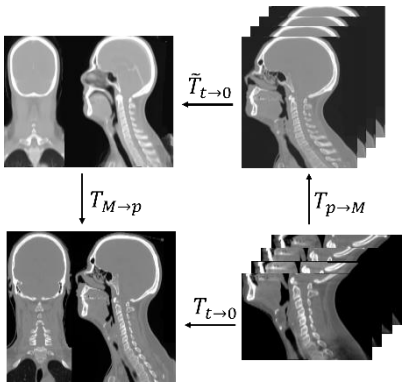

Figure 1 - Schematic representation of inter- patient correspondence $T_{M\to p}$, and it's inverse $T_{p\to M}$. Intra-patient correspondence is shown in patient space $T_{t\to 0}$ and model space $\tilde{T}_{t\to 0}$.

3. Evaluation and Results

We previously presented and evaluated an average population model[9], similar to the average component of PM proposed here, $a_1 = a_2 = 0$. This was built and evaluated using just Dataset 3. This preliminary study indicated that the average models could provide a good estimate of the progressive anatomical changes seen in most patients, but not all, due to the variability of the changes seen across the population of patients. Therefore, this study aims to test whether by including the nine different scenarios of anatomical changes of the PM, provided by the nine instances of C_{PM}, improves on the performance of the average model at estimating the actual anatomical changes seen in the test patients.

A geometric evaluation was performed to quantify the progressive anatomical changes and test the ability of the PM and average model to capture these. When evaluating

the PM models all nine C_{PM} were considered in combination, since no single instance of C_{PM} was expected to be better for all patients. Therefore, for each patient the instance of C_{PM} that provided the minimum error was used. In this evaluation, the SMs were used to provide the gold standard progressive anatomical changes for the test patients, as they have been validated in previous experiments[9]. The evaluation was performed at the last day of the models range by using the models to generate transformations with t = 35.

The transformations generated by the gold standard SM, average model, and PM were transported to the patient space and used to resample the pCT structures for each patient in the test set. The structures included the brainstem, spinal cord, left and right parotid gland, high and low dose clinical target volume (CTV), and body (only available for dataset 3). The structures resampled by the SM were compared on average surface distance to the structures (1) from the pCT, (2) resampled by the average model (3) resampled by the PM (Figure 2). The average surface distance for Datasets 1&2 is shown in Figure 3 (which are from the same institution as the patients used to build the model) and the test set from Dataset 3 in Figure 4 (from an external institution). Note that axes are scaled differently on both figures.

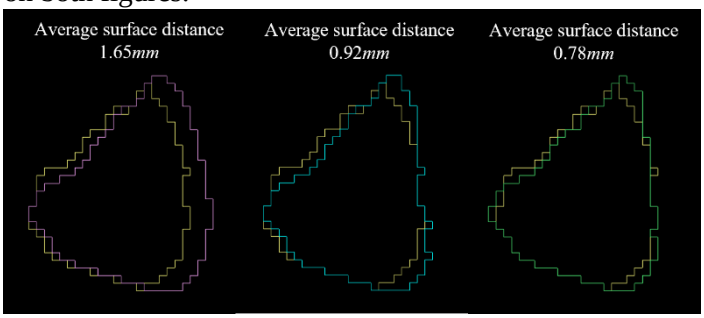

Figure 2 – Example left parotid gland structure resampled with patient specific model (yellow) compared to 1) pCT contour (pink), 2) pCT structure resampled with average model (blue), and 3) pCT structure resampled with best fitting population model (green). This structure is from a test patient in Dataset 3.

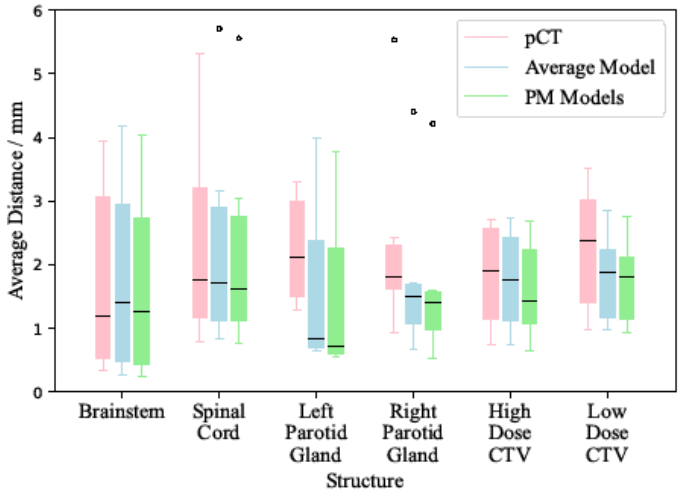

Figure 3 – Average surface distance calculated between the planning CT (pCT) structures resampled with the patient specific model and (1) the pCT structures, (2) structures resampled using the average model and (3) structures resampled using the population model (PM) which provides the best correspondence. The median, range and interquartile range are shown. The test data used in this comparison is from the same institutions from which the models were built.

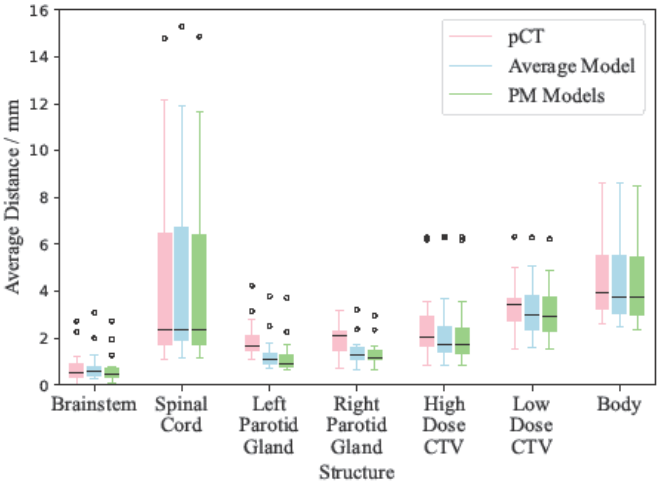

Figure 4 – Average surface distance calculated between the planning CT (pCT) structures resampled with the patient specific model and (1) the pCT structures, (2) structures resampled using the average model and (3) structures resampled using the population model (PM) which provides the best correspondence. The median, range and interquartile range are shown. The data used in this comparison is a hold-out test set; patients were treated at a different institution and all patients in this cohort were replanned.

Larger anatomical changes were seen in the pCT comparison and therefore over treatment in Dataset 3 than in Datasets 1&2. In Datasets 1&2 all anatomical changes are <2.39*mm*. In Dataset 3, the low dose CTV and body structures exceed that with median average surface distances of 3.45*mm* and 3.93*mm*. Larger anatomical changes were expected in Dataset 3, since all patients in this cohort were replanned.

The average model provides an improvement on the median average surface distance across all Datasets and structures, except for the brainstem. For Datasets 1&2, and 3, the average improvement in median average surface distance is 0.46*mm* and 0.44*mm*, respectively.

The PM model provides an improvement over the average model for all structures and datasets. For Datasets 1&2, and 3, the average improvement in median average surface distance is 0.14*mm* and 0.10*mm*, respectively. This supports the hypothesis, that for some patients there exists a scenario from the nine PM generated scenarios that matches the progressive anatomical changes better than the average model.

4 Discussion

In this work we present a novel methodology for developing statistical population models, for progressive anatomical changes and their variability as seen in head and neck cancer patients over the course of treatment. The models are continuous, despite the studied population of patients having a different number of images taken at different days.

The datasets used in this study were from three different institutions and contained patients which had a wide range of tumour types, locations and sizes. Although an attempt was made to partially mitigate for any location differences, by flipping left-right, these factors introduce additional variability into the models.

All patients used in this work were treated with photon radiotherapy. The aimed application of these models however, is to enable the generation of proton radiotherapy plans that are robust to the expected anatomical changes. As these changes are strongly linked to nutritional deficiency and primary tumour/nodal shrinkage, we expect the changes to present similarly in the two patient cohorts. This will be investigated in future work, and if necessary new models could be built from a cohort of proton therapy patients using the same methodology.

Anatomical changes experienced by a patient were estimated using deformable image registrations. Running the registration with the parameters used in this work typically required up to 3 hours and 3GB RAM per registration. So for the approximately 1500 registrations required for this study a considerable amount of computation was required.

For each patient, a SM was built using the registration results, to extract the progressive anatomical changes and remove day to day random variations in anatomy. A cubic B-Spline with four temporal control points was fit to the registration results over time. Preliminary experiments indicated this could approximate the progressive changes well without overfitting the data, even when relatively few images were available (the minimum number of CBCTs was five in this study). However, future work will investigate the number of control points used.

The anatomical changes experienced by a patient, were encoded into a regular grid of spatially and temporally aligned control points, which define B-Splines. This produces a very compact model, which is smaller than the daily voxel wise information by a factor of 10^4.

A geometric evaluation, using pCT structures showed that the statistical population models are able to capture progressive anatomical changes, and that considering the nine scenarios generated by the PM improves on just considering the average model for some patients.

The PM models considered in this work involve only two principal components. These generated nine scenarios of potential anatomical changes per patient. By considering more principal components, the total variability included in the model would increase and therefore, so would the number of scenarios. The aim of this work is to incorporate the predicted anatomical scenarios into robust optimization for proton therapy treatment planning. It is expected that the more scenarios which are included in the optimization, the more robust the treatment plan becomes. This, however, often comes at the cost of conformality and computation time. In future work, we will search for an optimal balance, by investigating how the number of scenarios impacts the robustness and conformality of a proton therapy treatment plan.

5 Conclusion

Head and neck cancer patients commonly experience anatomical changes over the course of their radiotherapy. In this work we present a novel methodology to model the progressive anatomical changes and their variability. The models are continuous in time and can estimate the changes for any day during treatment.

The statistical population models were based on principal component analysis. The evaluation showed that by using just two principal components to generate nine scenarios, the PM improves on using the average model for some patients.

In future work we aim to investigate the use of the generated scenarios in robust proton therapy treatment planning.

An anatomically-informed correspondence initialisation method to improve learning-based registration for radiotherapy

Edward G. A. Henderson[1], Marcel van Herk[1], Andrew F. Green[2], and Eliana M. Vasquez Osorio[1]

[1]Division of Cancer Sciences, The University of Manchester, M13 9PL, UK
[2]European Bioinformatics Institute, EMBL-EBI, Cambridge, UK

Abstract We propose an anatomically-informed initialisation method for interpatient CT non-rigid registration (NRR), using a learning-based model to estimate correspondences between organ structures. A thin plate spline (TPS) deformation, set up using the correspondence predictions, is used to initialise the scans before a second NRR step. We compare two established NRR methods for the second step: a B-spline iterative optimisation-based algorithm and a deep learning-based approach. Registration performance is evaluated with and without the initialisation by assessing the similarity of propagated structures. Our proposed initialisation improved the registration performance of the learning-based method to more closely match the traditional iterative algorithm, with the mean distance-to-agreement reduced by 1.8mm for structures included in the TPS and 0.6mm for structures not included, while maintaining a substantial speed advantage (5 vs. 72 seconds).

1 Introduction

Non-rigid registration (NRR) is widely used for many applications in radiotherapy to spatially align images, including fusion of complementary images, contour propagation, evaluating treatment response, dose mapping [1, 2]. Traditional image registration algorithms function by performing iterative updates to parameters of a chosen deformation model to optimise either an intensity- and/or feature-based metric [1]. Intensity-based metrics use the images greyscale intensity information directly to evaluate similarity. Feature-based metrics use features extracted from the images such as anatomical landmarks, structure boundaries, contours and fiducial markers to evaluate alignment.

Hybrid image registration techniques have been developed which aim to combine the strengths of intensity- and feature-based algorithms, leveraging greyscale information as well as anatomical structures or landmarks to guide the registration [3, 4]. However, hybrid methods tend to be slow and labour intensive, taking a long time to set up as they require landmark annotation or structure contouring.

Recently image registration methods using deep learning (DL) have garnered much attention as they can offer large time savings over iterative algorithms [5]. DL approaches are trained ahead of time on large datasets of examples; once trained, these methods can estimate a full deformation vector field in a single function evaluation, often taking less than a second on modern hardware [6]. However, current learning-based approaches are predominantly applied to easier tasks such as the registration of brain MRI scans where the inter-subject variability is relatively low and the soft-tissue contrast is high [5, 7]. There has been little evidence to show that learning-based registration methods are suitable for large deformations, such as inter-subject CT registration [6, 8].

Many learning-based registration approaches are trained to optimise intensity-based metrics. Some can leverage segmentations present in the images, but only at training time through semi-supervised learning [5]. In this study we incorporate ideas from hybrid registration methods to improve learning-based registration performance. To achieve this we introduce a new anatomical correspondence-informed non-rigid initialisation to align labelled anatomical structures prior to using established methods to register non-labelled tissue.

2 Materials and Methods

We used an open-access dataset of 31 head and neck CT scans with highly consistent organ-at-risk (OAR) segmentations [9].

2.1 Registration pipelines

We propose the use of a previously developed learning-based correspondence model [10] and a thin plate spline (TPS) to form an anatomically informed method to initialise inter-patient non-rigid registration. The impact of the proposed initialisation was compared for two established NRR methods: a) NiftyReg, a traditional B-spline iterative-optimisation based image registration method [11] and b) Voxelmorph, an unsupervised, DL-based approach [12]. From now on, the proposed initialisation method is referred to as CorrTPS.

2.1.1 Anatomically informed initialisation (*CorrTPS*)

Correspondence model In a previous study, we showed an unsupervised geometric learning model could be trained to identify dense, point-to-point, correspondences for head and neck OARs [10]. The developed model can automatically identify corresponding anatomical points on the surface of 3D organ shapes and was shown to be effective for the brainstem, mandible, parotid glands, spinal cord and submandibular glands. The input for the correspondence model is two organ shapes which are converted to triangular meshes. The model predicts an assignment linking all vertices from the source to the target organ. Correspondence predictions are based on the organ geometry alone, however, CT imaging was utilised in the training process to improve prediction quality [10].

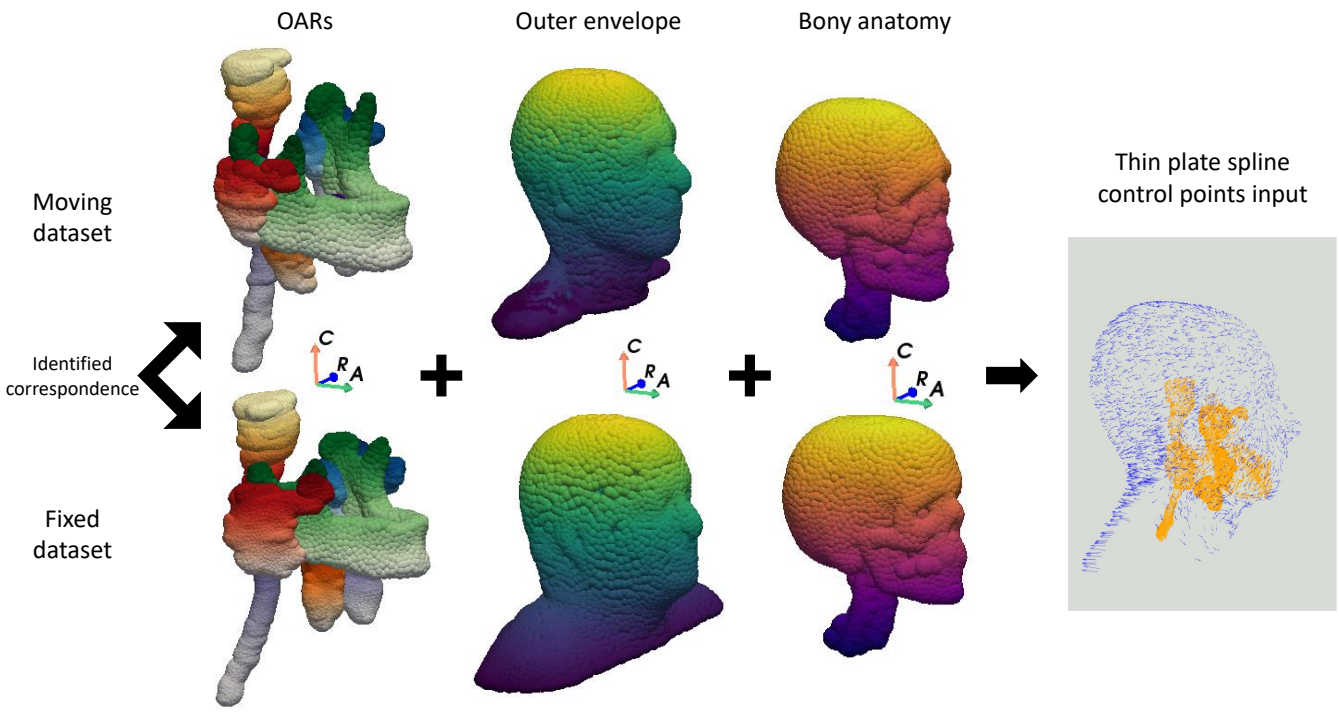

Figure 1: Correspondence of each structure between the fixed and moving datasets, represented by matching colours. Different colour maps are used for each structure and identified correspondences are only shown in the cranio-caudal direction for clarity. The resulting deformation vectors (OARs in orange, bony anatomy and envelope in blue) are the input for the TPS to set up the non-rigid initialisation.

Mesh generation To create triangular meshes of the OAR structures, we used the marching cubes algorithm followed by Taubin smoothing, mesh decimation, optimisation and simplification operations. The full details of this process have been described fully in our previous work [10].
A segmentation of the bony anatomy was acquired automatically from the CT scan by removing the table, thresholding at 400 Hounsfield units (HU), cropping at the base of the neck, and meshing using the marching cubes algorithm. A mesh of the external envelope comprising of the patient's body was generated using a lower threshold level of -200 HU.

Correspondence inference For non-rigid initialisation, dense correspondences were estimated for all segmented structures in the HN, as well as the bony anatomy and outer envelope of each patient (Figure 1).

Thin plate spline setup Once estimated, the correspondences were used as the control points to set up a TPS deformation model [13]. The TPS is generalizable to 3D and has a regularisation parameter, λ_{TPS}, which controls the allowed degree of local deformations.
Control points from each structure were gathered and a single TPS was created for each registration pair. In total, the TPS deformations were performed using about 14,000 control points (range: 10,500 - 16,000). Regions that were identified as null correspondences were excluded from the control point set driving the TPS. In this way, we prevent the creation of anatomically infeasible scenarios, e.g. inverting and folding around tissue mismatches.

For each fixed-moving image pair, we generated a displacement vector field by evaluating the TPS on the grid positions of the moving image. Then, we resampled the fixed image by inverse warping using the *DisplacementFieldTransform* from the *SimpleITK* package. We refer to these as non-rigidly initialised scans. A second NRR algorithm was then used to fine-tune the registration using the image intensities for the whole anatomy.

2.1.2 Non-rigid registration

To demonstrate the added value of CorrTPS, we compared the performance of two established intensity-based NRR methods with and without our proposed initialisation.

Deep learning-based registration (Voxelmorph) We trained multiple Voxelmorph models from scratch [12]. Image volumes were automatically cropped to dimensions of $128 \times 288 \times 480$ such that the whole HN anatomy was within the field-of-view while retaining the original voxel spacing. Additionally, the images were normalised from Hounsfield units onto the range [0,1] using contrast windowing with wide window settings (W 1600HU, L 0HU). The weight of the smoothing loss term which regularises the predicted deformations was set to 0.005.
When performing the five-fold cross-validation, each fold contains 7 testing patients. This leads to a 7×6 testing pairs for each fold (trivial self-registration cases excluded). The same Voxelmorph models were applied to the non-rigidly initialised scans.

Table 1: Mean execution time for all registration pipelines. These times include all necessary pre-processing steps for each method such as rigid pre-alignment, cropping, normalisation, and execution of the second non-rigid registration. All pipelines required rigid pre-alignment. The average time added by CorrTPS is shown in brackets and separated by the contributions of mesh generation and optimisation, correspondence estimation, TPS fitting and resampling respectively.

	Rigid pre-alignment (s)	Pre-processing steps and non-rigid registration (s)	Overall time to register image pair (s)
Voxelmorph	1.6	0.3	1.9
Voxelmorph + CorrTPS		(1.2 + 0.1 + 1.4 + 0.2) + 0.3	4.8
NiftyReg		70.7	72.3
NiftyReg + CorrTPS		(1.2 + 0.1 + 1.4 + 0.2) + 70.7	75.2

Iterative registration (NiftyReg) NiftyReg was first used to non-rigidly register the CT scans after rigid pre-alignment alone [11]. Following an empirical parameter evaluation, the configuration settled upon was a GPU-accelerated cubic B-spline using normalised mutual information loss with a bending energy of 0.001. The same configuration of NiftyReg was then used to register the non-rigidly initialised CT scans.

2.2 Evaluation

For every pipeline, we report the execution time including all the necessary pre-processing steps and the results image- and segmentation-based metrics.
The mean distance-to-agreement (mDTA) was calculated for each of the structures included within CorrTPS as well as the brain, cochleae, optic nerves, orbits following non-rigid alignment of the moving anatomy to the fixed reference patient. Wilcoxon signed-rank hypothesis tests were used to compare each registration algorithm with and without the CorrTPS initialisation. A Bonferroni correction was applied to minimise the risk of type I errors from multiple hypothesis tests (corrected p value: 0.0045).

Implementation details Model training and evaluation was performed on a workstation with an AMD Ryzen 9 3950X 16-Core Processor, 64GB of RAM and an NVidia GeForce RTX 4090 GPU.

3 Results

The average runtime for each approach is shown in Table 1. Figure 2a shows boxplots of the mDTA results for the organ structures included in the CorrTPS, while 2b shows similar results for structures not included in CorrTPS. Significant improvements in registration performance were observed for most structures included in CorrTPS across both methods when using the proposed initialisation. For structures not included in CorrTPS, some improvements were observed for the learning-based registration method (the brain, orbits and lacrimal glands), however, the performance of the traditional registration algorithm was degraded.

4 Discussion

We proposed a novel method to non-rigidly pre-register an image pair prior to inter-subject registration of head and neck CT scans using correspondence of anatomical structures. The initialisation method is based on a geometric learning-based correspondence model which, when coupled with a TPS deformation, allowed the moving scans to be deformed to align segmented OARs before a final registration using established NRR methods. Our initialisation approach showed promise to improve the registration performance of the learning-based NRR method, Voxelmorph, improving the quality of the registrations in terms of the segmentation-based evaluation measure. The performance of our proposed method with the traditional iterative algorithm, NiftyReg, was less clearly defined, with some improvements for structures included in the initialisation and degradations for those not included. The use of CorrTPS required a limited increase in execution time. In terms of the mDTA, the benefit of our proposed initialisation method is evident for structures included within CorrTPS. The one exception to this was for the spinal cord when using NiftyReg, in which the use of the initialisation method harmed registration performance.

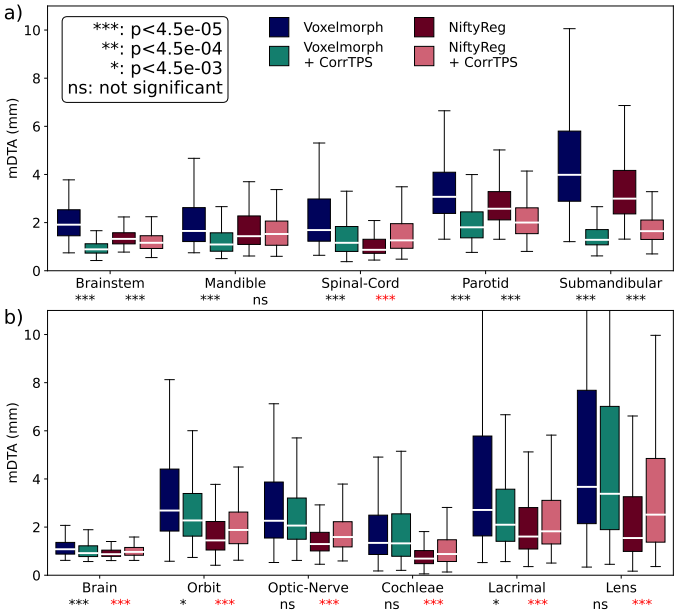

Figure 2: Mean distance-to-agreement results for each registration pipeline. The structures in a) were included in CorrTPS, i.e., their surface correspondence was used to set up the TPS, whereas the structures in b) were not. Significant deviations between methods with and without CorrTPS, as identified with a Wilcoxon signed-rank test, are indicated. Black asterisks show an improvement using CorrTPS, whereas the red show performance reductions.

Little improvement was observed when using our method for the structures not included in CorrTPS, which were predominantly in the superior region of the head. This is likely due to the TPS deformation in this region comprising of an interpolation between the envelope and bony anatomy and the controlling structures which were mainly further inferior in the head and neck region. This shows a sensitivity of the proposed method to the spatial distribution of controlling structures. For registrations with the iterative algorithm, the use of the proposed method degraded the performance for all structures not included in CorrTPS.

While we included some of the structures in this study and excluded others from CorrTPS, the proposed method is applicable to any of the OAR structures segmented for this study, i.e., the complete set of structures could also be included in CorrTPS, thereby fitting a wider distribution of control points within the head and neck anatomy. The implementation of TPS used is fast, estimating a deformation within a second for $\sim 14,000$ control points.

We deployed our proposed initialisation method with an intensity-based traditional NRR algorithm and a DL-based method. In future it would be useful to compare the performance of our hybrid-inspired registration framework against a hybrid registration methods such as ANACONDA [3] to further assess the efficacy of the proposed method.

In this study we focused solely on performing inter-patient registration, despite the task of intra-patient registration being more common within the radiotherapy treatment pathway. Inter-patient registration is important for tasks such as outcome modelling and can be challenging due to the increased variability in anatomy between subjects. We hypothesize that our initialisation method would be particularly effective in intra-patient cases such as in the re-irradiation setting, where large and complex anatomical changes are common, e.g. resulting from surgical interventions, which hinder the accuracy of currently available image registration algorithms [2, 14].

The segmentations used in this study were manually performed. Future introduction of auto-segmentation could mitigate the impact of inter- and intra-observer variation and improve correspondence reliability. Additionally, the use of auto-segmentations with the proposed framework would facilitate the implementation of a fully automated anatomically-informed registration pipeline.

5 Conclusion

The proposed method to initialise an image pair prior to NRR using anatomical correspondence shows particular promise to enhance the registration performance of DL-based registration methods to more closely match that of a traditional iterative NRR algorithm, whilst maintaining a substantial speed advantage. With further development and validation, the proposed approach could additionally raise the performance of traditional iterative NRR algorithms.

Abstract Predicting potential deformations of patients undergoing radiotherapy can improve treatment planning for both adaptive and conventional radiotherapy.
Denoising diffusion probabilistic models (DDPMs) were developed to generate fraction-specific likely anatomical changes. Three distinct DDPM models were developed. The image model was trained to directly generate likely future CBCTs. The DVF model was trained to generate deformable vector fields (DVFs) that deform a reference CBCT. The hybrid model also generates DVFs with the advantage that it does not rely on an external deformable image registration algorithm. Visual inspection showed that the generated images exhibit random daily anatomical changes and systematic weight loss over fractions. Moreover, for the image and hybrid models, the distributions of the generated volume and position changes of the body, esophagus, and parotids followed a similar distribution to the real CBCTs. Using the generated images for robust optimization of simplified treatment plans showed increased target coverage for equal integral dose compared to treatment plans optimized with only set-up robustness.
In conclusion, we developed and evaluated three DDPMs that generate likely anatomical changes in head and neck radiotherapy patients. The results show that the models generate distributions similar to the real anatomical changes on a population level and have the potential to be used for robust anatomical optimization.

1 Introduction

Medical imaging plays a crucial role in monitoring patients before, during, and post-treatment. However, imaging is time-intensive for the medical staff and patients and often uses ionizing radiation, increasing the risk of radiation-induced cancers [1]. Image-guided radiotherapy is particularly imaging-intensive [1], exposing patients to daily volumetric imaging for positioning or treatment adaptation. Therefore, the ability to predict or generate plausible time-series of images without actual acquisition presents a valuable advancement.
Predictive modeling of anatomical changes can be helpful in retrospectively completing datasets missing some images. Using these to simulate daily dose delivery can aid in comparing treatment modalities [2]. Prospectively, such models can be used for adaptive radiotherapy with a plan library [3]. Alternatively, prospective image generation can contribute to robust anatomical optimization [4], where alternative delivery scenarios are incorporated into the optimization to ensure target coverage even when the patient deforms.
Several anatomical deformation models have been proposed in the literature [2, 5], mostly using principal component analysis (PCA) on the deformable vector fields (DVF) generated with deformable image registration (DIR) over a population of patients. However, these models depend on the DIR quality, the choice of reference anatomy and are mostly not patient-specific [2, 5].
Recently, deep-learning-based image synthesis has achieved state-of-the-art performance for various applications [6]. One recent work used deep learning to predict anatomical changes in radiotherapy [7]. As in PCA, it uses a lower dimensional distribution of anatomical changes, which is sampled to generate new deformations. Contrary to PCA, it uses neural networks to learn this distribution and to decode a low-dimensional sample, yielding better results. In natural image synthesis, however, a new type of model has gained much traction: denoising diffusion probabilistic models (DDPMs) [6, 8]. These models learn to predict likely images based on some conditional information. Additionally, such models are inherently probabilistic and can predict many different images based on the same prompt.
In this work, we aim to predict likely interfractional anatomical changes using DDPM models for patients with head and neck cancer. Based on a single, patient-specific reference CBCT and the treatment dose, the models aim to predict several fraction-specific likely anatomical deformations.

2 Materials and Methods

2.1 Data

Our dataset contained 14 patients with head and neck cancer. Each patient had one planning CT with manually annotated clinical target volume (CTV) and organs at risk (OARs), as well as the planned dose distribution and daily cone beam CTs (CBCT) ($\sim$ 30). All daily CBCTs had Raystation ANACONDA contour propagated structures. For 5 patients the structures were reviewed and corrected by an experienced radiation oncologist. These patients were used for validation, and the other 9 for training.

2.2 Denoising Diffusion Probabilistic Model

DDPMs are a category of generative models designed to approximate a given data distribution by inverting a gradual,

*These authors contributed equally to this work

multi-step noise addition process [8]. DDPMs are trained using a *forward process*, in which Gaussian noise is incrementally added to a known image x_0, until the image is transformed into pure Gaussian noise $x_T \sim N(\mathbf{0},\mathrm{I})$. This is followed by the *reverse process*, where a neural network (NN) is trained to predict the parameters of a normal distribution, $p_\theta(\mu(x_t,t),\Sigma(x_t,t))$ that gradually denoises such noisy images back to the initial image x_0. After training, new images can be generated by starting the *reverse process* with pure Gaussian noise. This process can be conditioned on specific information, e.g. a text prompt, to generate samples belonging to a subgroup of the training data [8].
Our DDPM implementation extended the *improved DDPM* [8] from 2D to 3D images. Two approaches were explored to calculate $\mu_\theta(x_t,t)$. In the first approach, the U-Net aims to directly predict the initial image x_0 from the noisy input x_t, and $\mu_\theta(x_t,t)$ is calculated with:

$$\mu_\theta(x_t,t) = \frac{\sqrt{\alpha_t}(1-\overline{\alpha}_{t-1})}{1-\overline{\alpha}_t}x_t + \frac{\sqrt{\overline{\alpha}_{t-1}}\beta_t}{1-\overline{\alpha}_t}x_{0,\theta}(x_t,t) \quad (1)$$

where $\overline{\alpha}_t$ and β_t are predefined parameters of the diffusion process. In the second approach, the network instead predicts the noise ε_θ at step t, and calculates $\mu_\theta(x_t,t)$ as [8]:

$$\mu_\theta(x_t,t) = \frac{1}{\sqrt{\alpha_t}}(x_t - \frac{\beta_t}{\sqrt{1-\overline{\alpha}_t}}\varepsilon_\theta(x_t,t)). \quad (2)$$

To generate patient- and fraction-specific images, the first fraction CBCT_1 and the treatment dose were concatenated to the noisy x_t as conditional information before input in the 3D U-Net (Fig. 1). Since the anatomical changes in our dataset were captured on the daily CBCTs, we trained the models to generate CBCTs based on the CBCT_1, instead of the planning CT. The diffusion step t and the fraction number j were further included by adding their transformer sinusoidal position embedding into each residual block.
We developed three different DDPMs. The **Image Model** directly generates the j fraction specific CBCT_j. It was trained using the CBCT_j as x_0, and $\mu_\theta(x_t,t)$ was calculated using Eq. 2. The **DVF Model** generates DVFs that warp CBCT_1 to the new likely anatomy. It was trained using the DVF_j created with `plastimatch` as x_0, and $\mu_\theta(x_t,t)$ was calculated using Eq. 1. The **Hybrid Model** generates DVFs that warp CBCT_1 to the new likely anatomy. It was trained using the CBCT_j as x_0 but the network generates a $\mathrm{DVF}_{j,t}$ that warps the CBCT_1 to x_0 during training. $\mu_\theta(x_t,t)$ was calculated using Eq. 1 and the model included an additional bending energy penalty to smooth the generated DVF.

2.3 Evaluation

For each model, we generated 10 images for every 3rd fraction, yielding $\sim$ 100 CBCTs per patient. For the DVF and hybrid model, the generated DVF was also used to propagate the planning structures. For the image model, the generated

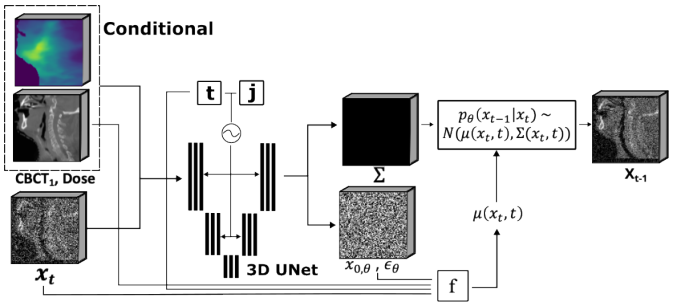

Figure 1: At each diffusion step t of the denoising process, the noisy image x_t is concatenated with the conditional CBCT_1 dose as input to a 3D U-Net. The sinusoidal position embedding [9] of the fraction number j and the step t are further included in each residual block. The network predicts Σ, and ε_θ or $x_{0,\theta}$ depending on the DDPM selected. For the image and DVF model, the function f calculates μ using x_t and t and Eq. 2 or 1. For the Hybrid model, f warps the CBCT_1 with the generated DVF to calculate x_0 and then calculates μ with Eq. 1. Finally, x_{t-1} is sampled from the normal probability density $p_\theta(\mu(x_t,t),\Sigma(x_t,t))$.

samples were registered to CBCT_1 with `plastimatch` and the resulting DVFs were used to propagate the contours.

The generated images were first qualitatively assessed with visual inspection to intuitively judge the image quality and interpret the main modes of deformation. The models were further quantitatively evaluated by comparing the changes in volume and geometrical center (GC) of the body, parotids and esophagus of the generated samples with the changes obtained from the real daily CBCTs. The real and generated distributions were compared with the Wasserstein distance (WD). A lower WD indicates more similar distributions.

As a proof of concept, we tested the suitability of the generated images for robust optimization in a simplified planning study. Since the model was trained with CBCT images, all images, both real and generated, were first converted to *corrected* CBCTs in Raystation [10]. Proton therapy plans with 2 anterior fields with $\pm$ 65° gantry angles were optimized on the *corrected* CBCT_1 to deliver 60 Gy to the CTV. No organs at risk (OARs) were considered, the only additional objective aimed at reducing the integral dose to the body. For all patients, the treatment plans were first optimized using worst-case robust optimization with 1, 3, and 5 mm set-up uncertainty (*standard robust plans*). Secondly, the treatment plans were optimized without set-up uncertainty but including 1, 2 or 3 generated images for every third fraction (*anatomical robust plans*). Lastly, we combined 1, 3 or 5 mm set-up uncertainty with 1 sample image for every third fraction (*combined robust plans*). The objective weights were kept the same for each patient and each different robustness setting. All plans were subsequently recalculated on the *corrected* daily CBCT_2 to CBCT_n. The daily doses were evaluated by calculating the integral dose and the percentage of the volume of the CTV that received 95% of the prescribed dose (V95).

3 Results

The images generated by all models looked realistic based on the author's visual inspection. Furthermore, for all three models, both systematic anatomical changes (e.g. weight loss) and random changes (e.g. changes in the oral cavity and shoulders positioning) were observed (Fig. 2). More detailed inspection indicated that changes in the initial fractions are mostly random anatomical changes, especially the positioning of the shoulders with respect to the neck. In later fractions, all models generated images showing weight loss.

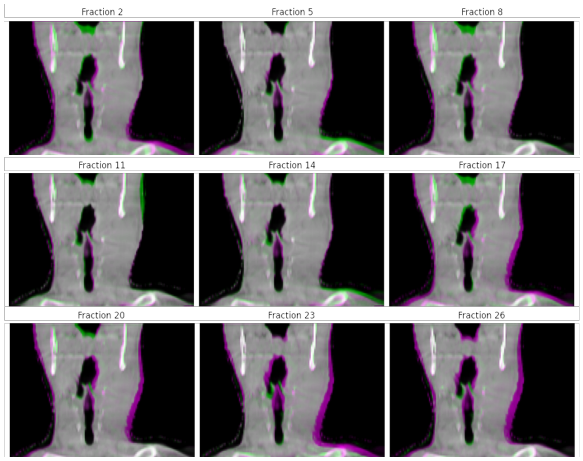

Figure 2: Coronal view of randomly generated image samples with the hybrid model for one patient of the validation dataset. The initial image is in pink, the sample is overlayed in green. The generated samples exhibit random changes and weight loss towards the later fractions.

The population-wise distribution of the changes in volume and GC position of the body generated by the image and hybrid models were overall similar to the real body changes (Fig. 3). However, for one specific patient, the real change of volume was much larger than predicted (red arrow of Fig. 3a). It was verified with the clinical personnel that the anatomical change in this patient was indeed highly exceptional and, therefore, outside the range of changes the model can predict. The distributions generated using the DVF model do not fit well to the real body changes.

The higher similarity in body change distributions for the image and hybrid models than for the DVF model is also confirmed quantitatively by a lower WD (Tab. 1). Furthermore, for the esophagus, the hybrid model performed better than the other models in both ΔVolume and ΔGC. For both parotids, the distribution of the metrics is best predicted with the image model. However, the differences in WD between the different models in the parotids are much less pronounced than for the body and esophagus.

For all the models, the anatomically robust plans improved the worse-case target coverage compared to the standard robust plans for the same integral dose (Fig. 4). Additionally, the hybrid model's anatomically robust plans also improve the average target coverage compared to the standard robust plan (Fig. 4 c). These enhancements were less prominent for the image model and negligible for the DVF model.

The anatomically robust plans are not substantially affected by including more samples per fraction in the optimization, which implies that their robustness cannot be increased this way. Robustness can, however, be increased by combining the samples with set-up uncertainty (combined robustness), which also shows improvements over only using set-up uncertainty for the image and hybrid models (Fig. 4).

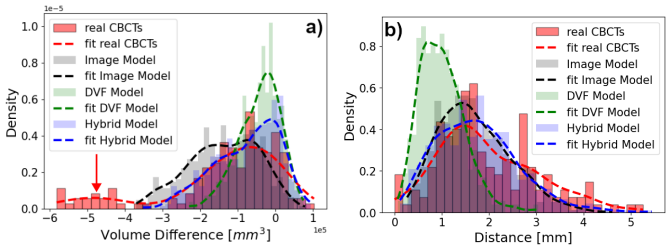

Figure 3: Population-wise distribution of changes of the body between $CBCT_1$ and $CBCT_j$ for the real changes (red) and those generated with the image (black), DVF (green) and hybrid (blue) models. a) Changes in the body volume. The red arrow points toward data points for a patient who had uncommon weight loss. b) Shift of the geometrical center (GC) of the body.

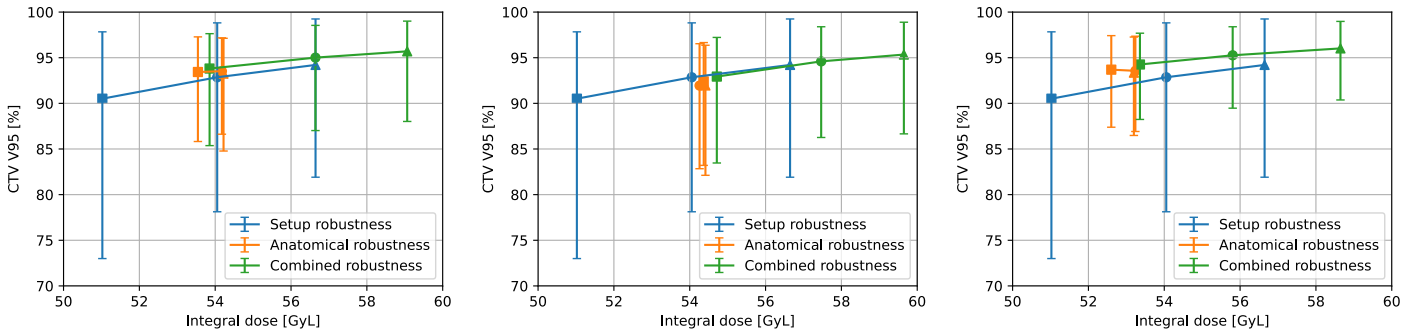
Table 1: WD between the real and predicted distributions of anatomical change over all 5 patients. ΔVolume is the change in volume of a structure between $CBCT_1$ and the subsequent images $CBCT_j$ (for the same patient). ΔGC is the distance between the geometrical center of a structure of the $CBCT_1$ and the same structure in a subsequent fraction $CBCT_j$. The best metric (lowest value) is indicated in bold.

Metric	Structure	Image Model	DVF model	Hybrid model
ΔVolume	Body	**0.21**	0.56	0.22
	Esophagus	0.40	0.44	**0.24**
	Right Parotid	**0.20**	0.28	0.23
	Left Parotid	**0.25**	0.28	0.33
ΔGC	Body	**0.24**	0.56	**0.24**
	Esophagus	0.46	0.33	**0.28**
	Right Parotid	**0.19**	0.26	0.27
	Left Parotid	**0.13**	0.17	0.19

4 Discussion

In this work, we developed three DDPMs that can generate likely anatomical changes in head and neck radiotherapy patients based only on the fraction number, one reference image, and the treatment dose distribution. Unlike other models reported in the literature [2, 7], our models generate fraction-specific changes.

The visual analysis of the generated images indicates that all models produce plausible images with systematic weight loss and random anatomical changes in the oral cavity and positioning of the patient. These results were in line with the observed changes in the real data. The image and hybrid models outperform the DVF model in terms of segmentation



(a) Image model **(b)** DVF model **(c)** Hybrid model

Figure 4: Target coverage (V95%) versus integral dose for all fractions of the evaluation patients. The markers indicate the mean, and the bounds the 5% and 95% quantiles from evaluating the dose in all the fractions. The set-up robustness includes 1 (▪),3 (●) and 5 (▲) mm set-up uncertainty (with increasing integral dose in that order). Anatomical robustness was optimized with 1 (▪), 2 (●) and 3 (▲) samples for every third fraction. Combined robustness used 1 sample for every third fraction and 1 (▪),3 (●) or 5 (▲) mm set-up uncertainty.

distribution analysis, especially regarding the volume of the body mask. Furthermore, they are more suitable for robust optimization.

Each model has unique advantages and limitations. The hybrid model does not rely on an external DIR algorithm. Furthermore, it generates a DVF that warps the reference image to the new likely anatomy, allowing to also propagate the reference structures. However, using a DVF constrains the deformations that can be predicted. Some changes, like nasal cavities or rectum fillings, cannot be modeled well with a DVF. This limitation does not impact our results because our CBCTs field of view doesn't include nasal cavities. However, it may become more crucial for images involving the abdomen or sinonasal area. The DVF model's advantage lies in its ability to be trained on a multimodal image dataset, as it only requires the DVFs that can be generated with multimodal DIR.

All models showcased the ability to enhance the robustness of the simplified treatment plan. The improvements seem to correlate with the models' proficiency in predicting body volume changes, as the hybrid and image models exhibited more enhancements compared to the DVF model. However, our simplified treatment plans did not consider OARs, and the objective functions and weights were not adjusted to obtain an optimal plan per robustness setting. For this reason, the conclusions highlighted before cannot be translated directly to clinical cases.

The models were trained to generate CBCT images based on the initial CBCT of the treatment. These images require correction before beeing suitable for dose calculation. However, since the initial CBCT is not accessible during planning at clinics, the models cannot be used for planning in clinical settings. Ideally, the models should produce daily CT images derived from the planning image, but such data was unavailable for this study. Nevertheless, the approach is analogous, and if the data becomes available, the models could be readily retrained. We anticipate that the outcomes will be comparable.

Choice of Colourmaps for Radiotherapy

Alex Davies[1], Mark Fleckney[1], and Marcel van Herk[2,]

[1]Department of Radiotherapy Physics, Kent Oncology Centre, Maidstone, United Kingdom
[2]Radiotherapy Related Research, University of Manchester, Manchester, United Kingdom

Abstract Colourmaps are used in medical imaging to allow the simultaneous display of multiple datasets. A large observer study was conducted to investigate whether choice of colourmap should be a consideration in radiotherapy. A simulated low-contrast phantom was displayed in eight colourmaps, and users asked which test regions were visible using each colourmap. Analysis of 214 observers showed that more test regions were visible in the rainbow, red, viridis, and orange colourmaps compared to grayscale, whilst fewer regions could be seen using blue, green, and purple. A k-means clustering analysis showed 6 distinct clusters of response type, indicating user-specific benefits to different colourmaps for this detection-type task.

1 Introduction

Over the past forty years, advances in medical imaging, understanding of oncology, and therapy techniques have led to significant improvements in cancer outcomes. Frequently, multiple patient datasets are utilised to aid with target and organ at risk delineation prior to radiotherapy planning. A number of studies have investigated the use of alternative colourmaps when viewing patient datasets to aid in diagnosis[1,2] and surgical planning[3]. In radiotherapy, colourmaps are used in image fusion and image guidance.

Within the data science community, there is an increasing awareness of the importance of choosing an appropriate colourmap to avoid misinterpretation of data. Crameri et al.[4] describe that the non-linearity of the eye can lead to visual errors >7% when observers review data presented in the "jet/rainbow" colourmaps. Additionally, such colourmaps are often poorly interpreted by viewers with Colour Vision Deficiencies (CVD). Crameri et al.[4] suggest that perceptually linear colourmaps should be used, where incremental changes in data values are displayed with incremental changes in colourmap lightness.

Despite an increase in the use of AI, auto-contouring, and auto-matching algorithms in radiotherapy in recent years, review of image segmentation and registration by human observers remains essential[5]. A literature review into choice of colourmaps found a small number of articles investigating this issue within diagnostic imaging, but did not highlight any previously published works describing the optimal of colourmaps for use within radiotherapy. This research aims to use a large observer study to investigate whether there is a "best" colourmap to review images for radiotherapy purposes, and examine whether the best colour choice is observer-specific.

2 Materials and Methods

To allow a large number of observers to contribute to the investigation, and enable control of the images viewed by participants in the study, a web survey with simulated images was designed. A low-contrast phantom designed to mimic the commercially available CATPhan™ was created in Python (v3.10.9) using the Numpy module (v1.23.5). The pixel values for eight low-contrast test regions, labelled A-H, were selected at random from a pre-defined list of values close to the phantom background. The Cv2 module (v4.8.0) was used to add both structural noise using a Gaussian filter, and image noise using a Gaussian noise array, with the noise distribution selected to visually match real CT scans. Matplotlib (v3.7.0) was used to display and export the phantom image in the PNG format in six single colour colourmaps: blue; green; orange; purple; red; grayscale, and two multi-colour colourmaps: rainbow and viridis (Figure 1).

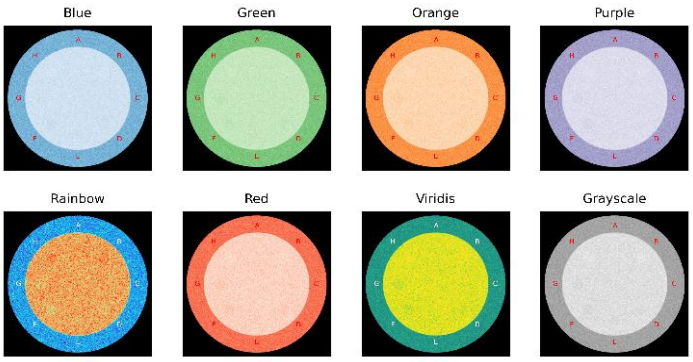

Figure 1: The simulated phantom displayed in the eight colourmaps

The script to generate simulated phantom images was run three times to create three sets of eight images in the chosen colourmaps with varying test region pixel values.

To investigate whether viewing the simulated phantom images in colour offered an improvement in the number of visible test regions, a Qualtrics™ survey was created. This displayed each of the 24 images one at a time to participants, asking them to record which of test regions A-H were visible for each image. The images were displayed in a preset random order for all sets and all respondents. At the end of the questionnaire, participants were invited to answer some additional questions that asked for their current role, and whether they worked with "*medical images*". Finally, respondents were asked "*…to the best of your knowledge do you have any colour vision deficiencies (also known as colour blindness)?*".

The Qualtrics™ survey was shared within the authors' local departments, and posted on the UK Medical Physics mailbase. No restrictions or recommendations to

respondents' backgrounds, the equipment they used to complete the survey, or environmental conditions were made to encourage as many responses as possible.

3 Results

Colourmap perceptional linearity was verified using the Colorspacious module (v1.1.2) by converting the full-colourmap RGB values into the International Commission on Illumination's (CIE) CAM02-UCS colour appearance model, and assessing the lightness component, J. Colourmaps with constantly increasing lightness are thought to have better perceptual linearity for observers[4]. The calculated J values for a series of test images displaying the full range of available colours for each colourmap were compared, and the dynamic range of the grayscale colourmap was reduced by creating a new "partial grayscale" colourmap to match the range of lightness of all colourmaps, as shown in Figure 2.

During creation of the web survey, lightness component (J) values of the simulated phantom test regions were reviewed prior to adding Gaussian noise, and the Matplotlib image rendering settings were adjusted by editing the range of pixel values that the colourmap was applied to. This method ensured that the test regions were of comparable lightness for each colourmap, and that the only variable between the images was the displayed colour.

The Qualtrics™ survey was fully completed by 214 respondents, with a range of backgrounds and experience in medical images.

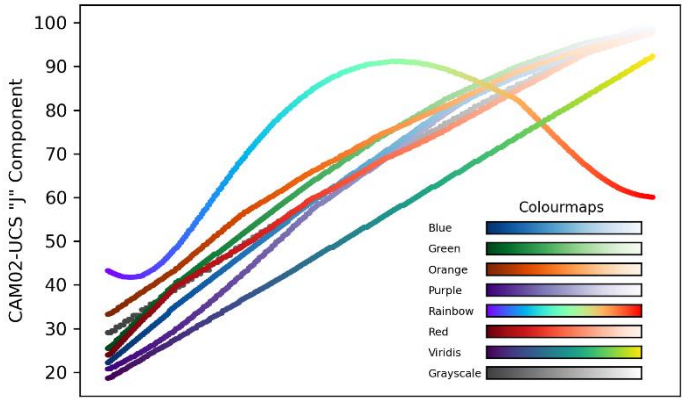

Figure 2: Colourmap lightness "J" across the full-range of each colourmap. Obviously the 'rainbow' colourmap is not perceptually linear, but the other colourmaps are approximately linear. The lightness values for the phantom test regions were found to be 86.6 < J < 92.6, where all colourmaps (excluding rainbow) are approximately linear.

The majority of survey participants were Medical Physicists (64.0%), of which 74.5% were Radiotherapy Physicists, 18% were Diagnostic Imaging Physicists, and 5% were Nuclear Medicine Physicists. Those describing themselves as fitting within the "*Other*" category (15%) included Radiotherapy Engineers, Nurses, Clinical Technologists, and PhD students (Figure 3). The majority of those surveyed (67%) said that they worked with medical images.

When asked if they had a colour vision deficiency, 6% replied "*Yes*", and 86% replied "*No*".

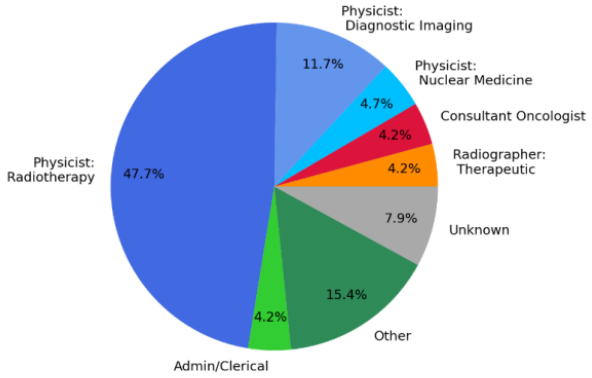

Figure 3: Pie chart showing survey participant roles

To account for differences in viewing conditions, display equipment, and end users' abilities, all analysis was performed relative to participants' own responses rather than comparing across different users. Within each set of eight images, respondents' answers for each colourmap were compared to their responses for grayscale. This showed whether a specific test region was visible when viewed in the colourmap but not in grayscale (scored as a positive improvement), or alternatively visible in grayscale but not the colourmap (scored as a negative improvement). Averaging across all respondents and all colourmaps, the most additional test regions could be seen in the rainbow colourmap, followed by red, viridis, orange, green, purple, and blue (Figure 4).

To generalise the results, and investigate whether colour improvement was more significant for brighter or darker hues, the Contrast to Noise Ratio (CNR) was calculated as the difference in mean values between a given test region and background region, divided by the background standard deviation. When results were plotted to show relative benefit for each colourmap ordered by CNR, it was noted that some colourmaps appeared to offer equal advantage and disadvantage in test region visibility dependent on end user (Figure 4). This suggested subgroups within the cohort where different colourmaps were more or less helpful in visualising the test regions.

The scikit-learn (v1.2.1) k-means clustering algorithm was used to group the respondents into 6 clusters of similar response types, where each cluster contained between 30 – 50 participants. Comparison between the clusters showed a number of features and general trends, summarised below in Table 1.

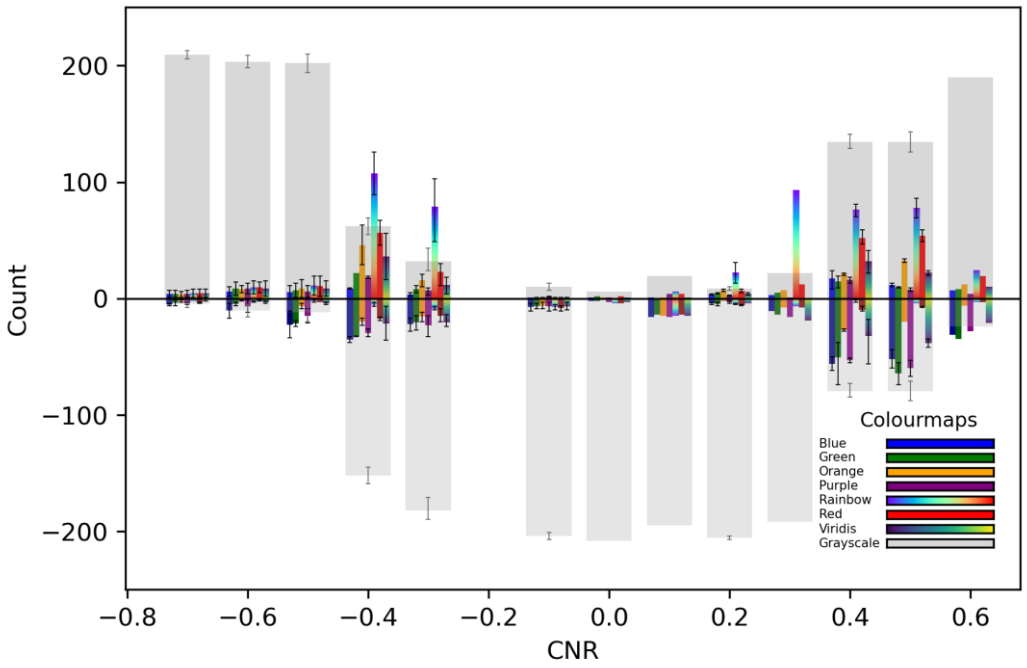

Figure 4: Improvement with colour at varying CNR. Grayscale bars show total number of visible (positive count) and non-visible (negative count) test regions in grayscale images. Positive colour bars show test regions detected by users in the displayed colour but not grayscale. Negative colour bars show colourmap specific regions not seen in colour, but detectable in grayscale. Where multiple CNR values were displayed across the entire survey, counts have been averaged, and the error bars show the range in values.

4 Discussion

This research investigated the potential benefit to using colour in radiotherapy image interpretation through a large observer study. To account for relative differences in viewing conditions, equipment, and observers all analysis was performed relative to the grayscale phantom images.

Whilst the rainbow colourmap was found to be most helpful, followed by red and orange; the blue, green, and purple colourmaps were generally not beneficial. The use of contrast to noise ratios allows these results to be applied to other colour research projects. The cluster analysis performed on the dataset shows that there were differences between participants and potentially trends to responses within user roles.

Previous studies of the benefits of using colourmaps have used small numbers of observers (Whitehead et al.[2] – a single Neuroradiologist, Saba et al.[1] – four radiologists), and reviewed clinical diagnostic images. These studies allowed participants to adjust image window and level on a patient-by-patient basis. A potential limiting factor to this previous clinically-focused research is that the results are a convolution of the inherent patient-specific image complexity and allowed windowing adjustments. In contrast, this research included a far greater number of observers and did not allow changes to windowing. Use of an artificial phantom image ensured that CNR was controlled and reproducible across repeated image sets.

There are however, a number of limitations to this work. The Qualtrics™ survey asked users if the labeled test regions were visible, leading them to only examine a specific area of the image, simplifying the task.

Cluster	Key Feature	Key Participants
0	Most significant learning/experience benefit	
1	Variable benefit in colourmaps across CNR.	30% of non-medical image users[1]. 31% of respondents with CVD[2].
2	Most significant benefit to rainbow. Colour benefit generally at negative CNR	30% of Radiotherapy Physicists[3]. 33% of Consultant Oncologists[4].
3	Consistent benefit to Rainbow & Red colourmaps	56% of Admin/Clerical respondents[5].
4	Cluster with least benefit to colourmaps	44% of Diagnostic Imaging Physicists[6].
5	Only Orange, Rainbow, Red, Viridis colourmaps beneficial	

Table 1: Summary of respondent clustering

Test regions were also reproducibly sized and positioned throughout the experiment. The results therefore do not show true detectability, although these shortcomings were necessary to allow for relative comparison between different images. Variability in test region size and position between images and colourmaps would require the experiment to be repeated in controlled conditions, limiting the number of participants. Despite some limitations, the

[1] Non-medical images users in other clusters: 8-21%
[2] CVD respondents in other clusters: 8-23%
[3] Radiotherapy Physicists in other clusters: 9-19%
[4] Consultant Oncologists in other clusters: 11-22%
[5] Admin/Clerical respondents in other clusters: 0-11%
[6] Diagnostic Imaging Physicists in other clusters: 8-20%

survey images are comparable to real-world use of low contrast phantoms where the same phantom and test region configuration is used for repeated qualitative tests.

Across all respondents, more additional test regions were visible in rainbow than any other colourmap, despite this colourmap lacking perceptual linearity as shown clearly in Figure 2. On review, this improvement is thought to be more due to coincidence rather than an inherent benefit to the rainbow colourmap. Within the survey images, the hues change rapidly from aqua to red/orange at the approximate level of the background noise. This change allows observers to infer the presence of a test region from colour changes in the noise rather than by directly visualising the test region. The rainbow colourmap therefore offers potential benefits in object detection, providing the windowing is optimised to allow change in hues at the correct level. It unlikely this benefit could improve radiotherapy delineation as this task generally involves reviewing a larger range of Hounsfield Units. Viridis is a Matplotlib multi-colour colourmap, designed to be perceptually linear. Images displayed in viridis showed a similar although less pronounced benefit than rainbow. Further research could investigate rainbow and viridis to determine whether colourmap perceptual linearity is a requirement for delineation tasks.

In general, the warmer colourmaps; red and orange, offered more benefit to the respondents, whereas fewer test regions were visible in the cooler colourmaps; blue, green, and purple. With the relative analysis approach adopted within this study, it is not possible to determine whether this trend is due to a human visual processing tendency, lighting conditions in office environments, computer monitors, or even web browser dependent. Repeating the experiment in controlled conditions would be needed to deconvolve these factors. It is hoped however, that most participants completed the survey using the equipment and environment of their routine clinical work, and that the results are therefore representative of the real-world benefits of alternative colourmaps.

Review of the clustering results showed that participants could be grouped into response type. Studies involving human subjects will always show a combination of physiological and psychological factors. This is visible in cluster 0, where the blue, green, and purple colourmaps were beneficial for these participants, but only for the first set of images. This is believed to be a learning/experience artefact, with review of further images these respondents became more confident of their interpretation of grayscale images leading to a reduced benefit to the alternative colourmaps. The majority of participants opted into sharing information about their role and whether they looked at medical images. This allowed for some generalisations about clusters and their members to be made. Cluster 4 consistently showed the least benefit to the alternative colourmaps, and contained the largest proportion of Diagnostic Imaging Physicists. This could indicate that these users felt most confident with grayscale due to their day-to-day role, or were in an environment or using equipment that had been optimised for grayscale images. Similarly, cluster 3, containing the largest proportion of Admin/Clerical participants, and self-reported non-medical Images users, showed a consistent benefit to alternative colourmaps across CNRs. This supports Saba et al.'s[1] finding that less experienced reviewers benefitted more from colourmaps than users with more clinical experience. A number of survey participants reported a CVD. These respondents were split across all clusters, although the majority was found in cluster 1. Although this could be indicative of a trend, the relatively small number of survey participants with a CVD and range of possible types of CVD suggest this might be more coincidence than correlation.

At the end of the survey, participants were asked whether they could recall which colourmaps they found easiest and hardest to interpret. A significant number of users found this question difficult to answer, suggesting that if optimal colourmaps are individual-specific, it is not possible to determine which colourmap is preferred without a feedback process.

5 Conclusion

Use of alternative colourmaps can improve test object detectability across a range of CNRs. Cluster analysis shows different trends within respondents suggesting that the most beneficial colourmap may be specific to an individual, although in general, users perform better with warmer rather than cooler colourmaps. Further research is required to investigate whether these findings are also applicable to target delineation and image fusion.

Abstract

Polygenic risk scores (PRS) can consider the cumulative impact of multiple SNPs on radiosensitivity. Epistasis is also likely to affect the toxicity risk, and it is essential to include SNP-SNP interactions in PRS.

Voxel-based analysis (VBA) [1] examines dose distributions for insights into radiobiological heterogeneity across tissues to enhance understanding of the dose-response relationships.

We propose a method to couple PRS and VBA with application to modelling late urinary toxicity after prostate cancer radiotherapy.

We included 778 patients prostate cancer patients receiving radical radiotherapy enrolled and followed up in the REQUITE and RADPrecise studies and considered three late toxicity endpoints: urinary frequency, heamaturia and rectal bleeding.

We incorporated the PRSi within VBA via proportional adjustment of the single voxel doses. On the resulting PRSi-modulated DSMs, we performed Cox VBA and identified the bladder/rectum subregions to be spared within personalised radiotherapy optimisation.

1 Introduction

Polygenic risk scores (PRS) can consider the cumulative impact of multiple SNPs on radiosensitivity. Epistasis is also likely to affect the toxicity risk, and it is essential to include SNP-SNP interactions in PRS.

Voxel-based analysis (VBA) considers full, 3-dimensional dose distributions, offering biological intuitions on the possible heterogeneity of the radiobiology across tissues. There is a need to include single-patient dose modifying factors into VBA to account for the inter-patient variability. Green et al. [1] proposed multivariable modelling at a voxel level; they produced maps of hazard ratios (HRs) for doses and patient-specific risk factors. This method is methodologically and statistically straightforward, yet the variation of HRs at a voxel level has poor biological justification.

We propose a novel approach to include patient-specific factors in VBA, allowing HRs at a patient level. As a first application, we analyse bladder and rectum dose-surface maps (DSMs) incorporating a polygenic risk score with interections (PRSi) [2,3].

2 Materials and Methods

We included prostate cancer patients enrolled in the prospective REQUITE international study. REQUITE recruited in 8 countries in Europe and the US (April 2014-

March 2017). Here, we considered the sub-cohort of patients receiving radical radiotherapy (RT).
Patients were treated according to local regimens, but centres used standardised data collection. Blood samples were collected for DNA extraction and genotyping.
We considered grade≥2 urinary frequency (Grade 0 or Grade 1 before RT), grade≥1 haematuria (Grade 0 before RT) and grade≥2 late rectal bleeding as separated endpoints.

A pool of 43 SNPs associated with late RT toxicity from the literature was tested, and a deep sparse autoencoder method identified the SNPs affecting the toxicity risk at 2-year follow-up [2]. A new method for accounting for SNP-SNP interactions (PRSi) was developed; the PRSi shows which SNPs and alleles are included, whether they increase or decrease the risk of toxicity and their combined effect sizes [3].

The PRSi for frequency, haematuria and rectal bleeding included 13 validated SNPs [2,3].

We generated DSMs using a dedicated Python tool. For the bladder, we cut DSMs anteriorly, aligned maps at the most caudal slice, and normalised their lateral extent to the population's maximum bladder diameter. In the cranial-caudal direction, we fixed the most caudal 1.5 cm (~corresponding to the bladder neck) and normalised the remaining surface to the median bladder height. For the rectum, we cut DSMs posteriorly, aligned maps at the most caudal slice, and normalised their lateral extent to the population's maximum rectum diameter. In the cranial-caudal direction, we fixed the most caudal 3 cm (~anal canal) and normalised the remaining surface to the median rectum height.

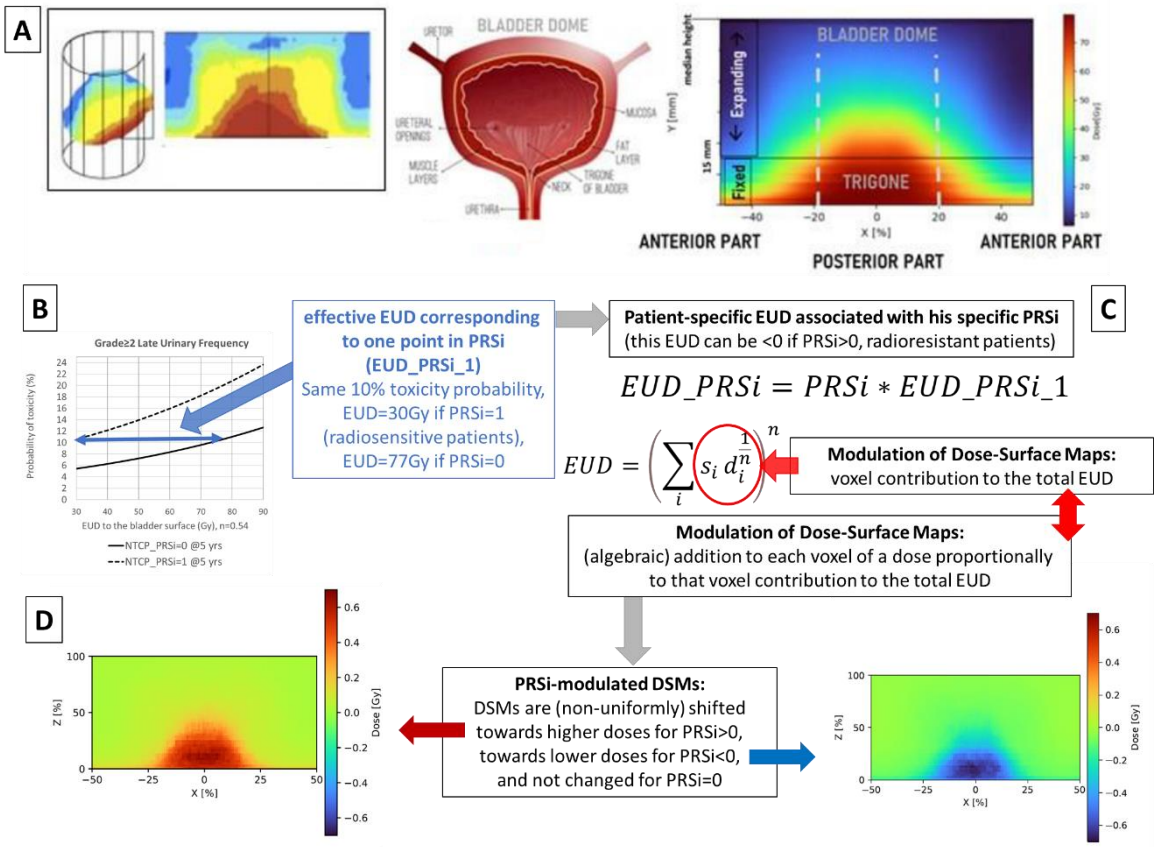

Figure 1: Steps of the approach to generate Dose Surface Map (DSMs) modulated by the Polygenic Risk Score (PRSi). A) Computation, alignment and normalisation of DSMs. B) Determination of the effective Equivalent Uniform Dose (EUD) corresponding to one point increase in PRSi through Cox-NTCP regression. C) Computation of the patient-specific EUD associated with his PRSi and the single voxel's contribution. D) Modulation of DSMs using the distributed single patient EUD_PRSi.

To establish the contribution of the PRSi, we used multivariable Cox-Normal Tissue Complication Probability (NTCP) [4] including dosimetry and PRSi. The Cox-NTCP models based on Equivalent Uniform Doses (EUDs) corrected for fractionation (alpha/beta=3Gy, gamma=0.7Gy/day, fixed) and derived from bladder and rectum dose-surface-histograms. The volume parameter n was 0.5 for the bladder (fitted) and 0.10 for the rectum (from QUANTEC).

We used the HRs for the PRSi to compute effective EUDs [5] corresponding to one point in PRSi (PRSi_EUD_1, Figure 1) for the different considered endpoints. The patient-specific EUD associated with the specific PRSi (PRSi_EUD) is the patient-specific PRSi times the PRSi_EUD_1 (i.e., for each patient PRSi_EUD=PRSi*PRSi_EUD_1). This quantity is established at a patient level.

For each patient, we included his PRSi_EUD in the DSM, adding to each voxel a dose proportionally to that voxel's contribution to the total EUD (i.e., the contribution is associated with the volume effect parameter n and the dose value, Figure 1).

We obtained PRSi-modulated DSMs: DSMs were (non-uniformly) shifted towards higher doses for PRSi>0, towards lower doses for PRSi<0, not changed for PRSi=0 (Figure 1).
We performed Cox-VBA on the obtained PRSi-modulated DSMs and considered correction for multiple testing for clusters using the permutation test coupled with Benjamin-Hockenberg (BH) correction.

3 Results

674 patients had long-term follow-up, DSMs and PRSi for the urinary endpoints, 778 for the rectal bleeding endpoint. The median follow-up was 24 months (75th percentile 60 months). 75% of patients had conventional fractionation (60-81 Gy), 25% received hypofractionation.

Toxicity crude rates were 4.8% for grade≥2 frequency, 7.5% for grade≥1 haematuria and 6.9% for grade≥2 rectal bleeding.
The PRSi associates with toxicity: mean PRSi 0.61/-0.40 in patients with/without toxicity, p<0.0001 (t-test) for frequency, 0.38/-0.02, p=0.02 for haematuria and 0.18/0.08, p=0.03 for rectal bleeding. The effective EUDs corresponding to one point in PRSi were 47 Gy for urinary frequency, 25 Gy for haematuria, and 69.3 Gy for rectal bleeding.

For grade≥2 frequency, the PRSi-modulated VBA (after BH correction) identifies a caudal-posterior region (also including the trigone) with a lateral extension covering 30% of the bladder wall and a cranio-caudal extension of 54%. HRs for the dose in this region are ~1.01-1.12 (per 1Gy), and the p-values range between 10E-8 and 0.05 (Figure 2). We found no specific area (after BH correction) without the inclusion of the modulation from the PRSi, and we had an increase in the slope of the dose-response relationship, with HRs up to 0.06 higher (per 1Gy, PRSi-modulated vs no modulation).
For grade≥1 haematuria, PRSi-modulated VBA detects a large region covering the whole extension of the bladder wall, except for two small areas located centrally in the cranio-caudal direction, one in the anterior part and the other in the posterior position. HRs for the dose are ~1.01-1.07 (per 1Gy) and p=0.0002-0.05. The extension of the region exhibiting statistically significant differences increased by 11% compared to VBA without PRSi-modulation, and HRs increased up to 0.03 (per 1Gy).

For grade≥2 late rectal bleeding, the PRSi-modulated VBA detects a region in the posterior rectal wall covering the central third of the rectum in the cranio-caudal direction. HRs for the dose are ~1.02-1.06 (per 1Gy) and p=0.0002-0.05. (Figure 3)

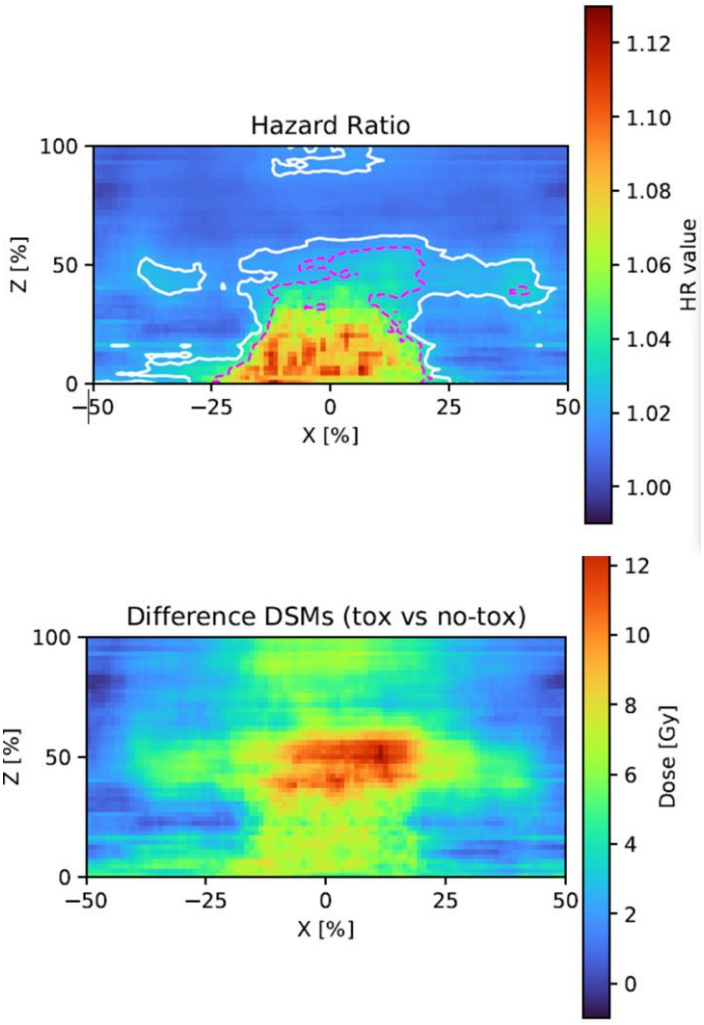

Figure 2: Results of the genetically-adjusted Voxel-Based Analysis for grade 2+ late urinary frequency: map for Hazard Ratios (left) and map of differences (right) in the genetically adjusted doses. Solid white lines depict the iso-p value level 0.05, dashed magenta lines the iso-p value level 0.05 after the correction for the false discovery rate (Benjamin-Hockenberg).

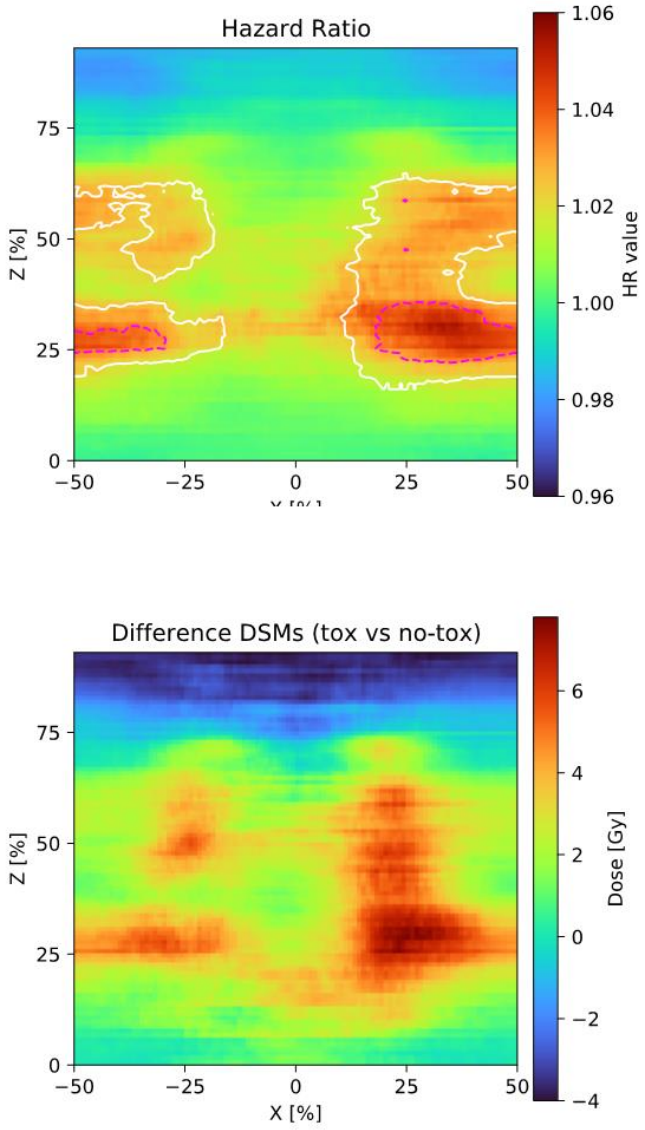

Figure 3: Results of the genetically-adjusted Voxel-Based Analysis for grade 2+ late rectal bleedingy: map for Hazard Ratios (left) and map of differences (right) in the genetically adjusted doses. Solid white lines depict the iso-p value level 0.05, dashed magenta lines the iso-p value level 0.05 after the correction for the false discovery rate (Benjamin-Hockenberg).

4 Discussion

We have here proposed a new method to include the single-patient genetic risk at a patient level in VBA and showed the benefit through an application on a large cohort of prostate cancer patients with long-term follow-up.

The method creates PRSi-modulated dose maps and can be naturally translated and extended into the inclusion of modulation from other patient-specific risk factors, even considering multiple features together.

In the present analysis, we identified specific bladder and rectal subregions associated with late urinary frequency, haematuria, and rectal bleeding.
The modulation by the PRSi increases the heterogeneity of dose distributions in the patient population, escalating the doses for radiosensitive patients and de-escalating the doses for radioresistant patients. The enhanced heterogeneity rises the areas classified as significantly different and re-gains steepness for the dose-response curve at a voxel level

.5 Conclusion

These results suggest the value of clarifying patient-specific risk factors to synergistically clarify dose-response relationships and the identification of heterogeneity in the radiobiology across tissues.

Prediction of survival outcomes and relevant tumor immune infiltrates using radiomic network analysis

Jung Hun Oh, Aditya Apte, Harini Veeraraghavan, Amita Shukla-Dave, and Joseph O. Deasy

Department of Medical Physics, Memorial Sloan Kettering Cancer Center, New York, USA

Abstract We propose to utilize a network-based method to analyze radiogenomic (radiomic/genomic) data. This approach enables the construction of sparse radiomic networks using the graphical LASSO (Least Absolute Shrinkage and Selection Operator) algorithm based on partial correlations among radiomic features. We developed and applied an optimal transport-based *k*-means algorithm to the resulting radiomic networks to identify clusters. The differences in survival rates and immune cell types between the resulting clusters were then assessed. In this study, we analyzed computed tomography (CT) radiomic features and RNA-Seq data used to quantify CIBERSORT scores in head and neck cancer and lung cancer patients taken from the TCIA and TCGA databases. Our proposed method identified sub-groups with the significant differences in survival outcomes and immune cell types. The promising results suggest that the geometry-based radiomic network approach could help identify patients at high risk of poor prognosis.

1 Introduction

Radiogenomics investigates the relationships between quantitative features extracted from medical images and genomic phenotypes to characterize tumor heterogeneity and understand the underlying biological correlates associated with treatment response [1]. Most radiogenomic studies have focused on developing supervised machine learning approaches to identify a set of important features and build predictive models for clinical outcomes [2, 3]. The main disadvantage of supervised machine learning is the need of parameter fitting which may cause an overfitting problem and therefore hamper validation of the predictive models previously developed [4]. Furthermore, most machine learning methods lack the capability to visualize and interpret the correlations among various features.

To address these issues, we propose a novel unsupervised method to analyze radiogenomic data [5]. First, sparse radiomic networks are constructed employing graphical LASSO based on partial correlations among radiomic features, removing likely spurious or false positive connections and visually representing the dependency among radiomic features as a form of graph [6]. Subsequently, an unbalanced optimal transport-based *k*-means method is employed to cluster samples on the resulting networks. Lastly, we assess the differences in survival outcomes and tumor immune infiltrates between the resulting clusters. In this study, we will show the usefulness of our proposed approach in radiogenomic analysis applied to CT radiomic features and CIBERSORT scores in head and neck cancer and lung cancer [7].

2 Materials and Methods

Data: We analyzed radiomic features derived from pre-treatment CT scans and CIBERSORT scores computed on RNA-Seq gene expression profiles for two cancer types: head and neck squamous cell carcinoma (HNSCC) and non-small cell lung cancer (NSCLC). From primary tumors manually contoured on CT scans, IBSI compliant 397 radiomic features, consisting of first-order statistics, shape-based features, and higher order texture features, were extracted using our in-house computational environment for radiotherapy research (CERR) radiomics toolbox [8].

For HNSCC, CT DICOM data for 77 patients were downloaded from The Cancer Imaging Atlas (TCIA) [9, 10]. For the matched 77 cases, associated RNA-Seq gene expression profiles were downloaded from The Cancer Genome Atlas (TCGA) and 22 immune cell types quantified by the CIBERSORT deconvolution method were estimated by utilizing the R immunedeconv library [11].

For NSCLC**,** CT DICOM data for 117 patients were downloaded from the TCIA. RNA-Seq data for the matched 117 cases were downloaded from the Gene Expression Omnibus (GEO) database (GSE103584) and CIBERSORT scores were estimated for immune cell abundance analysis [12].

Methods: Prior to network analysis, radiomic features highly correlated with tumor volume were removed with a threshold of Spearman correlation coefficient of 0.8. For a network representation of radiomic features, a Gaussian graphical model was then employed, which optimized the fit of the regularized partial correlation network constructed using graphical LASSO [13, 14], by minimizing the extended Bayesian information criterion (EBIC). A network-based *k*-means algorithm we have developed was adopted to cluster samples on the resulting sub-networks. This method employs an unbalanced extension of optimal transport to minimize the sum of within-cluster Wasserstein distances between the data points and their respective cluster centroid [5, 15].

For the identified clusters, Kaplan-Meier survival analysis was then conducted with log-rank test. Further, the differential assessment of CIBERSORT scores between the resulting clusters was carried out.

3 Results

In the HNSCC cohort, 55 patients (71.4%) were alive without progression at the time of assessment. The median progression free survival time was 2.0 years. The median

age of patients was 61 years. Twenty patients (26.0%) were female and 13 (16.9%) had HPV-positive tumors. The network analysis resulted in two sub-groups denoted as higher and lower-risk groups. Kaplan-Meier analysis on the largest sub-network, consisting of 65 radiomic features, showed a significant difference in progression free survival between the higher and lower-risk groups with log-rank p = 0.02 as shown in **Figure 1**. CIBERSORT analysis indicated that the lower-risk group had increased presence of neutrophils with p = 0.022.

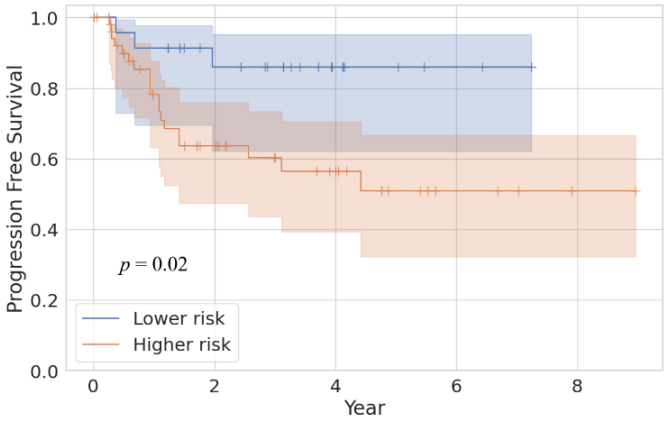

Figure 1: Kaplan-Meier survival analysis for 77 head and neck cancer patients.

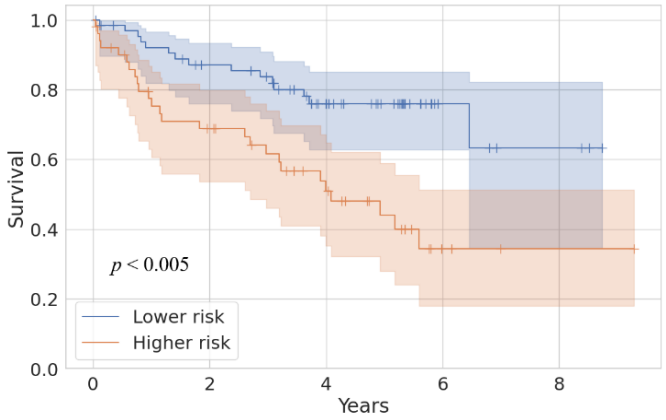

Figure 2: Kaplan-Meier survival analysis for 117 non-small cell lung cancer patients.

In the NSCLC cohort, 76 patients (65.0%) were alive at the time of assessment. The median survival time was 3.7 years. The median age of patients was 69 years and 29 patients (24.8%) were female. Kaplan-Meier analysis on the largest sub-network did not show a statistically significant difference between the higher and lower-risk groups identified using the optimal transport-based *k*-means method. However, Kaplan-Meier analysis on the second largest sub-network, consisting of 56 radiomic features, showed a statistically significant difference with $p < 0.005$ (**Figure 2**). Interestingly, 50 features were overlapping between the largest sub-network in HNSCC and the second largest sub-network in NSCLC. In CIBERSORT analysis, resting dendritic cells and activated mast cells indicated statistically significant differences between the higher and lower-risk groups with p = 0.0074 and 0.0025, respectively. For both the immune cell types, the higher-risk group had increased abundance.

4 Discussion

Radiogenomics explores the correlations between radiomic features and genomic profiles to address tumor heterogeneity and uncover the underlying biological correlates associated with clinical outcomes. However, little has been shown about the association between radiomic features and cancer immunity using a network analysis approach in an unsupervised manner.

The network form of radiomic features may be intractably complex due to their high correlations to each other. Regularized partial correlation network analysis can help remove spurious or false positive connections and make the network representation more interpretable, thereby facilitating the identification of plausible biological correlates in a downstream analysis. The optimal transport-based *k*-means method applied to the resulting sub-networks enabled the identification of patients at high risk of poor prognosis and showed that cancer immunity is likely to be relevant to the prognosis difference. The largest sub-network in HNSCC and the second largest sub-network in NSCLC resulted in the significant survival difference between the higher and lower-risk groups. Notably, 50 radiomic features between the two sub-networks were overlapping, suggesting that these are likely to be plausible biomarkers associated with survival outcomes. However, additional analysis is needed to validate the radiomic features and their associations with cancer immunity.

We plan to apply the network-based radiomic analysis approach to other imaging modalities and extend it to supervised modeling to build an individualized predictive model of clinical outcomes.

5 Conclusion

In this study, we showed the potential of using a network-based approach for radiomic analysis. The optimal transport-based *k*-means method applied to the resulting sub-networks enabled the identification of patients at high risk of poor prognosis with significantly different immune cell types. The approach is data-efficient because extensive parameter fitting is not required. This radiomic network analysis approach results in an embedding that can detect subtle differences or similarities between images, thus providing a data-efficient and robust tool to detect radiomic subtypes.

Abstract Radiomics has exploded in oncology applications to develop signatures capable of predicting cancer outcomes and survival. However, radiomic analysis suffers from inconsistent methodology, insufficient data availability, and a lack of open-source processing tools to handle common radiological image formats. In this work, we present the READII-2-ROCQ pipeline: an end-to-end pipeline using DICOM-RT objects, image pre-processing, radiomic feature extraction, and publishes an organized data structure on a publicly available repository (ORCESTRA). Further, new quality control methods to assess radiomic features through negative control image generation are included. As a proof-of-concept, we explored a large head and neck cancer dataset (RADCURE) and replicated three previously published radiomics models. Our results highlight the importance of determining if radiomic signatures are using underlying imaging data. The main contributions of this work are the pipeline, an analysis-ready radiomics dataset, and open-source code to generate negative controls, so all radiomic studies can be READII-2-ROCQ.

1 Introduction

With the purported future of oncological care being precision medicine, the hunt for predictive biomarkers has become a focal point. A potential source lies in radiological imaging, which has motivated the field of radiomics for the last decade [1–4]. Radiomics research, however, has been hampered by inconsistent methodology, despite efforts to establish standard features [5]. The release of the open-source PyRadiomics toolkit [6] was a significant and necessary step to standardize radiomics analysis, but the collation and distribution of publically available radiomics datasets remains poorly organized within the community. As a result, significant overhead remains when dealing with multiple training, testing, and validation datasets from both internal and external sources. Further, a recent study has raised the question of whether radiomic features with high predictive value are surrogates for tumour volume measurements [7]. There is a need for standard methodology for radiomic feature extraction, as well as large, publicly available radiomic datasets that have undergone rigorous processing to benchmark analyses.

In this study, we have developed Radiomic Extraction and Analysis for DICOM Images to Refine Objective Quality Control (READII-2-ROCQ): a reproducible, automated, open-source processing pipeline to generate analysis-ready radiomics data. We showcase the pipeline's capabilities by processing and analyzing the largest publicly available head and neck cancer (HNC) dataset, RADCURE [8], and compare three previously published radiomics models [1,7,9] using the resulting data. Data outputs have been made available via ORCESTRA (https://www.orcestra.ca), a web-app that hosts processed 'omics data.

2 Materials and Methods

The READII-2-ROCQ pipeline leverages three main tools: Med-ImageTools [10], Radiomic Extraction and Analysis for DICOM Images (READII), and ORCESTRA [11]. While the former two are imaging-specific, we have modified ORCESTRA to work with clinical radiological data.

The proposed pipeline was tested using the RADCURE [12] dataset, accessed through the Cancer Imaging Archive (TCIA). It consists of 3,346 HNC computed tomography (CT) image volumes, corresponding radiotherapy structure sets (RTSTRUCT) containing primary gross tumour volume (GTVp) contours, and clinical data.

The Med-ImageTools library was used to generate a database for each unique CT acquisition and RTSTRUCT, and record pertinent metadata, such as series identifiers and reference CT values, to be used in subsequent processing steps.

For each CT and RTSTRUCT, preprocessing, quality checking, and radiomic feature extraction was performed using the READII package. First, the summary file generated by Med-ImageTools was scanned to automatically determine the segmentation type present and then find the associated reference CT. This updated list of images was then passed to image loading and preprocessing.

The CT and RTSTRUCT were loaded in as SimpleITK image objects [13] using corresponding functions provided by Med-ImageTools. In loading, the GTVp segmentation was converted from a discrete point set to a 3D volume. Alignment of the GTVp was performed by setting the origin, direction, and spacing for the image based on the CT values. The contour label for voxels within the GTVp was automatically found by checking for non-zero values in the image.

For each GTVp, preprocessing, quality checking, and radiomic feature extraction was performed using PyRadiomics. For preprocessing, the functions utilized were: checkMask, which checks the alignment, dimension, and contour label; and cropToTumorMask, which crops both the CT and RTSTRUCT images to the boundaries of the GTVp to optimize the feature extraction. Feature extraction settings were passed in using a configuration YAML file as described in PyRadiomics documentation. Extraction settings from the RADCURE prognostic modeling challenge [8] were applied.

In order to test negative imaging controls including those proposed by Welch et al. [7], the READII package can generate three types of negative controls with three different mask options, for a total of nine settings. The negative control options are: shuffle, where voxel values are randomly permuted; random, where random voxel values are generated within the range of the original image; and random from distribution, where voxel values are randomly selected with replacement from the original image. The mask options are full image, target and non-target. To demonstrate the performance of the negative controls, we performed feature extraction as described above with the shuffle and random options applied to the full image mask. Examples of these negative control combinations are shown in Figure 1.

The standard for data organization on ORCESTRA [11] is the MultiAssayExperiment R object [14], designed to harmonize multiple experimental assays from an overlapping patient set. To leverage this for radiomics, each set of extracted features becomes an individual experiment with clinical data included as the primary metadata describing each patient.

To demonstrate the pipeline's utility, we replicated previously published survival analysis Cox proportional hazards models with the training and test cohorts from the RADCURE challenge subset [8]. Coefficients from the MW2018 [7] and Kwan [9] models were used to calculate prognostic index values for the test cohort. For comparison, we fit a Cox model to the RADCURE training cohort using the same radiomic signature and applied it to the test cohort. A univariate model for GTVp Mesh Volume was also tested. All models were compared using the concordance index (c-index).

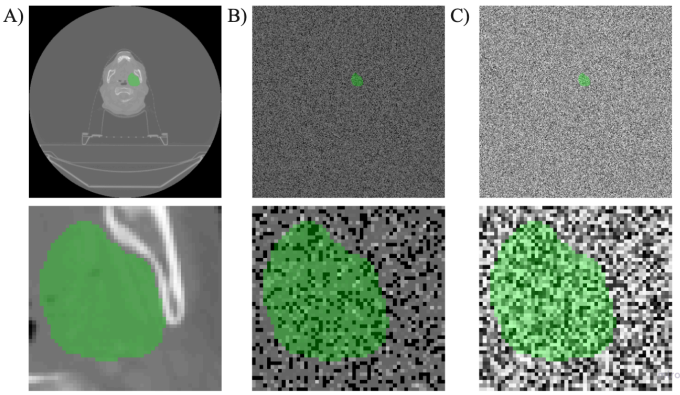

Figure 1. Original and cropped 2D axial slice extracted from example inputs to the radiomic feature extraction with the corresponding GTVp contour (green). (A) The original CT volume; (B) volume with shuffled voxel indices; (C) volume with randomly generated voxel values based on the range of original CT values.

To additionally explore the feature specific impacts of the negative controls on the PyRadiomics feature sets, cross-correlation plots were generated to display the correlation between feature extraction results for each PyRadiomics feature on both the original image and on each negative control image. The plots of correlation are grouped by PyRadiomics feature sets to show any feature group variations by feature class.

3 Results

We processed 2,994 patients with GTVp contours from varying primary tumour sites: 1076 patients with oropharynx, 713 with larynx, 319 with nasopharynx, 139 with hypopharynx, 81 with lip and oral cavity, 73 with paranasal, and 22 with esophagus. We extracted 1,317 radiomic features from the CT and negative controls for each GTVp.

The final data object containing all of these features, along with the clinical data and PyRadiomics configuration file, are available at https://www.orcestra.ca/radiomicset/10.5281/zenodo.8332910. The pipeline implementation for RADCURE is published at https://github.com/BHKLAB-DataProcessing/RADCURE_radiomics.

Results from our radiomics analysis are available in Table 1. The subset of 2,423 GTVps was split into training (n=1710) and test cohorts (n=713) based on the 'RADCURE-challenge' label in the clinical data. The Kwan model was tested with new oropharynx patients (n=366) not previously used in the Kwan paper. Model performance is similar whether the features were extracted from the CT or negative control samples, suggesting the radiomic signature is correlated with tumour volume, a known confounder of radiomics analysis, or at least invariant to the underlying imaging data. This is confirmed by the performance of the univariable volume model.

In Figure 2, we show the impact of a negative controls on different PyRadiomics features sorted by feature group by comparing the original image feature values to the shuffled or randomized image feature values. High Pearson correlations can be seen between the shape features of the original image and each of the feature groups in both the full image shuffled and randomized negative controls. In particular, features within the GLRLM, GLSZM, and GLDM groups. Correspondingly, feature groups with low correlations include first order and NGTDM, which reflects feature differences due to the underlying imaging data alterations.

	Image	c-Index (95% CI)	p.value
MW2018 [7]	Original	0.718 (0.668-0.770)	<0.001
	Shuffled	0.707 (0.657-0.757)	<0.001
	Random	0.699 (0.650-0.748)	<0.001
Kwan [9]	Original	0.273 (0.214-0.333)	<0.001
	Shuffled	0.708 (0.650-0.767)	<0.001
	Random	0.693 (0.633-0.752)	<0.001
Aerts RADCURE	Original	0.725 (0.675-0.776)	<0.001
	Shuffled	0.708 (0.659, 0.758)	<0.001
	Random	0.703 (0.653-0.751)	<0.001
Univariate Volume	Original	0.706 (0.656-0.756)	<0.001

Table 1: C-index and p-values from each of the replicated survival analysis models and a univariate volume model for comparison. 95% CI are shown for point-estimated c-index values. The replicate models all use the Aerts radiomic signature = Energy, Compactness 1, Gray Level Run Length Matrix Non-Uniformity, Wavelet HLH Gray Level Run Length Matrix Non-Uniformity.

When the 108 features shown in Figure 2 are filtered with a Pearson correlation threshold of 0.25, only 30 features pass in the shuffled image negative control and six pass for the randomized image.

4 Discussion

In this work, we present the READII-2-ROQC pipeline and demonstrate its use to explore negative radiomic controls with RADCURE by replicating three existing radiomics-based survival analysis models. In addition, we produced two of nine potential negative control images (Fig. 1) and performed correlative analysis to showcase how a common radiomic signature is impacted by negative controls.

Figure 2 highlights that there are a large number of high magnitude correlations between the original image feature values and the negative control image feature values indicating that some features may be largely invariant to the underlying imaging data.

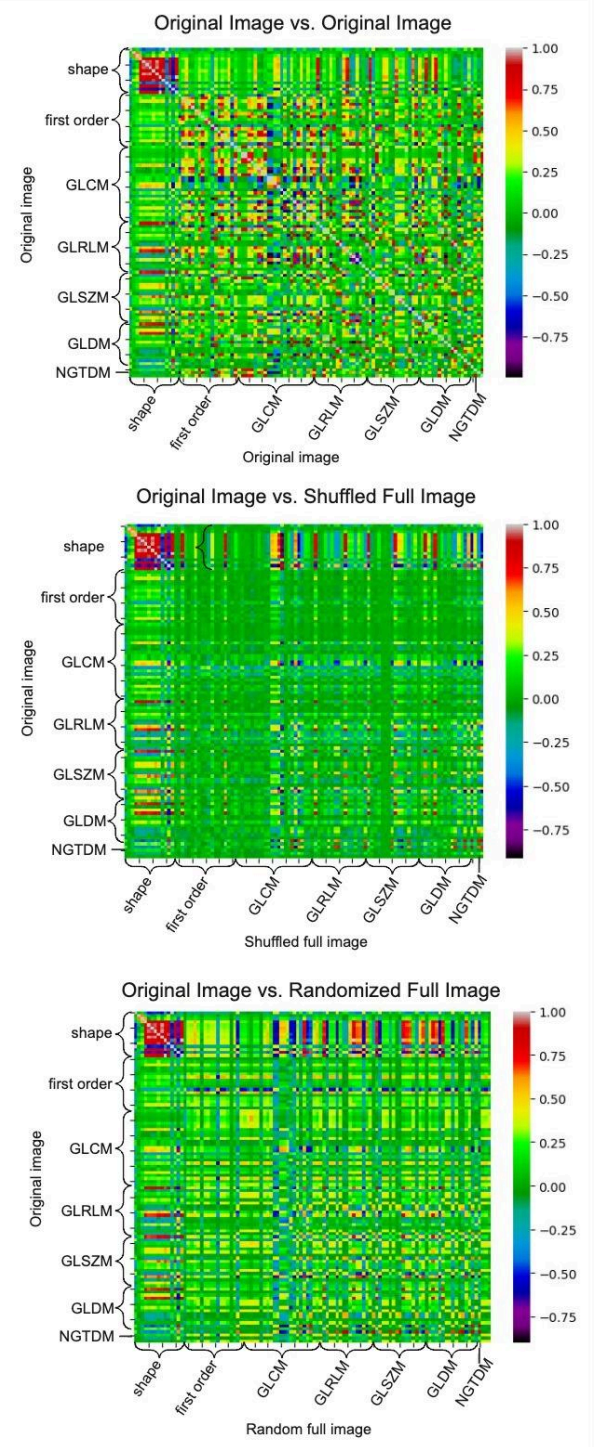

Figure 2. Cross-correlation heat map plots displaying the Pearson correlation between PyRadiomics features with no image filtering, sorted by feature groups, in the original image and the negative control images for the entire RADCURE dataset. The top heat map shows the cross-correlation of the features in the original image as a baseline reference.

Specifically, shape features, which are derived from the GTVp mask, are independent of the image information and highly correlated with the negative controls feature values. Therefore, if a radiomic signature is thought to be volume independent and is reflecting underlying image information beyond shape features, that model should perform poorly when given radiomic features extracted from negative controls generated by READII-2-ROQC.

In Table 1, we can see this is not the case for the radiomic signature we replicated. The MW2018 and Aerts RADCURE models both show comparable performance when radiomic features from original images and negative controls are used. Add in that the univariate volume model achieves similar results, and it becomes clear that this radiomic signature is not volume independent as expected.

As has been shown previously [7], radiomics features can be highly correlated with basic features such as GTV volume which limit the additional utility of radiomics models. To move forward, it is critical to implement standard methods to help identify features which are somewhat invariant relative to the underlying imaging characteristics to maximize the effectiveness of radiomics approaches.

Existing limitations of currently available analysis packages include a lack of support for raw DICOM files, the standard medical imaging format, as well as issues with implementing analysis pipelines in a consistent method. To address these issues, READII-2-ROQC provides end to end support for DICOM files via MedImageTools which then outputs the results of PyRadomics analysis with optional negative controls in an ORCESTRA object. As we have provided the final ORCESTRA objects for the RADCURE dataset, it allows anyone who has developed a radiomics model using PyRadiomics features to rapidly assess the extensibility of those models in our external dataset.

At present, the READII-2-ROQC pipeline has only been tested on CT DICOM images only but should be broadly applicable to any imaging dataset in DICOM format as the first step of the pipeline is based on Med-ImageTools has been tested on other DICOM data types (e.g. MR).

5 Conclusion

This standardized architecture framework and the publicly available processed RADCURE dataset can be used to benchmark new datasets or radiomics models semi-automatically. Future work will include organ at risk and nodal targets in the RADCURE dataset, evaluating more existing survival models with READII-2-ROCQ, and the production of ORCESTRA objects for other publicly available HNC datasets. We anticipate that this pipeline and the RADCURE objects generated could be a standard testing benchmark for future radiomics analyses and publications.

Abstract A radiomic model to predict radiation pneumonitis, an adverse effect of radiotherapy, has been developed and tested using data from 66 lung cancer patients that received radiotherapy treatment, 12 of whom developed grade 2 or above pneumonitis. Image features were extracted from radiotherapy planning CT images using a radiomic approach and by leveraging a deep learning based UNet model, that had been pre-trained to segment lung volumes, as a feature extractor. Radiation dose and clinical features were also included. The AdaBoost algorithm for gradient boosted decision trees was used to create a prediction model which was trained and tested using a leave-one-out cross validation approach. When using only the dose and clinical features, an AUC ROC of 0.63 was achieved which was improved to 0.836 when including all of the CT image features. This shows that CT images, which are not currently applied clinically for pneumonitis prediction, calculated by both radiomic and our UNet based feature extraction are a source of predictive power and can greatly improve predictions from standard dose and clinical information.

1 Introduction

During radiotherapy (RT) to treat cancer, damage to certain organs, caused by the unavoidable radiation dose to healthy tissue, can have significant health implications for a patient up to and including death. Radiation pneumonitis, an inflammation of the lung tissue, is one of these potential health implications which is common among patients receiving a lung dose during their treatment. Current standard clinical RT practice includes capturing a CT image to localise anatomy and calculate the attenuation maps necessary for RT planning but this planning CT image is currently not used beyond these purposes. We have applied methods for the extraction of features from the lung region of RT planning CT scans of patients treated for lung cancer using both radiomic approaches and the utilisation of a CNN pre-trained for lung segmentation. Our methods show a large improvement to pneumonitis prediction on our dataset when using both methods for CT feature extraction compared to using only radiation dose and clinical features. Additionally, combining our method for feature extraction from a pre-trained UNet model with a radiomic feature extraction produced a further improvement to the prediction model.

Related Work Currently in clinical settings, the dose to organs at risk during RT is limited by simple dose metrics that have been determined from studies such as the QUANTIC study [1] which established dose-volume effects in all regions of human anatomy. Prediction of radiation pneumonitis from pre-RT data has previously been shown to be possible in the literature with much of the focus being on dosimetric and dosiomic approaches. Dose volume histogram features, calculated from the lung volume, including the mean lung dose (MLD), V_5 ,V_{10} and V_{20} have been shown to act as a predictor for radiation pneumonitis [2, 3]. More recently, spatial features extracted from the RT dose distribution, have been included in predictive models through radiomic [4] and CNN based [5] approaches.

Beyond the dose based prediction models, there has been previous work on imaging modalities for pneumonitis prediction. Radiomic approaches have been used to determine if a patient developed pneumonitis [6]. Less commonly, radiomic approaches have been applied to the pre-RT CT images to predict radiation pneumonitis [7–10].

Previously, pre-trained CNNs have been applied as feature extractors in the medical imaging domain for a variety of applications such as overall survival prediction from CT scans [11] and tuberculosis detection from x-ray images[12]. These works rely on CNNs previously trained for image classification tasks as opposed to our approach of using a CNN previously trained for image segmentation.

Contribution In this work, we have developed a method for feature extraction from a pre-trained segmentation CNN and applied it to the task of radiation pneumonitis prediction. Additionally we have applied more traditional radiomic approaches for feature extraction and combined this with the CNN based approach. This has advanced the sparse previous work on radiation pneumonitis prediction from CT scans. Additionally, the use of our dataset validates previous pneumonitis prediction work.

2 Method

2.1 Dataset

The dataset used in this retrospective study consists of intensity-modulated radiotherapy (IMRT) data from patients with non-small cell lung cancer (NSCLC) that were treated at the Edinburgh Cancer Centre, Western General Hospital, Edinburgh, between 01/01/2009 and 01/10/2010. During data collection, the occurrence of pneumonitis in each patient was determined from that patient's medical records by

experienced clinicians. Any patients with unclear medical notes regarding pneumonitis were not included. This generated a dataset of 66 patients, 12 of whom developed grade 2 or above radiation pneumonitis after their RT treatment where grade 2 radiation pneumonitis is pneumonitis presenting symptoms where some form of clinical intervention has been performed as defined by CTCAE (v5.0) [13]. The RT data available included the patients' RT planning CT scans, the RT planning dose distribution maps and the anatomical segmentations produced during the RT planning. Examples of a planning CT and dose map segmented to the lung volume, defined during RT planning, are shown in figure 1. The CT scans all had voxel dimensions of 1.0x1.0x3.0mm and slices in the transverse plane had a resolution of 512x512. Also available were some of the patients' clinical parameters such as their age. Of the 66 patients in the study, IMRT was applied to; 52 patients on a Varian Clinac 600C/D, 3 patients on a Varian Clinac iX and 9 patients on a Varian Clinac 21EX. All radiotherapy plans were calculated using the Varian Pencil Beam Convolution algorithm (v8.1.2).

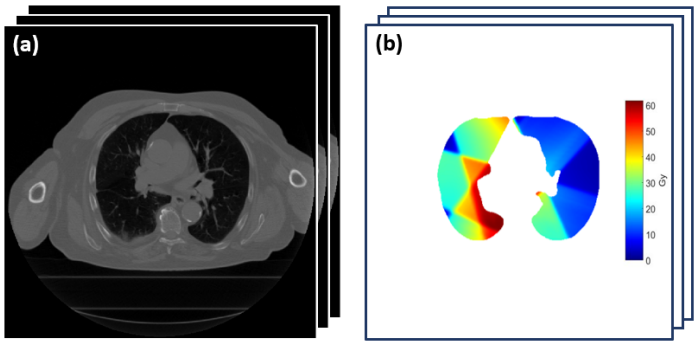

Figure 1: Examples of **(a)** a 3D planning CT image stack and **(b)** a 3D dose map of only the lung volume.

2.2 Radiomic CT Features

Prior to radiomic feature calculation, CT image preprocessing steps were applied and the volume of interest, which defined the voxels that radiomic features were calculated for, needs to be defined. The lung volume, segmented using the contours available from the RT planning process, was used as the initial volume of interest. This was then thresholded to only include voxels with Hounsfield unit (HU) values ranging from -1000 HU to -600 HU to specifically target the soft lung tissue by removing any vessels and the tumour volume. Before the radiomic features were calculated, the CT images were isotropically resampled to have voxel dimensions of 1.5x1.5x1.5mm. Quantisation was applied to the image to reduce the number of grey levels. A quantisation bin size of 25 was used which produced 16 grey levels in the defined volume of interest. Radiomic features were computed from the defined volume of interest within the CT images in Python using the PyRadiomics package (v3.1.0) [14]. All features from the following classes were included; first-order, GLCM, GLRLM, GLSZM, NGTDM and GLDM, further information on these metrics can be found in the PyRadiomics documentation. These features conform to the Image Biomarker Standardisation Initiative (IBSI) recommendations [15] and, where possible, the radiomic features were calculated in 3D. This process produced a feature table comprising 94 distinct radiomic features, each calculated from the CT lung region for every patient.

2.3 UNet CT Features

In addition to the PyRadiomics CT features, a publicly available pre-trained UNet segmentation model was leveraged as a feature extractor. The reason that a segmentation model was chosen as opposed to a classification model is that the features learned by a segmentation model trained on a varied medical dataset are likely to be more generalisable than features from a classification model trained for a specific medical task. Additionally, there are more publicly available medical image segmentation models available than classification models so there is a larger pool of previous work.
The UNet model, used as our feature extractor, was originally trained for segmenting lungs in 2D CT images, this network is referred to as "UNet (R231)" [16] and is available from *https://github.com/JoHof/lungmask*. Details of the models architecture and training can be found in the original paper [16]. Prior to extracting features from the CT image, no additional training of the model was performed. This approach of using a pre-trained model with no additional training was chosen due to the small size of our dataset, specifically the low number of positive cases, and the lack of public data available with radiation pneumonitis outcomes meaning training our own supervised classification CNN model was not possible. The activations from the convolutional layer before the final convolutional layer making the pixel-wise classifications were used as the features. This layer has a size of 256x256x64 meaning 64 features were extracted for every pixel. These pixel-wise features were converted to global features for the classification by averaging them over the spatial dimensions using a global average pooling layer added to the model so that for each slice of the 3D CT image, 64 features were calculated. The location of this global average pooling layer in the model architecture and the convolutional layer used for feature extraction is shown in figure 2. This feature averaging was done for every transverse slice of the 3D CT image containing any lung area. The features were then averaged in the z-direction producing 64 features from the 3D CT image for every patient.

2.4 Dose and Clinical Features

Dose and clinical features have previously been shown to be predictive features for radiation pneumonitis on their own as well as features that improve the performance of models based on additional features from separate sources, when included in a predictive model [1, 3, 4, 6–9]. For these

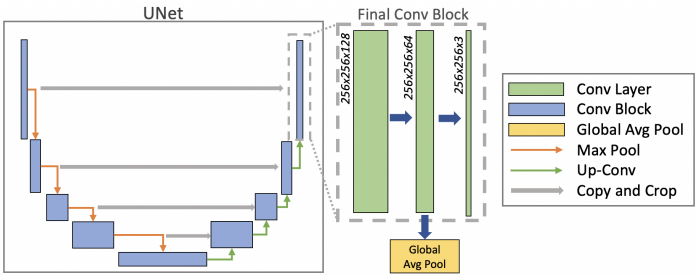

Figure 2: Location of the global average pooling layer, used to extract features from the second last convolutional layer of the UNet model. Further details of this UNet model can be found in the paper [16].

reasons, as well as fact that dose and clinical features will always be available pre-RT, they should always be included in radiation toxicity prediction studies as has been done here.

Clinical Features: Clinical features were extracted from the patients' medical information based on data that was deemed to be relevant to the classification task. The clinical features that were included were chosen based on their availability for all of the patients in the dataset as well the ability to present these features numerically. In total, 7 clinical features were used, these are; age, smoking status, COPD status, chemotherapy status, T-stage, N-stage and the primary tumour volume.

Dose Features: Dose volume histogram features were calculated from the RT planning dose map, segmented to only include the whole lung volume, excluding the tumour region defined by the gross tumour volume (GTV). The lung volume and GTV were available from the RT planning data. The dose volume histogram features calculated are; the mean lung dose (MLD), V_5, V_{10} and V_{20}. Here V_x is the percentage of the total lung volume receiving a dose above x Grays. The planned RT maximum dose and RT dose fractions were also included as features which were not calculated from the dose volume histogram but are parameters of the dose planning process giving a total of 6 dose features.

2.5 AdaBoost Classification

For the classification, boosted decision trees were used with the AdaBoost algorithm [17] in MATLAB (R2023a). Training and testing were applied using a leave-one-out cross validation (LOOCV) scheme. This involves training the model on all the data except one sample and then testing the model on that left-out sample to get a prediction. The trained model is then discarded and a different patient is selected as the one to be left out from training and the process repeats until testing has been completed on all of the patients. This is the same as k-fold cross validation where k equals the dataset size, so in this case it is 66-fold cross validation. During training, an increased misclassification cost was applied to the underrepresented class based on its proportional size in the dataset. Due to the small size of the dataset, it was not possible to perform parameter tuning of the model as this would require another hold-out set to validate the parameter tuning. The parameters used during training of the AdaBoost model are displayed in table 1.

The training and testing scheme was repeated on six different sets of features so that the contributions of the different features to the overall model performance could be observed. The six feature sets were; **1.** dose and clinical features, **2.** PyRadiomic features only, **3.** UNet features only, **4.** dose, clinical and PyRadiomic features, **5.** dose, clinical and UNet features, **6.** dose, clinical, PyRadiomic and UNet features.

Training Parameter	Value
Learning rate	1.00
Learning cycles	200
Maximal number of decision splits	10
Minimum observations per leaf	1
Minimum observations per branch node	2

Table 1: The training parameters used for the AdaBoost prediction models.

3 Results

The metrics produced during the LOOCV testing scheme are the accuracy, sensitivity, specificity and the AUC ROC with the AUC ROC being the most descriptive of the overall predictive power of the models and most commonly applied metric in the recent radiation pneumonitis prediction literature [4, 5, 7–10]. The results for the six different feature sets are shown in table 2.

Features	Acc	Sens	Spec	AUC
Dose, Clin	63.6	41.7	68.5	0.633
PyRad	72.7	66.7	74.1	0.760
UNet	66.7	58.3	68.5	0.717
Dose, Clin, PyRad	77.3	75.0	77.7	0.790
Dose, Clin, UNet	78.8	75.0	79.6	0.814
Dose, Clin, PyRad, UNet	**80.3**	**75.0**	**81.5**	**0.836**

Table 2: Results from the LOOCV over the whole dataset. The accuracy (Acc), sensitivity (Sens), specificity (Spec) are presented as percentages.

4 Discussion

The model using only the dose and clinical features achieved an AUC of 0.633. The models using only PyRadiomics and only UNet based CT features produced an AUC of 0.760 and 0.717 respectively, both an improvement on the model using only dose and clinical features. While it performed lower than the radiomic method, our technique of extracting features from the UNet model has achieved comparable results. Combining the CT features with the dose and clinical features achieved an AUC of 0.790 and 0.814 when using the PyRadiomics and UNet features respectively. This shows a

large improvement in the AUC of over 0.15 for both CT feature sources when combined with dose and clinical features compared to only using dose and clinical features. There is a large clinical relevance here as this shows that CT image features could improve the treatment planning process by allowing for the production of more personalised treatment plans. Finally, the model achieving the highest AUC used the dose, clinical, PyRadiomic and UNet features. This shows that combining CNN-based features with radiomic features can further improve radiation pneumonitis prediction model performance.

While these results are promising, it is important to highlight where future improvements can be made. The main limitation of this work is the dataset size. With a larger dataset, a validation dataset could be used for model hyperparameter tuning. Additionally, expanding this work to data from multiple centres would improve the robustness of the methods. Establishing a large benchmark dataset for radiotherapy outcome prediction would also allow for different methods to be directly compared. Model explainability is also an important future direction, when applying the UNet model for feature extraction, we have disregarded the spatial information but is possible to keep this information and isolate features to specific anatomical regions which would increase explainability.

5 Conclusion

In current clinical practice, only the dose and clinical features are considered during radiotherapy planning. This work has shown that CT images, which are collected during standard RT planning, can be a source of valuable information when predicting patient outcomes, specifically the occurrence of radiation pneumonitis. Additionally, we have shown that a pre-trained CNN for lung segmentation can be used as a feature extractor for this application and can improve the performance of radiomic based prediction models when the two CT image feature sources are combined.

Abstract This paper compares harmonization methods in the context of positron emission tomography / computed tomography (PET/CT) radiomics analysis for predicting recurrence-free survival (RFS) in head and neck cancer (HNC) patients, using the multicentre HECKTOR 2022 challenge dataset. We present harmonization techniques—HarMSTD and HarCenter—as alternatives to the popular COMBAT method. Notably, these methods do not require model retraining with new data, enhancing their practical utility. Our results demonstrate the benefit of harmonization in this context, with improved concordance index (C-index) values. The paper also compares our findings with existing literature, positioning our methods favorably in the context of the HECKTOR 2022 challenge. These novel approaches offer promising advancements in oncological predictive modeling, emphasizing the need for tailored harmonization techniques in multicenter clinical studies.

1 Introduction

The prediction of recurrence-free survival (RFS) in head and neck cancer (HNC) patients treated with radiotherapy (RT) can contribute to personalized management. In this context, large-scale datasets, like the one from the Hecktor 2022 challenge [1], play a crucial role. They serve not only as a resource for the development and validation of predictive models but also enable the identification of patients at heightened risk of local recurrence in the primary tumor volume[2]. The HECKTOR challenge presented two main tasks: automating detection and segmentation of lesions (tumors and lymph nodes) in Flurodeoxyglucose (FDG) positron tomography emission (PET)/computed tomography (CT) scans, and predicting RFS using PET/CT images and clinical variables. During the 2022 challenge, the best teams achieved C-index values between 0.66 and 0.68 [3] [4], [5], [6]either by relying on radiomics feature engineering modeling or deep learning approaches. We focus in the present work on the RFS prediction task, in which we aim to evaluate data harmonization methods, including novel and established techniques (e.g. ComBat). Significantly, none of the existing work has addressed the variability that resides between different acuiqisition centers. This is a key contribution of this paper.

2 Materials and Methods

2.1 Dataset

The HECKTOR 2022 challenge provided a dataset of FDG-PET/CT images of 828 HNC patients from 9 acquisition centers. The dataset is already splitted into 489 patients for training/validation and 339 for testing. Evaluation of RFS prediction model was carried out using the concordance index (C-index).

2.2 Methods

2.2.1 Data Collection and Preprocessing

We exploited the available PET/CT images, along with corresponding mask images and clinical information. This included extracting patient identifiers from file names and merging image paths with clinical endpoints and patient information to form a unified dataset. Clinical data were cleansed of missing values, and categorical variables like gender were numerically encoded for subsequent analysis. Special attention was given to handling errors such as dimension mismatches and mask value inconsistencies, ensuring comprehensive and accurate feature extraction.

2.2.2 Feature Extraction

Radiomic features were extracted from the PET and CT images using the corresponding masks. We computed 112 IBSI (imaging biomarker standardization initiative)-compliant radiomic features (shape, intensity and textures) for each PET and CT scan, with the *RadiomicsFeatureExtractor* from the *pyradiomics* library, configured to correct for mask inconsistencies.

2.2.3 Harmonization Techniques

Given the multicenter nature of the dataset, we implemented and compared several harmonization techniques to mitigate batch effects and inter-scanner variations and compare with the combat method. For all harmonization methods under comparison, our first step was to determine a reference center.

We selected Center 5, which had the largest patient cohort (397 patients), as our reference. This choice was based on the premise that a larger dataset would provide a more robust and representative statistical distribution for normalization purposes.

Mean, STandardDeviation Variable Harmonization (HarMSTD) : The MSTD Harmonization process is designed to align the statistical characteristics of feature datasets derived from various centers. This harmonization is achieved by adjusting the target dataset to match the mean and standard deviation of the corresponding features in the reference dataset. The transformation of each feature x in the target dataset is governed by the following equation:

$$x_{\text{new}} = \frac{\sigma_{\text{ref}}}{\sigma_{\text{target}}} \times (x - \mu_{\text{target}}) + \mu_{\text{ref}} \quad (1)$$

where:

- μ_{ref} is the mean of the reference dataset's feature.
- μ_{target} is the mean of the target dataset's corresponding feature.
- σ_{ref} is the standard deviation of the reference dataset's feature.
- σ_{target} is the standard deviation of the target dataset's corresponding feature.

This formula ensures that each feature in the target dataset is scaled in such a way that its statistical properties align with those of the reference dataset, thereby enabling a consistent and comparable analysis across datasets from different centers.

ComBat Harmonization (HarComBat) : The ComBat Harmonization method is tailored to correct for batch effects in multi-center studies. This method uses an empirical Bayes framework to adjust data for known batch effects, ensuring comparability across different datasets. The ComBat model is formalized as follows:

$$Y_{ij} = \alpha + X_i\beta + \delta_{ij} + \gamma_{ij}\varepsilon_{ij} \quad (2)$$

where:

- Y_{ij} represents the observed value for the ith subject in the jth batch.
- γ_j denotes the multiplicative batch effect for the jth batch.
- X_i represents covariates for the ith subject.
- β is the coefficient for the covariates.
- δ_{ij} is the additive batch effect for the ith subject in the jth batch.
- ε_{ij} is the residual error term.

ComBat adjusts each feature in the dataset by estimating and correcting for these batch-specific effects while preserving the biological variability. This process involves standardizing the data within each batch, estimating batch effects, and then re-scaling the data to remove these effects.

Center-Based Harmonization (HarCenter) : In our approach, titled Harmonization Based on Center, we focused on addressing the multicenter nature of the dataset by identifying a reference center and applying iterative transformations. Our primary goal was to align the data distribution of each center with that of the reference center, within a specified standard deviation range. Data were grouped by CenterID, derived from the initial three digits of each patient's ID. We combined clinical data with radiomic features, ensuring numeric consistency across all variables. Non-numeric columns were excluded to maintain a focus on quantitative analysis. The resulting dataset comprised both training (x_train) and testing (x_test) subsets. StandardScaler was initially considered for normalization; however, we opted for a custom alignment strategy. For each feature, we calculated the mean and standard deviation of the reference center. We then normalized the data from other centers, aligning each feature iteratively. Features were adjusted to fall within the mean $\pm$ 2 standard deviations of the reference distribution. This iterative approach aimed to minimize distributional discrepancies across centers, thus reducing batch effects and enhancing the comparability of multicentric data. Upon aligning the data, we constructed the harmonized dataset, combining the aligned radiomic features with the original clinical data. The final datasets, included both clinical and harmonized radiomic features, segregated into training and testing cohorts with the indexes of patients for training and testing provided by the challenge.

2.2.4 Post Harmonization Processing

Following the harmonization of features extracted from PET and CT scans, Principal Component Analysis (PCA) was employed on the concatenated feature set to both train and subsequently transform the test set based on the PCA model. The dimensionality reduction via PCA was configured to retain components that account for 95% of the explained variance, a strategic choice aimed at reducing the feature space while preserving the majority of the informative variance. This reduction was imperative to streamline the subsequent survival analysis, ensuring the model's efficiency and effectiveness by focusing on the most relevant features derived from the imaging data.

2.2.5 Survival Analysis using DeepHitSingle

In our study, we employed the DeepHitSingle model from the *pycox* library for survival analysis. This deep learning-based

approach is tailored to handle time-to-event data, aligning with our objective of predicting patient outcomes. DeepHitSingle is distinguished by its capability to simultaneously address competing risks, offering a nuanced approach to survival analysis beyond traditional methodologies. Model fitting was conducted through Optuna-based hyperparameter optimization, an automatic optimization framework that facilitates the selection of optimal model parameters. Key hyperparameters adjusted included the learning rate (1e-5, 1e-2) and the dimensions of the hidden layers (2 or 3 layers) and hidden neurons (32,64,128) within the neural network. The selection of these parameters was guided by the goal of maximizing the C-index. To evaluate the robustness of our approach, 20 different splits were used for the survival analysis for each technique.

3 Results

The results, as shown in Tables 1 and 2, evaluate the impact of various data harmonization methods on the predictive accuracy of RFS using the c-index as a measure. These evaluations were performed on the test set of the HECKTOR 2022 challenge dataset. Table 3 compares existing works related to Task 2 of the HECKTOR 2022 challenge, situating our approach within the broader research context.

Harmonization Method	c-index Value on PET/CT
HarMSTD	0.794 ± 0.102
HarCenter	0.784 ± 0.134
HarCombat	0.773 ± 0.138
No Harmonization	0.764 ± 0.132

Table 1: C-index values over 20 runs without or with each harmonization methods, not including clinical variables.

Harmonization Method	c-index Value on PET/CT
HarMSTD	0.801 ± 0.113
HarCenter	0.767 ± 0.129
HarCombat	0.777 ± 0.105
No Harmonization	0.777 ± 0.122

Table 2: C-index values over 20 runs without or with each harmonization methods, including clinical variables.

These tables comprehensively display the c-index values for different harmonization methods, with and without clinical variables, over 20 runs. They also summarize the c-index scores of various research teams in the HECKTOR 2022 challenge, highlighting the competitive position of our approach.

Reference	Method Type	C-index

Table 3: Summary of HECKTOR 2022 challengers results.

4 Discussion

4.1 Analysis Without Clinical Variables

The comparative evaluation presented in Table 1 emphasizes the impact of harmonization methods on predictive accuracy using only PET/CT imaging as inouts, using the c-index as a measure. The baseline performance (without harmonization) was already higher than the best results of challengers during the HECKTOR 2022, with an average C-index of 0.764, associated with a relatively high variability across the 20 runs (standard deviation of 0.132). HarMSTD demonstrated the highest efficacy in harmonizing PET/CT imaging features, achieving a c-index of 0.794 ± 0.102. Note the variability was also smaller than without harmonization. HarCenter and HarCombat led to intermediate performance between no harmonization and HarMSTD, with C-index values of 0.784 and 0.773, but similar variability as without harmonization (standard deviations 0.134 and 0.138 respectively).

5 Analysis With Clinical Variables

Integrating clinical variables in addition to the PET/CT imaging features did not significantly modify the hierarchy between the compared methods, and with higher overall performance except for HarCenter, as shown in Table 2. HarMSTD still achieved the best result (0.801 ± 0.113). On the other hand, HarCenter actually decreased the performance compared to no harmonization (0.767 ± 129 vs. 0.777 ± 0.122), whereas HarCombat led to the same average but slighlty decreased variability (0.777 ± 0.105). These results suggest that clinical variables significantly contribute to predictive modeling, potentially offsetting the lack of harmonization to some extent. The findings underscore the importance of tailored harmonization approaches, especially when clinical variables are included, with HarMSTD exhibiting potential as a versatile and effective method.

5.1 Comparing to Literature

Reflecting on the harmonization-focused analysis, our pipeline demonstrates a notable improvement over literature benchmarks (referenced in Table 3), particularly with

harmonized PET/CT imaging. The best harmonized result of 0.809 (achieved with HarMSTD in the presence of clinical variables) illustrates the substantial benefits of harmonization. This performance, significantly above the challenge's top performers, highlights the efficacy of our approach, for instance the use of PCA for dimensionality reduction in combination with the DeepHitSingle model, as the baseline without harmonization was already higher than the best challenge result. The variability observed in our results emphasizes the inherent challenges in predictive modeling, further contextualizing the comparison with literature benchmarks by the constraints faced by challengers, including limited submission opportunities and time constraints, which precluded the reporting of variability across multiple runs. Furthermore, our reliance on pre-provided lesion masks for radiomic feature extraction afforded us an advantage over the challenge participants, who did not have access to these masks in their testing set. This necessitated either the generation of lesion masks or the adoption of alternative strategies, such as feature extraction from entire bounding boxes or the deployment of convolutional neural networks without segmentation. Our approach, thus, not only underscores the effectiveness of harmonization techniques in enhancing predictive accuracy but also illustrates the potential impact of methodological advantages in comparative analyses.

6 Conclusion

Our study demonstrates the efficacy of harmonization techniques, particularly HarMSTD, in improving predictive accuracy for radiomics extracted from PET/CT imaging, achieving a notable c-index up to 0.794 in analyses without clinical variables and 0.801 with them. These results highlight alternative solutions in scenarios where ComBat may not be suitable, and underline the potential of these methods in diverse contexts within oncological predictive modeling. Our future work will include investigating the robustness of the harmonization approaches when choosing a different reference center, as well as a comparison with deep learning based harmonization using image synthesis.

Can bootstrapping increase robustness of voxel-based-analysis?

Abstract: Bootstrapping is a well-established resampling method in statistics, allowing measures of accuracy to be assigned. Using bootstrapping in a voxel-based-analysis (VBA) workflow has potential to increase robustness for identifying anatomical regions where dose is significantly associated with outcome. In this work, we implement bootstrapped VBA, and assessed its impact across progressively smaller datasets.

1101 Non-Small-Cell Lung Cancer patients were available. Bootstrapping was implemented, performing 100 bootstraps of the full VBA analysis performing a t-test per voxel against survival at 12-months. Results demonstrate that bootstrapped VBA defines a smaller, more targeted region in the base of the heart. Dose extracted from the bootstrapped VBA region showed improved model performance in multivariable models compared to the standard VBA workflow. VBA showed utility in progressively smaller dataset sizes up to 250 entries. Datasets of 100 and 50 showed high uncertainty in defining significance. Bootstrapped VBA emerges as a valuable internal validation approach.

1 Introduction

Bootstrapping is a resampling method often applied to complex sampling designs and deemed to be an appropriate way to control and check the stability of the results [1]. Bootstrapping uses random sampling with replacement. This technique constructs new datasets by sampling the complete dataset randomly, allowing the same element to appear multiple times. This allows assigning a measure of accuracy to model building and provides confidence interval estimates of the parameters.

Bootstrapping is a well-established statistical technique but, as yet, its benefit in voxel-based-analysis (VBA) has not been fully explored. VBA is becoming an established spatial outcome modelling technique which incorporates the full, 3-dimensional, dose distribution within a dose-response modelling framework [2]. VBA is desirable as it (1) removes the need for prior assumptions on anatomy to consider; (2) removes the need to use summary statistics for radiotherapy dose, which often assume an organ to have a homogeneous dose-response. Instead, the full dose distribution is analysed on a voxel level, performing a statistical test per-voxel to identify anatomical regions with significant association between dose and outcome. VBA has been applied in numerous studies and results are now entering clinical practice [3,4].

In this work we investigate the potential of bootstrapping data for VBA. This work aims to show whether bootstrapping can be used as an internal validation approach to assess robustness of VBA and to explore the effect of dataset size.

2 Materials and Methods

1101 Non-Small-Cell Lung Cancer (NSCLC) patients were available from a previous data analysis [5], with institutional approval in place to analyse the data. First, bootstrapping with replacement was implemented in the data mining workflow. A binary endpoint of survival at 12-months was used with a t-test per voxel performed. To account for multiple comparisons, permutation testing was implemented: outcomes labels were permuted 100 times and the max t-statistic across the image calculated to summarise each permutation. From the distribution of the max t-statistics the 95th percentile threshold was selected as the significance value. This value is then used to threshold the real t-map to identify anatomy associated with the outcome. 100 bootstraps were performed, and for each, the full VBA workflow was performed, including permutation testing.

For each bootstrap, a t-map and threshold value is available. The significant region from each bootstrap was threshold as a binary mask and summed. This provided a map of the number of times a given voxel was included in the significant region. From this map, the 50th percentile was selected to define the anatomical region at the 95th percentile confidence interval.

Comparison with the standard workflow without bootstrapping was performed. First the location of the identified region was compared. Second, the dose to the standard and bootstrapped regions was extracted for all patients and evaluated in a multivariable Cox-proportional hazards model including known prognostic factors (sex, age, T-stage, N-Stage and performance status). We used the Akaike information coefficient (AIC) to compare model, where lower AIC indicates models with better discrimination power and a reduction of at least 2 points is considered significant [6].

Next, experiments were performed to establish if bootstrapped VBA has utility to improve performance with smaller datasets. New datasets with 500, 250, 100 and 50 entries were created by randomly sampling from the full dataset. Sampling was nested, i.e., the 100 entries were in the 250 entries which were in turn in the 500 entries dataset. Bootstrapped VBA was performed as described with the final region identification compared.

Finally, to further test the utility in small datasets a simple simulation workflow was implemented following the described workflow. A single voxel was simulated to represent a significant region of anatomy in real data. Simulations identified if there was a significant difference with outcome in the dummy data and tested for robustness across the bootstrapping, i.e., if each bootstrap identified or miss-labelled the significance. The simulation created progressively smaller datasets as described for the real data, with 1000, 500, 250, 100, 50 samples used.

To feed the simulation, data was generated from the identified region from the 1101 NSCLC patients and outcome survival at 12-months. This allowed testing with real data ranges. Simulations were run 100 times and summary statistics calculated to describe robustness of bootstrapped VBA.

3 Results

Figure 1 includes the results from the standard and bootstrapped VBA workflows, including the 95th percentile confidence intervals for the identified region using the bootstrapped data. The regions overlap, the standard workflow provides a region of 35.4cm^3 and the bootstrapped VBA a smaller region of 13.2cm^3. Across all bootstraps, the region volume showed a standard deviation of 30.1cm^3 suggesting reasonable agreement across all bootstraps. The 95th percentile confidence intervals show greater difference in the cranial-caudal direction, demonstrating the greatest uncertainty in the result is in this direction.

The survival models included in table 1 show results for both the standard and the bootstrapped VBA workflows. The variables show comparable hazards across all variables. The dose from the bootstrapped VBA workflow showed greater significance compared to the dose from the standard workflow. The AIC significantly reduced from 8033 to 8026 indicating improved model performance using the bootstrapped VBA region.

N	Mean volume (range) (cm3)	Standard Deviation of region volumes	Bootstraps with no significance
1000	31.2 (0 – 142)	31	1
500	31.7 (0 – 286)	36	6
250	24.0 (0 – 117)	28.8	16
100	22.8 (0 – 301)	47.3	38
50	72.4 (0 – 1276)	176	33

Table 2. Summary statistics from the experiments reducing the size of the datasets. Good consistency in region volumes are identified to 250 samples. 100 and 50 dataset sizes show greater instability with increasing standard deviations and greater number of bootstraps with no significance found.

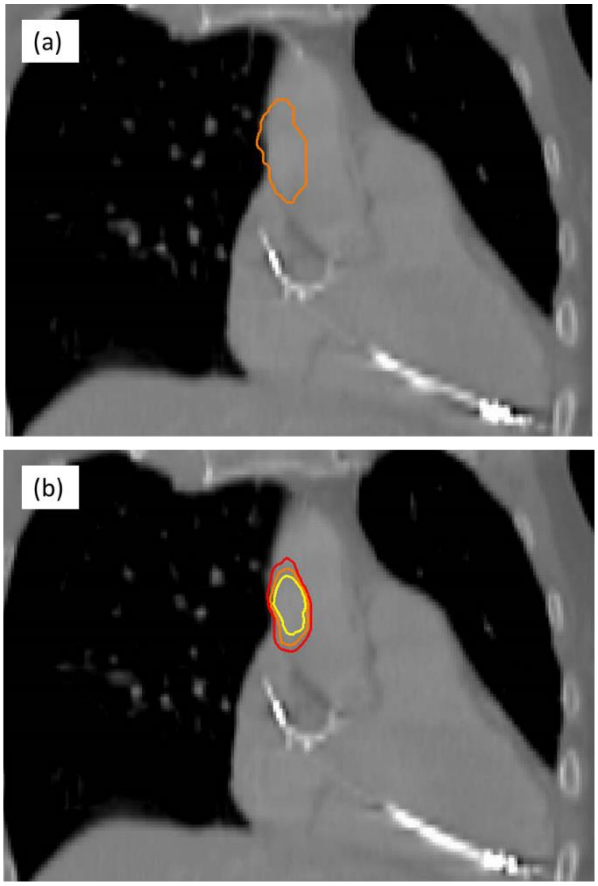

Figure 1. coronal views of the (a) the 95th percentile threshold (orange) using the standard VBA workflow and (b) the 95th percentile threshold (orange) with the 95th percentile confidence intervals (red and yellow). The bootstrapped VBA region is smaller than the standard workflow, the confidence intervals suggest greater uncertainty in the cranial – caudal direction.

Results from investigating progressively smaller datasets are summarised in table 2. Results demonstrate consistent volumes and standard deviations of the identified region volume across all bootstraps for dataset sizes of 1000, 500 and 250. For sample sizes of 100 and 50 datasets greater instability is demonstrated with increasing standard deviation and a large number of bootstraps where no significant region was identified. Visually, consistent regions in the base of the heart were found for 100, 500 and 250 samples; 100 and 50 show little consistency with a number of small regions throughout the patients anatomy.

Finally, since the VBA bootstrapping is computationally intensive, simulations were performed to ensure the results generated in table 2 were representative. The dose extracted from the defined bootstrapped region in the full dataset (figure 1b) is used. Table 3 presents the summary statistics from the 100 simulations for each dataset size. For the 1000, 500 and 250 dataset sizes, the mean number of bootstraps correctly defining significance was 100, 99 and 94 respectively across all simulations. The minimum

Variable		Standard VBA		Bootstrapped VBA	
		Hazard ratio (confidence interval)	p-value	Hazard ratio (confidence interval)	p-value
Age *(years)*		1.02 (1.01 – 1.03)	<0.001	1.02 (1.01 – 1.03)	<0.001
Sex *(comparator male)*		1.30 (1.14 – 1.52)	<0.001	1.29 (1.10 – 1.50)	<0.001
T-stage *(comparator T-stage 1)*	2	1.29 (1.01 – 1.66)	0.04	1.26 (0.98 – 1.62)	0.07
	3	1.58 (1.21 – 2.06)	<0.001	1.54 (1.18 – 2.01)	0.001
	4	1.54 (1.15 – 2.07)	0.003	1.56 (1.16 – 2.01)	0.003
N-Stage *(comparator N-stage 0)*	1	0.86 (0.67 – 1.10)	0.22	0.88 (0.69 – 1.12)	0.28
	2	1.37 (1.11 -1.69)	0.003	1.35 (1.09 – 1.67)	0.005
	3	1.47 (1.07 – 2.02)	0.02	1.47 (1.07 – 2.03)	0.02
Performance status *(comparator PS 0)*	1	1.22 (0.95 – 1.56)	0.12	1.21 (0.95 – 1.56)	0.13
	2	1.39 (1.08 – 1.79)	0.01	1.44 (1.11 – 1.86)	0.01
	3	1.60 (1.11 – 2.31)	0.01	1.59 (1.10 – 2.31)	0.01
Dose to region *(Gy)*		1.01 (1.01 – 1.02)	0.002	1.01 (1.01 – 1.02)	0.001

Table 1. Results from the Cox-proportional hazards model using the dose extracted from the anatomical region defined by the standard VBA and bootstrapped VBA workflows. All variables show comparable hazards in both models. The dose extracted from the bootstrapped VBA region shows a greater significance and the AIC of the model is significantly reduced, indicated a better model performance.

for a simulation correctly defining significance in the 250 dataset was 53 out of 100 bootstraps, therefore, there were sets of simulated data showing large uncertainty and others showing good agreement across bootstraps. For the 100 and 50 dataset sizes a high degree of uncertainty was seen across all simulation runs with many not identifying any significance. The minimum and maximum numbers of bootstraps correctly identifying significance within each simulations run covers the full range, demonstrating a high sensitivity to patients sampled. These simulation results agree with the analysis of the clinical data (figure 1 and table 2) for our exemplar. Dataset sizes of 250 provide good region stability with low variation on the identified region volume and small number of bootstraps not correctly defining significance. Dataset sizes of 100 and 50 showed higher instability to patients sampled and bootstrapping the data does not improve stability.

4 Discussion

In this abstract, we have investigated the role of bootstrapping for region identification in VBA, assessing its impact in small datasets. In our exemplar dataset, patients with NSCLC treated with radiotherapy, bootstrapped VBA defined a smaller region in the base of the heart where dose was significantly associated with survival. Dose extracted from this region demonstrated improved model performance, suggesting this is a more targeted and clinically important anatomical location. Bootstrapping provided robust region detection for datasets of 250 or more entries, both in the clinical data and in simulation experiments.

Bootstrapping is well used across statistics and recommended in TRIPOD guidelines as an internal validation approach [7]. The implementation with VBA also acts as internal validation that the region detected is reproducible. Additionally, it can provide confidence intervals or the region allowing visualisation of the modelling uncertainties.

N	Correct classification Mean (SD) range	No significance found Mean (SD) range	Incorrect classification Mean (SD) range
1000	100 (0) 100 - 100	0	0
500	99 (0.7) 0 - 5	0.3 (0.7) 0 - 5	0
250	94 (8.2) 53 - 100	6 (8.1) 0 - 45	0.1 (0.2) 0 - 2
100	66.5 (24.7) 3 - 100	32.5 (23.3) 0 - 79	1 (2.7) 0 - 22
50	50.2 (30.8) 0 - 100	45.2 (25.6) 0 - 100	4.6 (10.91) 0 - 60

Table 3. Summary statistics from the simulation experiments. For each dataset size, 100 simulations were performed. The mean number of bootstraps showing correct significance, no significance or incorrect significance across the simulations are included with the standard deviation. The range is also included showing the maximum and minimum times each category was selected across the simulations.

Further work is needed to fully explore the role of bootstrapped VBA across different treatment sites, clinical endpoints and statistical analysis. However, our exemplar shows promise of benefit. Here, we analysed a t-test with a binary outcome variable. In the future, this work should be extended to explore utility in other statistical tests, for example, continuous outcomes analysed voxel-wise with a Pearson or Spearman correlation [8], or multivariable approaches like linear regressions or cox-proportional hazards per voxel [9].

The simulation approach implemented showed agreement with the clinical dataset providing confidence in the results. The simulation can be further improved to allow user defined dose functions. These would allow the dose separation between outcome groups to be controlled and allow detailed exploration of bootstrapped VBA's power to resolve and identify these effects. Simulations can be extended to include correlations and multivariable models.

5 Conclusion

In conclusion, bootstrapping has shown utility as a form of internal validation within VBA. In our exemplar application, the defined significance region across all bootstraps showed improved model performance, indicating a more clinically relevant anatomical region was identified. Further clinical sites and endpoints should be investigated. If results hold, bootstrapped VBA should be recommended as best practice.

Abstract This work introduces a novel approach to introduce robustness into multicriteria optimization (MCO) in proton therapy. Our approach exploits a formulation of expected value optimization relying on precomputed total variance and expected dose influence. This facilitates merging robust optimization with Pareto front approximation while avoiding explicit calculation of scenarios during optimization. The method also introduces robustness as an objective, enabling interactive management of robustness trade-offs.
We demonstrate MCO including robustness trading with a single field proton plan on the TG119 phantom and a two field proton plan on a liver case. Trade-offs between robustness and dose metrics can be effectively approximated and visualized. Our approach allows planners more explicit control over robustness, and is directly translatable to other MCO approaches like lexicographic optimization.

1 Introduction

Radiotherapy treatment planning is most commonly modeled as a multicriteria optimization (MCO) problem, as trade-offs between multiple organs' toxicities and target coverage need to be managed. Approaches to solve this MCO problem have evolved from the manual weighted-sum approach, which involves repetitive manual tweaking of objective weights in consecutive optimization runs, to Pareto surface approximation techniques or automated lexicographic solvers.
In parallel, techniques like robust optimization were introduced to personalize the management of treatment uncertainties, particularly in particle therapy. In robust optimization, uncertainties are explicitly modeled through computation of error scenarios. These are then aggregated during optimization to minimize a robustness metric of the objective function, like its maximum over all scenarios or its expected value.
While the combination of robust optimization and modern MCO approaches has been suggested before [1], merging both is often limited by incompatible problem formulations or combination of both methods' increased computational demands. For MCO, computational complexity depends on the number of objectives. Performance of robust optimization depends on the number of error scenarios used during optimization. Introducing new robustness objectives computed from a large number of error scenarios to MCO is therefore limited by computational resources.
To address this challenge, we introduce a novel approach that incorporates total variance objectives into Pareto surface approximation techniques. Our method stands out as it formulates robustness objectives whose evaluation cost during optimization is independent of the number of the calculated error scenarios, thereby significantly enhancing computational efficiency without compromising on the robustness of the treatment plans. This independence is achieved by precomputing influence matrices of expected dose and total variance. Then, during approximation of the Pareto front, scenarios can be discarded or stored on disk and only these lightweight matrices are needed. For visualization or navigation of the solutions, the scenarios can be reloaded and the robustness trade-off can be visualized.
We presents the theoretical foundation of our method, the resulting algorithm and their implementation, and demonstrate the possible trade-offs in planning problems.

2 Materials and Methods

Our approach exploits a specific form of robust treatment planning, called probabilistic optimization or expected value optimization [2, 3], and combines it with Pareto surface approximation and navigation techniques.

2.1 Probabilistic Optimization

A common formulation of a probabilistic optimization problem would minimize the expected value $\mathbb{E}[f(d(x)]$ of an objective function f depending on beamlet intensities x [3]:

$$x^* = \arg\min_x \mathbb{E}[f(d(x))]\,. \tag{1}$$

The objective function f is usually formulated depending on dose d and chained to the beamlet intensities x by precomputation of a dose influence matrix D such that $d = Dx$.
For practical purposes, $\mathbb{E}[f]$ in eq. (1) is computed by averaging over a limited number of S samples from the assigned probability distributions. This, in turn, requires computation of S dose influence matrix samples D_s to be able to compute the dose during each iteration of an optimization run. This means that during optimization, the S samples of the dose influence matrix need to be kept in memory while keeping S as small as possible to guarantee computationally efficient treatment plan optimization.

2.2 Total Variance and expected dose influence

For the penalized least-squares objective function $f^{lsq}(d) = (d-d^{ref})^T P(d-d^{ref})$, where d^{ref} is the prescription dose and P a diagonal matrix encoding voxel penalty factors, it was previously shown [4] that its expectation can be separated into a total variance term (written as the trace over the doses' covariance matrix Σ) and an expected value term:

$$\mathbb{E}[f^{lsq}(d)] = \mathrm{tr}(P\Sigma) + (\mathbb{E}[d]-d^{ref})^T P(\mathbb{E}[d]-d^{ref}) \quad (2)$$
$$= x^T\Omega x + \mathbb{E}[D]x - d^{ref})^T P(\mathbb{E}[D]x - d^{ref}) \; . \quad (3)$$

Equation (3) introduces the "total variance" influence matrix Ω together with the expected dose influence matrix $\mathbb{E}[D]$. While the latter can easily be estimated by taking the elementwise mean over all D_s, computing Ω requires estimating the expected value of elementwise combinations of D via

$$\mathrm{tr}(P\Sigma) = \sum_{jk} x_j x_k \underbrace{\sum_i p_i \left(\mathbb{E}\left[D_{ij}D_{ik}\right] - \mathbb{E}\left[D_{ij}\right]\mathbb{E}\left[D_{ik}\right]\right)}_{\Omega_{jk}} \; , \quad (4)$$

with voxel penalties p_i in voxel i and intensity vector x.
Under the assumption that penalties are equal in certain voxels, i. e., voxels i belonging to the same volume of interest (VOI) V, corresponding Ω_V can be computed after pulling the penalty out of the sum, simplifying to

$$\Omega_V = \mathbb{E}[D_V^T D_V] - \mathbb{E}[D_V]^T\mathbb{E}[D_V] \; , \quad (5)$$

where D_V are the dose influence matrices for V.
Since Ω_V and $\mathbb{E}[D]$ can be precomputed during scenario dose calculation, we can now build objective functions depending on the total variance $x^T\Omega_V x$ or the expected dose $\mathbb{E}[D]x$ without requiring storage of scenarios during optimization. As $\mathbb{E}[D]$ and D have similar structure and Ω is a symmetric square matrix with number of rows/columns equal to the number of beamlets, optimization performance exhibits minimal overhead and is independent to the number of error scenarios used in the precomputation of Ω_V's and $\mathbb{E}[D]x$.

2.3 Multicriteria formulation and optimization

In general, an MCO problem is of the form

$$\text{"min"}_{x\in\mathscr{X}} \left[f_1(x), \ldots, f_k(x)\right] \quad (6)$$

where f_1 to f_k are objective functions for the treatment planning problem which should ideally all be minimized simultaneously by x. Hard constraints that must all hold (e.g. non-negativity of x) define the set $\mathscr{X}$. It is typically true that there exists no $x \in \mathscr{X}$ such that all objective function attain their individual minimum. Interesting solutions to (6) have the property that if one of the individual objectives should be further improved, at least one other objectives would necessarily have to degrade. This is often referred to as "efficiency" or "Pareto-efficiency" (after Vilfredo Pareto, an Italian economist). We label the set of all such efficient treatment plans the *Pareto front* (in some publications, this set is also referred to as the *Pareto surface*).
We formulate the MCO problem in this work by defining the following objectives for the planning structures. We distinguish between risk structures for which we want to analyze the trade-offs against all other objectives, and those for which we just want the dose to be within certain bounds.

- for a target structure $\mathscr{T}$, we define
  1. an objective $f^{lsq}_{\mathscr{T}}(\mathbb{E}[d_{\mathscr{T}}(x)])$ as defined above to minimize the squared deviation of expected dose from a reference dose (normalized by $\frac{1}{|\mathscr{T}|}$), and
  2. the total variance objective $f^{\Omega}_{\mathscr{T}}(x) := \frac{1}{|\mathscr{T}|}x^T\Omega_{\mathscr{T}}x$
- for risk structures $\mathscr{R}$ which we want to include in a MCO trade-off analysis, we define
  1. the 2-EUD as objective: $f^{EUD}_{\mathscr{R}}(\mathbb{E}[d(x)]) = \frac{1}{|\mathscr{R}|}\mathbb{E}[d]^T_{\mathscr{R}}\mathbb{E}[d]_{\mathscr{R}}$, and
  2. the total variance objective $f^{\Omega}_{\mathscr{R}}(x) := \frac{1}{|\mathscr{R}|}x^T\Omega_{\mathscr{R}}x$

Aside from the physical requirement $x \geq 0$, $\mathscr{X}$ also contains hard constraints on the over- and underdosing of target structures. We found that the constraints $g^{UD}_{\mathscr{T}}(\mathbb{E}[d_{\mathscr{T}}(x)]) := \frac{1}{|\mathscr{T}|}(d^{ref}_{\mathscr{T}} - \mathbb{E}[d_{\mathscr{T}}(x)])_+ \leq 1$ and $g^{OD}_{\mathscr{T}}(\mathbb{E}[d_{\mathscr{T}}(x)]) := \frac{1}{|\mathscr{T}|}(\mathbb{E}[d_{\mathscr{T}}(x)] - d^{ref}_{\mathscr{T}})_+ \leq 0.5$ work well for each involved target T. Here, $(\cdot)_+ := max(0,\cdot)$. Finally, for each risk structure not included in the MCO analysis, we add an overdose constraint $g^{OD}_{\mathscr{R}}(\mathbb{E}[d_{\mathscr{R}}(x)]) \leq 2$ with d^{ref} at half of the main target prescription dose.
Since all our objectives and constraints are convex functions, the Pareto front will be the surface of a k-dimensional convex body and we may directly apply well established methods *sandwiching methods* [5–8] to approximate this set. These methods iteratively produce efficient treatment plans and stop when the approximation quality is good enough. Details can be found in the references given above.

2.4 Implementation and Software

Computation of $\mathbb{E}[D]$ and Ω as well as the robustness analyses were done in matRad [9]. We use an in-house sandwiching method implemented by the Fraunhofer ITWM to approximate the Pareto fronts. Objectives are scaled to the [0,1] interval to prevent numerical distortions due to differing value domains. We set the termination criterion to stop the approximation when the ε-indicator [5–8] for the scaled objectives is below 0.05. For each case, we state the number of computed solutions to reach the required quality. This number corresponds to the number of plan optimizations. We use Ipopt [10] and KNITRO [11] to do the numerical optimization of the resulting scalar optimizations.

3 Results

3.1 TG-119 C-Shape

For a first low-dimensional demonstration, we used the TG119 phantom (directly available in matRad), a single proton field was set to cover the C-shaped Target and expose the distal Core structure to range uncertainties.
Setup uncertainties of $\pm 2.25\,\text{mm}$ and range uncertainties of $\pm 3.5\,\% \pm 1\,\text{mm}$ were assumed as standard deviation to sample 10 error scenarios from the respective multivariate normal distribution. These 10 scenarios were used to estimate $\mathbb{E}[D]$ and Ω before optimization.
Objectives and constraints were chosen according to section 2.3, resulting in a 5D MCO problem requiring 40 solutions for an acceptable Pareto surface approximation. For all solutions, robustness analysis was performed with DVHs and Standard-deviation-volume-histograms (SDVHs). SDVHs relate dose standard deviation to percentage volume for a given VOI to quantify the VOI-specific robustness. We illustrate the observed trade-off within the Core OAR in Figure 1.

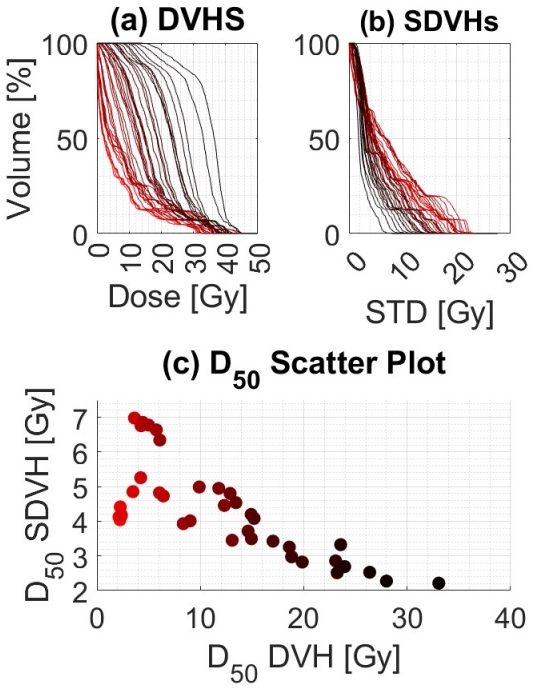

Figure 1: DVHs (a) and SDVHs (b) for all 40 solutions in the Core. (c) Scatter plot relates median dose and standard deviation (D_{50}). Similar colors correspond to the same solution in (a-c).

Figure 1 shows that the exposition of the Core to range uncertainties creates a direct trade-off between the Core robustness (total variance objective) and the dosage (EUD objective). With MCO, this trade-off can now be directly explored with Pareto surface navigation.

3.2 Liver case

To demonstrate our approach on a high-dimensional patient case, we planned a two-field proton plan for the Liver case available in matRad. One of the fields was chosen to expose the heart to range uncertainties. Similar uncertainty assumptions as in section 3.1 were applied using the CTV as target and liver and heart as OAR. A larger set of 100 scenarios was sampled to construct $\mathbb{E}[D]$ and Ω to demonstrate that our approach works with commonly unsuitably large numbers of scenarios. For optimization, again the protocol defined in section 2.3 was applied, resulting in a 7D MCO problem requiring 60 Pareto-optimal solutions. For all solutions, robustness analysis was again performed reloading the 100 scenarios initially used to construct $\mathbb{E}[D]$ and Ω.
Figure 2 illustrates the 7D MCO solution with navigation interface allowing trading robustness and dosimetric obejctives.

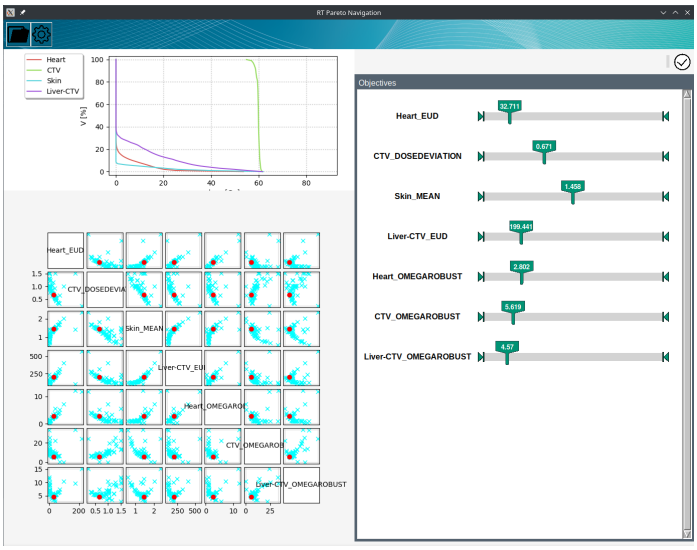

Figure 2: Pareto navigation for the liver case. Each slider on the right corresponds to an objective function. To improve one objective, the slider has to be pulled to the left. The bottom left is a scatterplot matrix of all pairs of objectives, showing the 2D projection of the Pareto front (in turquoise) as well as the currently navigated point (red). All elements then update in real time.

Figure 3 shows two exemplary solutions illustrating how heart robustness can be traded against CTV robustness and coverage; improved heart robustness will downregulate the proton beam exposing the heart to range uncertainties.
Figure 4 adds DVHs for the CTV and SDVHs for the Heart to the analysis and illustrates the correlation of target coverage with heart robustness, indicating a clear trade-off between the two that can be explored by Pareto navigation.

4 Discussion

One of the main clinical benefits of the presented methods is difficult to convey on paper: robustness can now be easily included in the interactive planning process. A common stage in modern multicriteria radiotherapy treatment planning is the interactive *Pareto Navigation* [12, 13] as implemented in Varian's Eclipse Treatment System and in RaySearch Laboratories' RayStation. This decision support conveys the shape

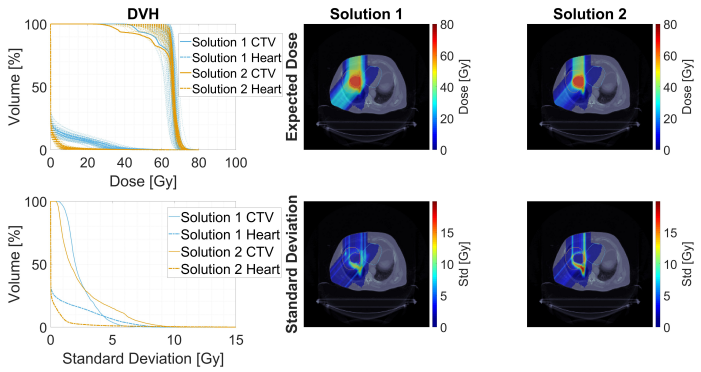

Figure 3: On the left, DVHs and SDVH for the CTV and Heart structures. Histograms are reported for all the 100 error scenarios nad for two solutions on the Pareto-front. On the right, expected dose and SD distributions for the two solutions are compared.

of a high-dimensional Pareto front and its implied trade-offs between the objectives to the decision-maker. It lets the planner explore the chances and limitations of the treatment by interactively manipulating the plan quality.
By adding the total variance objectives to the multicriteria formulation, the planner can interactively trade off the expected plan quality against the robustness on a structure level. We hope that this interactive analysis will improve the planner's and treating physician's confidence to apply robustness to their treatment plans.

5 Conclusion

We successfully introduced robustness as an objective into MCO for proton therapy. The approach limits computational overhead by precomputing expected dose and total variance influence before optimization, avoiding the need for explicit scenario evaluation. Trade-offs between robustness and dose metrics could be effectively calculated and visualized using Pareto surface approximation techniques.

Abstract Proton arc therapy (PAT) holds promise for enhancing target coverage and sparing normal tissues by incorporating all beam angles in treatment plan optimization. However, the conventional use of all possible energy layers for each angle significantly impacts delivery efficiency and increases planning complexity as treatment delivery time is heavily extended by energy switch and planning parameters are greatly amplified by including energy selection optimization. In this study, we propose a novel Mid-Range Proton Arc Therapy (MRPAT) framework that utilizes the mid-range beam, employing a single pre-selected energy layer for delivering mid-range spots at each beam angle in PAT and adopts a novel spot optimization strategy to efficiently solve large-scale PAT optimization problem. As the gantry rotates, the MRPAT enforces the scanning spots filling the target with the Bragg peaks well inwards away from the target's distal edge and effectively utilizes the high linear energy transfer (LET) of Bragg peaks to enhance Relative Biological Effectiveness (RBE) in the target while mitigating adjacent organs at risk (OARs) damage caused by range uncertainty. The mid-range energy smoothly varies with the beam angle without increasing delivery time as energy switching takes place during gantry rotation.

1 Introduction

The dosimetric advantage of proton arc therapy (PAT) has long been recognized. This is attributed to cross-firing radiation in rotational delivery, providing opportunities to enhance target coverage and spare normal tissues[1, 2]. However, PAT encounters three major challenges: 1) optimization complexity is substantial, given the numerous degrees of freedom involving spot position and intensity for each beam angle, 2) intra-beam energy switching extends the delivery time, and 3) the impact of range uncertainty grows with the number of beams. The conventional plan optimization for PAT relies on range modulation to generate spread-out Bragg peaks (SOBP), like the single field, where each beam angle can deliver spots to cover the entire 3D grid in the target. However, this approach is highly redundant for arc delivery, as arc therapy can deliver a complete 3D grid of spots without SOBP. Various strategies have been proposed to alleviate redundancies in PAT. Techniques such as distal edge tracking (DET) [3], mono- or binary energy delivery [4,5], and geometry-based layers [6] preselect energies before spot intensity optimization [7]. DET has been evaluated against the single field and was found to be less robust for range uncertainty [8]. Other energy layer preselection often aims to minimize energy switching but may encounter challenges in achieving both the efficiency and plan quality aims [7]. Integrated approaches which consider optimizing energy selection simultaneously with spot position and intensity, lead to increased optimization complexity and potential challenges with local minima from imposed energy switching constraints [9]. Hybrid methods involve sequential energy and spot intensity optimization, such as progressively adding energy layers [10] or redistributing them to neighboring beam angles by starting from full energy optimizations on a subset of angles [11]. Despite these efforts, the significant challenges associated with PAT remain unresolved. In this work, we propose using the mid-range beam [12] for each angle in proton arc therapy (MRPAT) combined with the low complexity global optimization framework [13] in tackling these challenges.

2 Materials and Methods

2.1 The mid-range proton arc therapy (MRAPT)

We start outlining MRPAT framework by explaining the mid-range layer definition and its efficacy. First, assume the target center is aligned with the machine isocenter. For each beam angle, we calculate the beam range at the isocenter using water equivalent path length (WEPL) obtained through ray tracing of patient CT volume. This beam range is selected to define the mid-range layer for this beam angle. The mid-range layer goes through the isocenter but may not be the same as the isocenter plane, as illustrated in Figure 1 The isocenter plane is a flat plane perpendicular to the beam direction and marked by the black cross, while the mid-range layer formed by scanning spots, as marked by the red cross, may lie ahead or behind the isocenter plane due to range variations along individual beam paths. A mid-range layer is selected for every beam angle, representing the sole energy utilized in arc treatment plan optimization for that angle.

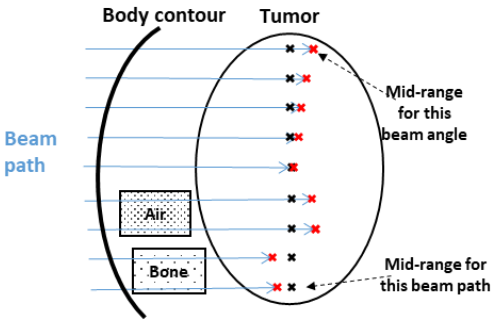

Figure 1: Illustration of the mid-range layer (red cross). The beam is shooting from the left side. The energy for the mid-range layer (red cross) is determined by the beam range at the isocenter point. The spots of the mid-range layer may be ahead or behind the isocenter plane (black cross). This is due to beam range variations along different beam paths.

Despite furnishing only a single energy layer per beam angle, the mid-range layers have the capacity to sweep across the entire 3D grid of spots as the full arc beams provide ample spot coverage for the target. This is illustrated in Figure 2 with small circles representing the spot (Bragg Peak) positions of mid-range layer, one color for one angle.

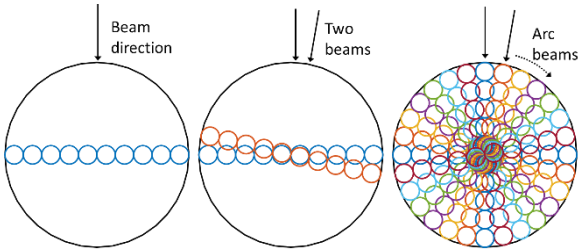

Figure 2: Illustration of mid-range layers that cover the target with spots. From left to right, a single beam delivers a mid-range layer of spots indicated by the small circles; with two beams, the second layer adds more spots. With arc beams, other layers sweep in the target and could fill the targets with spots.

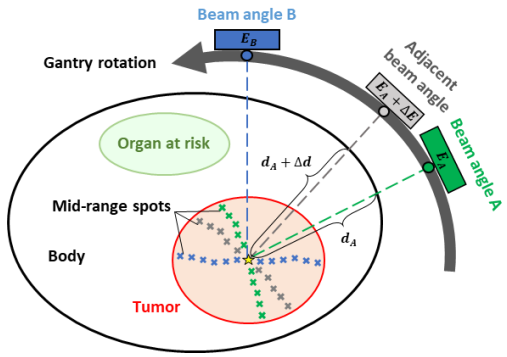

Figure 3: Illustration of proton arc delivery with mid-range energy layers and smooth energy variations with respect to gantry rotation. As the angle change from A to its adjacent angle, the energy changes from E_A to $E_A + \Delta E$, accounting for a small path length change Δd.

In addition to providing ample coverage to the target, the mid-range energy sequence has several features. First, the energy varies smoothly with respect to the beam angle because the WEPL from the patient surface to the isocenter (Figure 3) is a smooth continuous function of beam angles. Such smooth energy variation would not increase the delivery time as energy switching can take place during gantry rotation (typically 1 revolution per minute gantry rotation [11]). Second, the dose delivered by mid-range spots is mainly attributed to the Bragg peaks, which provide the maximum linear energy transfer (LET) and potential relative biological effectiveness (RBE) [14]. In contrast, the commonly utilized SOBP technique relies on a significant portion of dose from the entrance dose with low LET. Third, each time the delivered spots are the mid-range spots. This helps mitigate the range uncertainty issues, and the plan is more robust, as the mid-range spots are likely to remain in the target despite range uncertainty.

A MRPAT plan is created by optimizing intensity of all spots on the mid-range layers from all beam angles, we adopt the global optimization framework, in which [13], the spot dose is modeled by kernel decomposition [15], and optimization can be implemented through fast Fourier transformation (FFT), leading to complexity reduction by several orders of magnitude [13]. Figure 4 illustrate the entire workflow of MRPAT, and the optimization problem is formulated as Equation (1).

$$\begin{aligned} &\underset{w}{\text{minimize}}\, f(D) \\ s.t.\quad &D = K_0 \otimes w \\ &w \geq 0 \end{aligned} \tag{1}$$

where $f(\cdot)$ is a penalty function using medical constraints to evaluate the quality of the dose distribution D which is modeled via the convolution between reference kernel K_0 and corrected spot intensities w. And w is iteratively updated by the derivative shown as Equation (2) in which $K_0'(x) = K_0(-x)$.

$$\frac{\partial f}{\partial w} = \frac{\partial f}{\partial D} \otimes K_0' \tag{2}$$

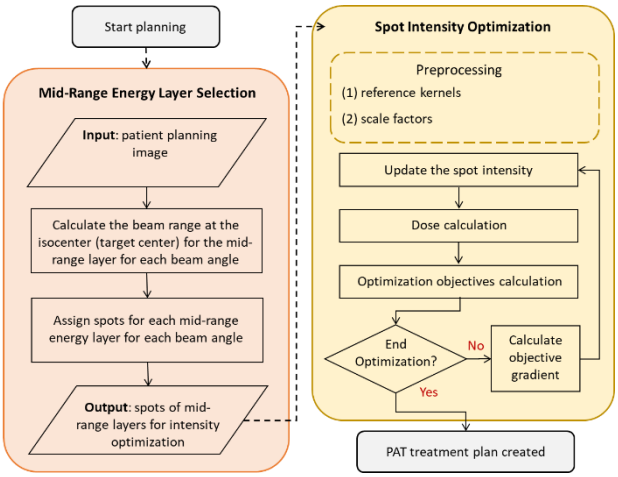

Figure 4: Workflow of MRPAT. The workflow starts with mid-range energy layer selection (orange box) followed by spot intensity optimization (yellow box).

We further elucidate the low-complexity advantage of MRPAT by listing the processes and corresponding computation complexity by steps in Table 1. Assuming that the dose grid has a dimension of $M \times M \times M$, spot sampling in dimension $N \times N \times N$ and the discretized beam angle number is K. For conventional fluence map optimization (FMO) using all candidate spots, the spatial and computational complexity both could grow up to $\mathcal{O}(K \cdot N^3 \cdot M^3)$ contributed from $K \cdot N^3$ spot candidates and M^3 dose voxels. In contrast, the MRPAT-FFT framework only need to store the reference kernels, thus the spatial complexity is $O(K \cdot M^3)$. Additionally, with the FFT, the highest computational complexity could be reduced to $O(K \cdot M^3 \cdot logM)$. For a numerical case, if we set $M = 2^7$, $N = 2^5$ and $K = 2^8$, both spatial and temporal complexity of full FMO problem are in the order of 16 T ($1\ \text{T} = 2^{40}$),

while for MRPAT, the spatial complexity reduced to 0.5 G ($1\ \mathrm{G} = 2^{30}$) and temporal complexity reduced to 4 G, which can be easily operated with a state of art computer workstation.

Spot Intensity Optimization in MRPAT

2.2 Simulation study

To demonstrate the feasibility of MRPAT, we compared three proton plans: single field full energy (denoted by full-1), conventional arc plan (full energy per angle for 128 angles, denoted by full-arc PAT), and MRPAT (the mid-range single energy per angle for 128 angles). Figure 5 illustrates the studied phantom, which is a cylindrical phantom (2D circle) with a centrally located target surrounded by four organs at risk (OARs).

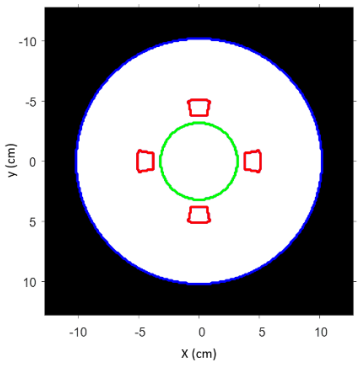

Figure 5: Phantom for our simulation study. It is a cylindrical phantom of density 1 (2D circle, radius of 10 cm) outlined in blue, with the target located at the isocenter with a radius of 3 cm outlined in green and surrounded by four organs at risk (OARs) outlined in red.

3 Results

The dose distributions of the three plans are shown in Figure 6. For the single projection plan, the entrance dose was higher. The other two plans, full-arc PAT and MRPAT, exhibit similar target coverage and OAR sparing, but their dose patterns are very different. MRPAT used more angles and spread out the low dose over the whole region. As noted previously, spot utilization is very redundant in arc beams with full energy. Therefore, though the MRPAT plan only utilized one energy layer per angle, it can achieve similar dose objectives as the full-arc PAT plan. The dose volume histograms (DVH) in Figure 7 also indicate that these two plans, MRPAT and full-arc PAT, had similar performance. The optimization results are summarized in Table 2. The total intensity utilized from lowest to highest was with full-1 beam, full-arc PAT, and MRPAT. This is because the proportion of high energy spots employed from highest to lowest was by full-1, full-arc PAT, and MRPAT, and the integral dose of higher energy spot is higher and thus requiring lower intensity to achieve the desired dose. The DVH points (D_2 and D_{98}) and homogeneity index indicate the two arc plans had similar plan quality and much improved OAR sparing compared to the single field plan with full energy layer utilization. However, the calculation time was substantially different. For arc beams, intensity optimization for full-arc PAT was around tenfold longer than that for MRPAT in this 2D study.

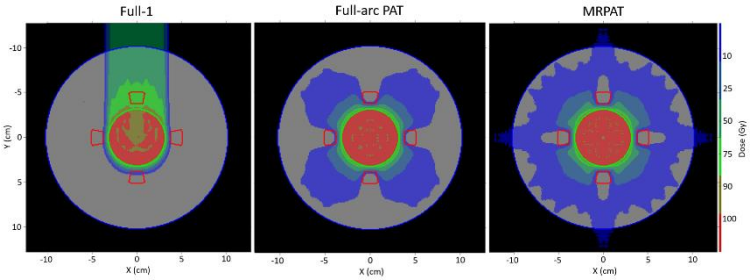

Figure 6: Dose distribution comparison. Left to right: single projection with full energy layers, arc beams (128 angles) with full energy for each angle, arc beams (128 angles) with a single midrange energy layer for each angle. The left side caption describes the structures, and the right-side color bar describes the dose levels.

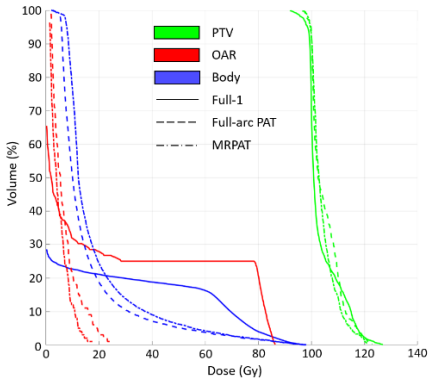

Figure 7: DVH comparison. The DVHs for the target PTV (green), OAR (red), and body (blue) are shown for the three plans: single angle with full energy (solid), arc beams with full energy (dash), arc beams with midrange energy (dash-dot).

Spot Mode	# Angle	# Energy	# Spots	Intensity	PTV D_2 (Gy)	PTV D_{98} (Gy)	OAR D_2 (Gy)	HI	CalcTime (s)
full	1	21	330	647.99	120.42	96.30	85.38	0.24	24.17
full	128	26	24626	670.42	120.64	97.90	21.69	0.23	7425.78
mid-range	128	1	1756	794.59	119.69	98.64	14.45	0.21	689.79

Table 2: Summary of the optimization results of the three compared plans, with the following column (number) labels: (1) the energy mode, (2) the number of utilized angles, (3) the number of maximum energy layers utilized per angle, (4) the total number of spots, (5) the total intensity of spots, (5) D_2 of PTV, (6) D_{98} of PTV, (7) D_2 of OAR, (8) homogeneity index, (9) and calculation time in second.

4 Discussion

We propose a novel MRPAT framework that employs a single pre-selected energy layer—the mid-range energy layer—for each angle to address the challenges of optimization, delivery time, and range uncertainty in proton arc therapy. Our phantom simulation shows MRPAT is feasible and produces plan quality comparable to that of conventional arc beams, as full energy utilization in arcs is redundant. In this investigation, we employed the WEPL to the target center to determine the mid-range layer. Alternative methods for mid-range layer selection exist, such as using the median or mean energy of midpoints along the beam paths that intersect the target. The choice between methods may depend on the specific characteristics of the target shape. With MRPAT, optimization is simplified without considering energy selection and optimization, reducing the problem size by an order of magnitude compared to a full-arc plan's optimization. Implementing MRPAT in the global optimization framework [13] drastically reduces computation time, making it suitable within clinical time frames.

Arc beam delivery time, which depends on the number of energy switches, can be extensive. With MRPAT, there is no intra-beam energy switching, and inter-beam energy switching can overlap with gantry rotation without additional time as energy varies smoothly with beam angle. The MRPAT enhances plan robustness, as each beam delivers spots primarily in the middle region of the target, likely remaining within the target despite range uncertainty.

An additional potential benefit of MRPAT is that the dose in the target is mainly attributed to the Bragg peaks, unlike in SOBP, where a large portion of the dose is from entrance dose. The region near Bragg peaks have maximum LET, potentially improving RBE. Future studies will include LET distributions for RBE-based MRPAT.

5 Conclusion

We introduced a novel MRPAT framework for proton therapy and demonstrated its ability to generate plan quality comparable to full-energy PAT delivery. MRPAT reduces optimization complexity, facilitates efficient arc delivery, and establishes robust plans by leveraging mid-range spots. Key advantages of MRPAT include harnessing Bragg peaks for dose distribution, offering the potential to maximize LET for enhanced RBE.

Abstract Most modern Treatment Planning Systems (TPS) come with Application Programming Interface (API) scripting capabilities, allowing for the development of custom applications that enhance the functionalities of commercial TPS. In our clinic, we have developed and integrated ECHO (Expedited Constrained Hierarchical Optimization), an in-house automated planning system, with the Eclipse TPS. ECHO has played a pivotal role in the treatment of over 10,000 patients. It streamlines the planning process: after preparing the contours and beams (IMRT fields or VMAT arcs), users launch the ECHO plug-in within the TPS, select optimization structures, and run the program. ECHO automatically retrieves necessary data from the TPS, constructs and solves optimization problems, and imports the final results (optimal fluence for IMRT, optimal control points for VMAT) back into the TPS. It then runs final dose calculation in TPS and notifies the user via email for plan review, all within 15-120 minutes. ECHO completely bypasses TPS optimization engine, however, it utilizes TPS's final dose calculation and, for IMRT, leaf sequencing. In this work, we discuss our development journey and clinical experiences, outlining both past and current technical challenges, along with the solutions we have devised. We have also recently introduced an open-source project, PortPy (Planning and Optimization for Radiation Therapy in Python), which aims to share our experience with the wider research community.

1 Introduction

Despite advancements, radiotherapy treatment planning remains a complex, time-consuming, and labor-intensive process, with the quality of plans often depending on the experience and skills of the planners. Automated planning has been a significant focus in the scientific community for approximately two decades, leading to many advancements[1–3]. However, the transition of research ideas into clinical practice by commercial vendors frequently takes years, and even when these innovations are introduced, clinics may not have access to the specific vendors or the products might not meet the unique needs of their criteria. For instance, a significant proportion of our patients (over 30% of our spinal patients) have undergone prior radiation, necessitating a customized plan that accounts for their previous treatments. Class-solution techniques, like the knowledge-based method found in the Eclipse system, is not applicable for these patients. Moreover, our clinical criteria undergo periodic revisions, potentially necessitating retraining for systems dependent on previous practices.

Most modern Treatment Planning Systems (TPSs) are equipped with API scripting capabilities, which allow researchers to enhance the functionalities of TPSs. Our group has developed a fully automated treatment planning system, named Expedited Constrained Hierarchical Optimization (ECHO), that integrates seamlessly with the FDA-approved Varian Eclipse system through API scripting and facilitated the treatment of over 10,000 patients to date. In this work, we will briefly explore some of the technical challenges we have faced, along with the solutions we have devised. To share our experience with the broader research community, our group has recently launched an open-source initiative, Planning and Optimization for Radiation Therapy in Python (PortPy). PortPy has seen over 7,000 downloads in the past four months, indicating its widespread adoption and use within the scientific community.

2 Materials and Methods

In the subsequent sections, we will briefly cover some of the hurdles encountered in creating a self-contained optimization engine designed to augment the commercial TPS. Table (1) provides a summary of these challenges, our technical solutions, their current implementation status within our clinic, and associated publications.

R&D	Proton uncertainty management	Robust/distributed optimization	[11,12]

2.1 Non-convexity and Local Sub-optimality. It is well-known that some treatment planning optimization problems lead to non-convexity, causing the optimization algorithm to potentially trap in a "local" sub-optimal solution and fails to reach the best "global" optimal solution. However, most of these non-convex problems can be solved to global optimality through the use of computationally demanding Mixed Integer Programming (MIP). While solving MIP

problems might require days or weeks for a single patient, making it impractical for regular use, they can be solved in the absence of time constraint and serve as valuable benchmarks for validating more computationally efficient algorithms. Figure 1 showcases the comparison between the global optimal solution (solid lines) and the results of our algorithms (dashed lines) for two distinct non-convex optimization problems: 1) Intensity Modulated Radiation Therapy (IMRT) optimization with Dose-Volume Histogram (DVH) constraints[7] (left figure), and 2) Volumetric Modulated Arc Therapy (VMAT) optimization including direct machine parameter optimization[6,8] (right figure). These comparisons verify that our algorithms can generate solutions near the global optimal. Our open-source package, PortPy, enables researchers to achieve global optimal solutions for complex non-convex optimization problems, including those with DVH constraints, VMAT, and beam orientation optimization, further facilitating the development and validation of new techniques by the research community[13].

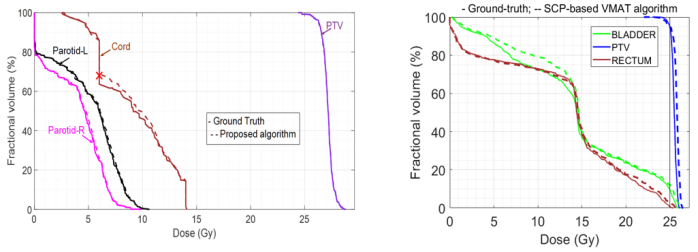

Figure 1. The global optimal solutions (solid lines) for DVH constraints (left) and VMAT (right) are compared against the results of our algorithms (dashed lines).

2.2 Dose Discrepancy Between Optimization and Final Dose Calculation. Treatment planning optimization necessitates the pre-calculation of the radiation dose delivered to the patient's body from thousands of small "beamlets", typically stored in a matrix known as the dose influence matrix or dose deposition matrix. This matrix represents the main computational challenge in optimization problems and is often truncated into a sparse matrix to enhance computational efficiency. However, this sparsification results in a discrepancy between the optimized dose and the finally calculated dose. While there are other sources of dose discrepancy, such as the tongue-and-groove effect and leaf transmission, their impact is usually much less significant. To mitigate this issue, a "correction loop" has been proposed in the literature[14], which periodically calculates a more accurate dose and reintegrates this information into the optimization problem for adjustments. This approach necessitates interruptions in the optimization algorithm, making it feasible only with simpler optimization algorithms like gradient descents, which are suitable for solving unconstrained optimization problems. Unfortunately, this technique is not applicable to more complex algorithms, such as interior point methods, which are utilized for solving constrained optimization problems. To overcome this limitation, we have proposed the reconstruction of an equivalent unconstrained version of a constrained problem using Lagrangian multipliers[2]. This approach allows for the correction of dose discrepancies without disrupting the optimization process. Although the "correction loop" strategy helps to reduce the dose discrepancy issue, it does not fully resolve it, and relying on such an *ad hoc* technique could potentially compromise the quality of the treatment plan. Upon a more detailed examination of the dose influence matrix, we have recently discovered that it is highly compressible, thanks to the correlations among machine parameters such as adjacent beams and beamlets. Our preliminary findings show an impressive compression rate of over 98% with a minimal error margin (approximately 2%). These results will be discussed in detail in a separate study. It is worth mentioning that our open-source initiative, PortPy, encompasses all necessary data for optimization, including the dose influence matrix, which has been pre-calculated for many patients (currently 50 lung patients) and extracted from the Eclipse system.

2.3 Optimally Balancing Plan Complexity and Dose Conformity. IMRT/VMAT effectiveness relies on conforming radiation dose to the tumor by modulating radiotherapy machine parameters (e.g., fluence, multi-leaf collimator). Although some modulation is necessary, increased modulation does not always enhance dose conformity, and excessive modulation can increase plan complexity and hinder the delivery accuracy. The importance of optimally balancing dose conformity and plan complexity has been long recognized, yet it remains a challenge as also noted in a 2020 Red Journal Editorial Note[15] and highlighted by ESTRO[16,17]. In IMRT, we have recently introduced a novel wavelet-based planning framework[9], which treats each beam's 2-dimensional modulated fluence as an image and utilizes advanced wavelet tools from imaging science to induce local and global fluence smoothness. This framework also allows for the proactive elimination of overly complex and clinically irrelevant plans by employing only low-frequency wavelets. For VMAT, we have recently developed a new VMAT planning framework, named Sequential Convex Programming[6,8] (SCP). The SCP-based VMAT framework is the first, to our knowledge, that fully integrates plan complexity into treatment planning and identifies a VMAT plan close to the “global” optimal plan.

2.4 Safety of In-house Developed Software. Integrating with a commercial TPS and conducting the final dose calculation and evaluation within it offers a level of reassurance. However, implementing a strict quality assurance (QA) protocol for in-house software development is crucial, particularly for applications like ours that entirely bypass the TPS optimization engine. Our team adheres to the guidelines outlined by Moran et al. (2022)[18] for the final evaluation and documentation of our in-house software projects. Moreover, we conduct thorough retrospective studies with randomly chosen patients, comparing the manually generated treatment plans used for treatment with those generated by our ECHO system, before introducing new disease sites

or fractionation regimens (see Figure 4). Film and portal dosimetry, in alignment with departmental policies, are also utilized for QA purposes.

3 Results

Figure 2 illustrates the ECHO's system design and workflow. Once the structure contours and beams/arcs are set up, users launch ECHO as a plugin from the Eclipse TPS, selecting structures for optimization. The API then retrieves necessary patient data (e.g., beam parameters, influence matrix) for optimization. The system solves the optimization problems, importing optimal machine settings (fluence for IMRT, control points for VMAT) back into Eclipse for the final dose calculation. There is a correction-loop to align optimized and calculated doses. Lastly, an automated email notifies the user when the plan is ready for review. This workflow is fully automated, requiring user input only for initial contour and beam setup.

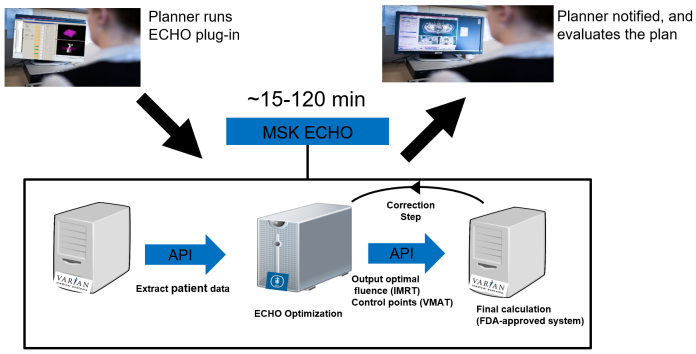

Figure 2. ECHO workflow is fully automated using API scripting. ECHO completely bypasses the TPS optimization engine, but it relies on the TPS for final dose calculation and, in case of IMRT, for the final leaf sequencing as well.

ECHO has played a pivotal role in the treatment of over 10,000 patients across a range of disease sites such as spine, prostate, lung, and oligometastases at our center. Figure 3 displays the monthly plan generation statistics through ECHO and the distribution across different disease sites.

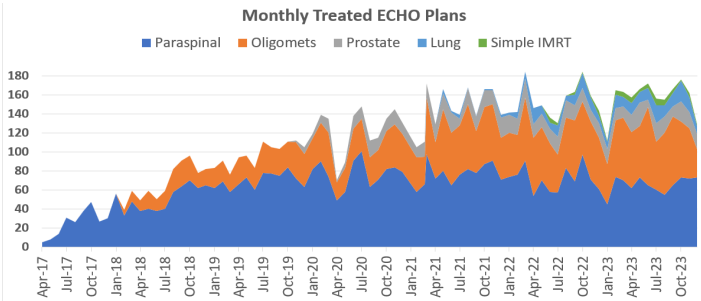

Figure 3. About 180 plans are generated monthly using ECHO.

As previously mentioned, we conduct a retrospective analysis of ECHO's performance prior to introducing a new site or prescription regimen. This analysis encompasses both quantitative comparisons using clinically relevant dose metrics, akin to those depicted in Figure 4, and qualitative evaluations of 3D dose distribution and DVH by experienced physicists and radiation oncologists.

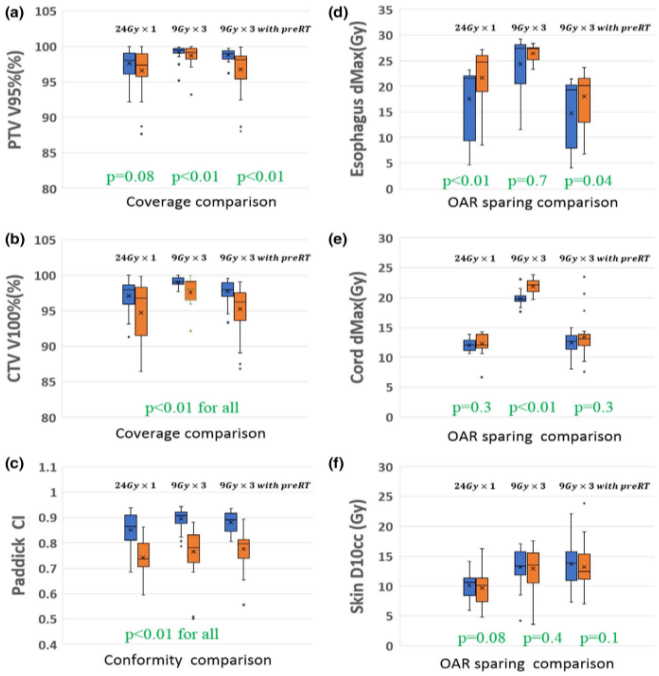

Figure 4. Pre-clinical validation, conducted prior to clinical deployment of new site or prescription, includes simulating ECHO plans for previously treated patients and performing a comparative analysis.

4 Discussion

API scripting, now accessible in major Treatment Planning Systems (TPS), serves as a robust mechanism to enhance clinical workflows through increased automation. This work demonstrates the integration of home-grown optimization techniques into clinical operations by extracting data from the TPS, executing optimization processes externally, and seamlessly reintegrating the results back into the TPS without manual intervention. However, it is important to acknowledge that API scripting, while transformative, is still an evolving technology and might not encompass all necessary functionalities. For instance, due to the limited API capabilities in the clinical version of Eclipse, we had to transfer patient data to a non-clinical version of Eclipse for processing. This process, though automated via Varian's DB Daemon transfer tools, introduces additional complexity.

The criticality of safety and quality assurance in the development of in-house software for critical applications like radiotherapy cannot be overstated. In addition to performing comprehensive and objective retrospective evaluations to determine the impact of the software on the quality of care, it is recommended to follow established guidelines, like those suggested by Moran et al.[18], to ensure the highest levels of safety and efficacy.

Finally, we hope our open-source project, PortPy, accelerates research in treatment planning optimization and

encourages the development of new treatment planning techniques. These could potentially be applied clinically using API scripting, bridging the gap between research and clinical use.

5 Conclusion

We have developed and successfully implemented ECHO, a fully automated treatment planning system. Thanks to the integration capabilities provided by Eclipse API scripting, ECHO is now fully integrated with commercial TPS and seamlessly incorporated into our clinical workflow. ECHO has been instrumental in the treatment of over 10,000 patients, reducing the average planning time by half—from a full day to just half a day—while significantly improving the quality and consistency of treatment plans.

Fully-automated integrated multi-criterial optimisation of transmission pencil beams in IMPT for penumbra sharpening

W. Kong[1], M. Huiskes[2], S. J. M. Habraken [2,3], C.R.N. Rasch[2,3], E. Astreinidou[2], B.J.M. Heijmen[1], and S. Breedveld[1]

Abstract

Objective: In intensity-modulated proton therapy (IMPT), Bragg peaks (BPs) result in a steep dose fall-off at the distal target end. Typically, the lateral dose fall-off is less steep. High-energy pristine transmission pencil beams (TPBs) with BPs outside the patient exhibit a sharp lateral penumbra at the target level. In this study, we hypothesised that by combining IMPT BPs with TPBs (denoted 'IMPT&TPB'), dose distributions in head-and-neck cancer patients could be improved in terms of OAR dose compared to conventional IMPT with only BPs. *Approach:* Our spot selection algorithm (SISS-MCO) for fully-automated IMPT treatmentplanning[1–3], embedded in Erasmus- iCycle, was extended for the combined optimisation of IMPT BPs and TPBs. It employs automated multi-criteria optimisation to generate for each patient a single Pareto-optimal plan using prioritised planning objectives and hard constraints, as specified in a generic wish-list[2]. For 8 nasopharynx cancer patients and 8 oropharynx cancer patients, the IMPT&TPB plan was compared to the competing IMPT plan. *Main results:* Clinical OAR and target constraints were met in all plans. On average, 11 of the 19 investigated OAR plan parameters improved significantly by allowing TPBs in the optimisations, while one parameter showed small but significant deterioration. *Conclusion:* For head and neck cancer patients, IMPT&TPB resulted in comparable target coverage with overall superior OAR sparing, the latter originating from sharper penumbras close to OARs.

1 Introduction

External beam radiation therapy with protons instead of photons can reduce radiation exposure to critical organs through the Bragg peaks (BP). However, the lateral dose fall-off may be relatively shallow, as proton pencil beams have a considerable penumbra at the patient's entrance level. This problem is especially relevant in intensity modulated proton therapy (IMPT) for head and neck cancer (HNC), where the applied range shifters, used to treat more superficial target regions, result in increased penumbras of pencil beams entering the patient. Inside patients, penumbras further increase due to unavoidable multiple Coulomb scattering, resulting in the largest penumbras close to the BPs.

Transmission pencil beams (TPBs) consist of high energy protons with BPs that are effectively outside the patient; tumour dose is deposited by the relatively flat entrance dose plateau of the pencil beams. Consequently, proton energies at the target level are still relatively high, and therefore, the lateral penumbras are relatively steep. The omission of range shifters in TPBs further contributes to relatively steep lateral penumbras in high-dose regions close to the targets. However, a notable drawback of using only TPBs is that it leads to increased irradiation of normal tissues located beyond the distal edge of the target.

In this study, we hypothesised that by combining IMPT BPs with TPBs (denoted 'IMPT&TPB'), dose distributions in HNC patients could be improved in terms of OAR dose compared to conventional IMPT with BPs only.

2 Materials and Methods

2.1 Patient data

This study used anonymised planning CT scans and delineations of eight patients with nasopharyngeal cancer (NPC) and eight patients with oropharyngeal cancer (OPC) who had previously been treated with IMPT. Informed consent was obtained from all patients for the retrospective use of the data.

For all patients, a simultaneous integrated boost scheme was applied, prescribing 70 Gy_{RBE} to the primary tumour (CTV70) and 54.25 Gy_{RBE} to bilateral neck volumes (CTV54.25). For all selected patients, the applied IMPT plan achieved for both CTVs the clinically requested coverage. Robust optimisation was performed for all targets, brainstem, spinal cord, cochlea, optic nerves, optic chiasm, eyes and mandible bone, while non-robust optimisation was performed for parotids, submandibular glands, oral cavity, oesophagus, larynx, pharyngeal constrictor muscles (PCM) (superior, middle, and inferior) and cricopharyngeus.

2.2 Treatment planning

Our algorithm for spot selection (SISS-MCO) for fully-automated multi-criterial IMPT treatment planning[1–3], embedded in Erasmus- iCycle, was extended for combined optimisation of IMPT with BPs and TPBs. For each patient, it generates a single Pareto-optimal plan using predefined prioritised objectives and hard constraints as specified in a generic wish-list[2]. The same wish-list was used for both IMPT and IMPT&TPB.

The SISS-MCO optimisation includes large-scale sparsity-induced BPs/TPBs selection in the first phase and multi-criteria optimisation with a subset of candidate pencil beams from phase 1 in Erasmus-iCycle [2, 4] in the second phase. The subset was chosen such that it constituted 99% of the total candidate pencil beam weight after phase 1. Pencil beams with monitor units (MU) below the clinically minimum deliverable MU were removed in the third phase. For IMPT plans, the optimisations started with 20,000 candidate BPs that were uniformly distributed in the CTVs with a 5 mm expansion, while in IMPT&TPB, 20.000 BPs and 18.000 TPBs were similarly distributed. TPBs were obtained using 244 MeV shoot through beams. The best combination of BPs and TPBs was chosen by the optimiser.

IMPT&TPB and IMPT plans were robustly generated using minimax optimisation with 19 robustness scenarios. For plan comparisons, obtained D98% in the voxel-wise minimum dose distributions for the high-dose CTVs (CTV70) were scaled to 95.0% of the prescription dose.

All plans were generated on a node on our high computing cluster equipped with two Intel Xeon Gold 6248 @ 2.5 GHz CPUs and a NVIDIA Quadro RTX 8000 GPU. Only six of the available 40 CPU cores were used for the calculation of the dose deposition matrices for the candidate pencil beams and for final dose calculations due to the limited multiprocessing capability of our implementation of the applied ASTROID dose engine [5].

2.3 Plan evaluations

For all robustly optimised target and OAR dose parameters, plan evaluations and comparisons were performed accordingly. For robustly optimised OARs, the voxelwise maximum D2% (VWmax D2%) or worst-case scenario mean dose (WC Dmean) were applied, in agreement with the applied wishlist. For non-robustly optimised OARs, the mean dose of the nominal scenario (Dmean) or the nominal scenario D2% was determined depending on the OAR. Differences in dosimetric metrics were tested for significance ($p < 0.05$) using two-sided Wilcoxon signed-rank tests.

3 Results

3.1 Dose evaluations

All IMPT and IMPT&TPB plans met the clinical OAR and target hard constraints applied in our institution. All D2% of the target VWmax dose distributions were below 107% of the prescribed dose. For both NPC and OPC, IMPT&TPB showed small increases in D2% of the target VWmax dose, albeit all values were below clinical constraints.

IMPT&TPB was superior for the majority of OAR plan parameters in both tumour localisations (Figure 1). Depending on the NPC patient, considerable dose differences favouring IMPT&TPB were observed in the WC Dmean in cochleae and, VWmax D2% of the brainstem, optic nerves, optic chiasm and lenses. Furthermore, for both NPC and OPC, reductions were also observed in the mean dose of the submandibular glands (SMG), parotids and the middle pharyngeal constrictor muscle inferior.

3.2 Dose distribution comparisons

The impact of TPBs on IMPT&TPB dose distributions is shown in Figure 2a for an NPC case and in Figure 2b for an OPC case. Often, the optimiser chose TPBs on the edges of the CTV that are proximal to OARs. For both tumour localisations, TPBs were often chosen to shoot between a CTV and a parotid, SMG, or cochleae, and along the edges of the CTVs. For nasopharynx cases, TPBs were also often chosen between the brainstem or optic nerves and a CTV.

3.3 Calculation times, numbers of spots and energy layers

On average, IMPT&TPB and IMPT plan generations took 3.7 and 2.7 hours, respectively. Dose calculations contributed significantly to plan generation times, i.e., 1.8 hours for IMPT&TPB and 1.1 hours for IMPT.

On average, IMPT&TPB plans constituted of 1761 BPs and 792 TPBs, while IMPT plans had 2179 BPs. The average number of selected energy layers was the same for both (39).

4 Discussion

This study has demonstrated that incorporating TPBs into regular IMPT with only BPs could improve the quality of treatment plans, by exploiting the sharper lateral penumbras of TPBs. IMPT&TPB and IMPT showed comparable target coverage, while OAR sparing was overall superior for IMPT&TPB. In nations that employ a model-based selection approach for proton therapy, lower OAR doses can result in more patients treated with proton therapy.

In this work, we have assumed that TPBs were delivered without a range shifter in the beam to maximise the steepness of lateral TPB penumbras. In our institution, two out of the six applied IMPT beams in HNC are already delivered without a range shifter. For the other beams, clinical delivery of simulated IMPT&TPB treatments would require that part of the total dose be delivered without a range shifter, resulting in longer delivery times. Possibly, using the range shifter in these four beams also for TPBs only has a minor negative impact on the resulting IMPT&TPB dose distributions. This needs further investigation. Avoiding the

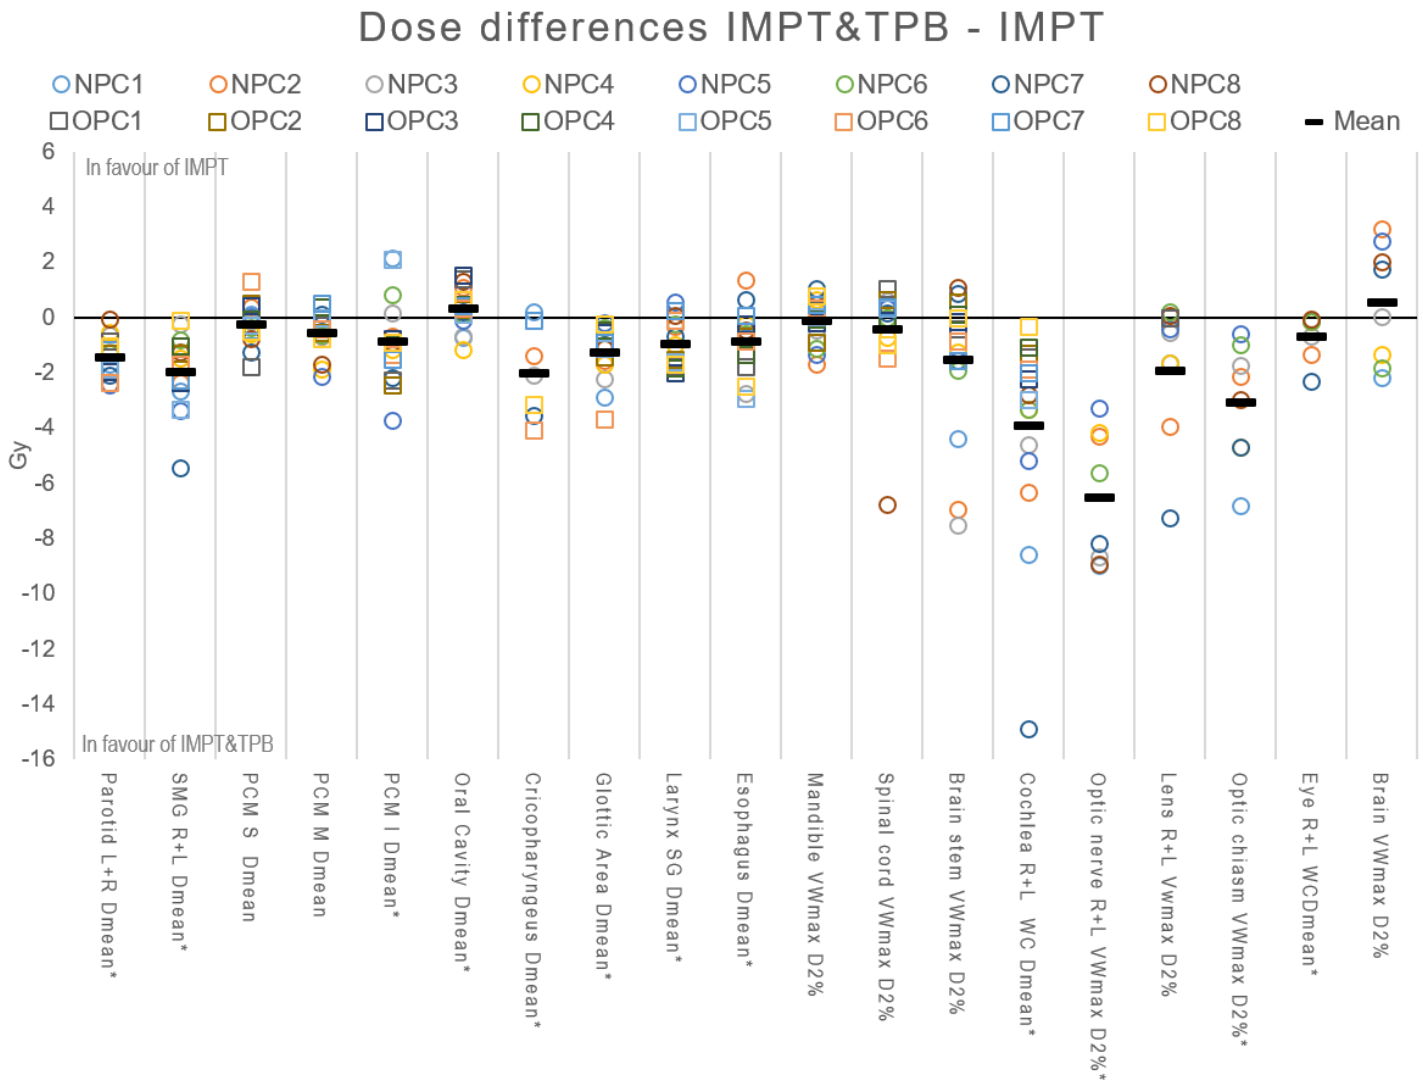

Figure 1: Differences in dosimetric plan parameters of IMPT&TPB and IMPT treatment plans. NPC cases are represented by circles and OPC cases by squares. Statistical significance is denoted by asterisks ($p<0.05$). Abbreviations: R=right, L=left, SMG=submandibular gland, PCM=pharyngeal constrictor muscle, S=superior,I=inferior, M=middle

use of range shifters for TPBs in all beams with only minor delivery time increases could be realised with a system for automatic range shifter insertion.

The added value of using TPBs is apparent but varies between patients. In this study, the planning wish-list that was used for both IMPT&TPB and IMPT was optimised for IMPT in a previous study. Possibly, tailoring of the wish-list to maximally favour penumbra sharpening with TPBs could further enhance OAR sparing for more patients. Also (automated) beam-angle optimisation for IMPT&TPB could maybe enhance the positive impact of TPBs.

For all included study patients, full coverage of CTV70 was achieved, while in general clinical practice, a substantial part of NPC patients can suffer from insufficient coverage of the high-dose CTV. Possibly, for this patient group, IMPT&TPB could enhance the attainable coverage compared to regular IMPT. These are all topics for further research.

5 Conclusion

The developed optimiser for fully-automated combined optimisation of IMPT Bragg peaks and transmission pencil beams significantly reduced OAR doses in head-and-neck cancer by using transmission pencil beams to enhance lateral target dose fall-off.

Interactive dose modification: a novel approach to proton beam therapy treatment planning

Matthew Lowe[1]

[1]Christie Medical Physics & Engineering, The Christie NHS Foundation Trust, Manchester, UK

Abstract A novel approach to treatment planning for pencil beam scanning proton therapy is presented by which the user can interact intuitively with a dose distribution to modify a treatment plan. In this proof-of-principle implementation, the dose distribution is displayed using standalone software independent of the treatment planning system (TPS). The user can mouse click or scroll to increase or decrease dose to any voxel. This is achieved by modifying spot weights in proportion to their contribution to the selected voxel using an influence matrix describing the contribution of each spot to each voxel. The dose distribution is updated in <180 ms on average, appearing real-time to the user. Minimum spot weights are accounted for, ensuring plan deliverability. Modified spot weights are returned to the TPS from which the normal pathway to patient treatment can continue. The proposed approach allows the user to produce a desired dose distribution without knowing how to describe it using optimisation objectives, reducing the expertise needed to modify plans.

1 Introduction

Proton treatment planning using pencil beam scanning (PBS) enables the production of highly conformal dose distributions through the delivery of proton pencil beams (spots) to different locations throughout a patient. Spots are assigned different weights (proportional to the number of protons delivered to each location) which are optimised to provide an individualised patient treatment plan. Typically, several thousand spots from multiple fixed beam directions are used and as such there are many degrees of freedom in producing a clinically desirable treatment plan.

While treatment planning is a multi-disciplinary process, particularly for complex cases, the creation of the plan is done by an expert planner. Spot weight optimisation is done through a process of inverse optimisation: the optimum dose distribution is derived using, e.g., steepest descent, conjugate gradient, or quasi-Newton methods, by minimising an objective function comprising multiple planning objectives, weighted by priority. e.g., the minimum dose to the target volume should be 100% of the prescription dose; the maximum dose to *x*% of a given organ at risk (OAR) should not exceed a dose, *y*. Such objectives do not necessarily replicate the exact clinical aims of the plan but may instead be chosen to drive the optimisation algorithm to the required outcome.

In complex cases, treatment planning can be an art of compromise, requiring a balance of the conflicting aims of target volume coverage and minimising dose to nearby or overlapping OARs. It is a resource intensive task, and the quality and timeliness of plan production is dependent on planner experience. Predicting the minimal achievable dose to OARs or the compromise to target coverage from meeting given aims can be difficult. The optimisation cycle may be initiated multiple times, with the planner responding to the resulting dose distribution by adjusting planning objectives or priorities. Desired changes in one part of the dose distribution can result in changes throughout the dose distribution as a result of the optimisation process.

Once the planner is satisfied with their treatment plan, it is reviewed by the prescribing oncologist who, in light of their own expertise, may request changes to the plan, providing feedback to the planner and requiring further investigation and optimisation before it is reviewed again.

The tool presented here aims to reduce both the time taken to produce a desired dose distribution and the barrier to entry for improving treatment plans. It aims to benefit planning staff as well as empowering oncologists who review treatment plans, but are not trained to produce them, to make changes to meet their requirements.

This tool exists as standalone software taking information from an existing PBS treatment plan and enabling the user to interact with the dose distribution using a mouse to add or remove planned dose from selected regions. This interaction changes the contributing spot weights and displays an updated, deliverable dose distribution in real-time, demonstrating the result of such a change. Once the desired dose distribution has been attained, spot weights are returned to the treatment planning system (TPS).

2 Materials and Methods

2.1 Implementation

The software is implemented in Python v3.10.9 and the results presented here are shown from running on an Intel Xeon 2.50 GHz CPU E5-2680 v3 with 64Gb RAM.

In this proof of principle implementation, initial treatment plans and structure sets are taken from Eclipse v16.1 (Varian Medical Systems). However, the proposed approach is independent of TPS, requiring only that an influence matrix can be exported and that the new spot weights can be imported. In this case, this has been done using the Eclipse scripting application programming interface (ESAPI).

2.2 Functionality

CT (computed tomography) scan, structure set and dose distributions are displayed co-registered along with the dose volume histograms (DVH) of selected structures. Figure 1 shows a representative image of the software.

The user can scroll through the CT scan using the keyboard up and down arrows. Left clicking or scrolling up with the mouse cursor over a given point will modify spot weights to increase the dose to this location. Right clicking, or scrolling down, will reduce the dose. Individual beam doses can be displayed allowing modification of spots from the

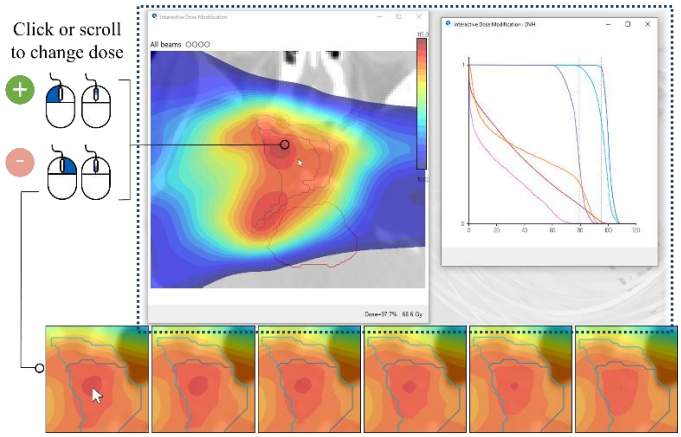

Figure 1. Graphical user interface (within the dashed box) with an example for case 1. Inset shows the effect of successive right clicks on reducing the dose to the selected point. In this example the updated dose distribution is shown within 120 ms of each click.

displayed beam alone.
The available functionality is shown in table 1.

2.3 Influence matrix

An influence matrix, D_{ij}, is extracted from the TPS describing the unit contribution of each spot, j, to each voxel, i, in the dose distribution. This is a large, but sparse array, allowing for sparse data structures to be used to minimise memory requirements.
Using the influence matrix, the dose, d, to a given voxel is given by:

$$d_i = \sum_j D_{ij} w_j \,,$$

where, w_j, is the weight of spot, j.
The influence matrix, and resultant dose distribution has the same resolution as the CT scan (e.g., for case 1, shown in figure 1, this is 0.97×0.97×1 mm).
In this implementation the influence matrix has been reconstructed using ESAPI to calculate the dose distribution for each spot. In some TPS this may be more directly accessible.

2.4 Spot-weight modification

On interaction with the dose distribution, all spots contributing to the interaction site are modified in proportion to their contribution to the interaction site—the weights of spots that have a large influence on the interaction site will change more than those of spots with a low influence on the interaction site. This is done by evaluating the relevant column of the influence matrix and multiplying by a factor that is positive when dose is to be increased and negative when dose is to be decreased to give a modification factor, α_j, for each spot (typically between -0.015 and 0.03). Updated weights for each spot, w_j' are given by:

$$w_j' = (1 + \alpha_j) w_j \,.$$

By default, all spots are considered when interacting with the dose distribution. This behaviour can be adjusted in two

Table 1. Interaction options and functionality

I	**Show isodose labels** displays isodose labels between 10% and 120% of the prescription dose.
S	**Show spot positions** displays spot positions as a circle with a size reflecting the spot weight and centred on the voxel with the highest dose from each spot. Locked or pinned spots are shown with a cross through them.
P	**Place pin** turns the cursor into a crosshair with which left clicking on the dose distribution places a pin which prevents modification of any spot contributing more than a threshold value to this location. The pin position is shown by the symbol 📌 and appears transparent on other slices. Multiple pins may be placed throughout the dose distribution.
[	**Remove all pins**
L	**Lock/unlock beam** when an individual beam is shown, prevents modification of spots from that beam when clicking on the dose distribution with all beams shown. Locked and unlocked beams are indicated on the display.
R	**Renormalise** scales all spot weights such that the mean dose to the normalisation structure matches the prescription dose.
X	**Export spot weights to TPS** spot weights are exported to a file which can be imported in to the TPS using a script.
← →	**Cycle through individual beam doses**
↑ ↓	**Scroll through CT slices**
0	**Restore initial spot weights** assigns the spot weights that were exported from the treatment planning system
Ctrl + Z	**Undo** reverts changes to the spot weights one interaction at a time
Ctrl + 1	**Save to bookmark** saves the current spot weights to a bookmark. Can be used for any number from 1 to 9. Existing bookmarks are shown in the top right of the screen.
1 / 2 ...	**Restore bookmark** assigns spot weights saved to a given bookmark
On dose display:	**Increase dose** when clicking or scrolling within the dose display the dose at the position of the cursor is increased.
On dose display:	**Decrease dose** when clicking or scrolling within the dose display the dose at the position of the cursor is decreased.
On DVH display:	**Reselect ROIs** reselect ROIs for display on the dose display and DVH display and reselect normalisation structure.
On colour bar:	**Set dose display** set the minimum and maximum dose display. Different values are set for the display of all beams and individual beams.
On colour bar:	**Switch between absolute and relative dose**
Ctrl	**Increase effect ×5** holding ctrl while clicking will increase the magnitude of spot weight changes by a factor of 5.
Shift	**Increase effect ×2** holding shift while clicking will increase the magnitude of spot weight changes by a factor of 2. This can be combined with holding ctrl to increase the magnitude of the change by a factor of 10.

ways: by locking individual beams (pressing 'L' when an individual beam is displayed) or by placing a pin in the dose distribution (pressing 'P' and selecting a point in the dose distribution). Locking individual beams prevents changes to spots belonging to those beams when interacting with the total dose distribution. Placing a pin on the dose distribution prevents the modification of any spot that contributes more than a threshold value to the pin position. This minimises the change in dose at the pinned position, allowing the dose at one location to be modified without affecting some other critical part of the dose distribution.

A record of spot weights on each click is stored so that changes can be reverted, and bookmarks can be stored for the current spot weights and restored later.

2.5 Ensuring deliverability

PBS enables different combinations of spot positions and weights to be combined to produce a treatment plan. Spot weights can take any value but are subject to a minimum deliverable weight, $w_{\min}$ which is dependent on the delivery system. In conventional optimisation approaches, this may be accounted for during spot weight optimisation or via post processing to ensure deliverability.

Here, the deliverability of the displayed dose distribution is guaranteed by considering two spot lists: a raw spot list, W_{raw}, and a post-processed spot list W_{proc}. When interacting with the dose distribution, W_{raw}, is used to determine the contribution of each spot to the selected location, and it is W_{raw}, which is updated in response. This spot list is then copied to W_{proc} in which spots below $w_{\min}$ are rounded up to the minimum deliverable spot weight (where they are $> 0.5\, w_{\min}$) or otherwise set to zero. The displayed dose is based on W_{proc}, such that the displayed dose distribution is deliverable.

In W_{raw}, spot weights are limited to $> 0.1\, w_{\min}$. These spots are set to zero during the post processing step (as they are $<0.5\, w_{\min}$) and as such do not contribute to the dose distribution but are not irreversibly removed from W_{raw}.

2.6 Performance optimisation

To ensure that user interaction with the tool is responsive a number of actions are taken. Firstly, dose calculation using the updated spot list is only performed for the displayed CT slice, rather than the whole dose distribution. When the user scrolls to another slice the displayed dose is updated based on the current values. One consequence of this is that although DVHs are displayed, DVH calculation is not performed in the same time frame, as it requires calculation of the dose to each voxel in the selected ROIs. The DVH display is updated whenever the user hovers over the display and is displayed with dashed lines whenever they are outdated. Secondly, a smaller calculation volume, cropped to the relevant volume is used to reduce the size of the influence matrix by reducing the number of voxels considered (see e.g., Figure 1 compared to the dose distribution from the TPS shown for case 1 in table 2). Finally, where possible, operations are parallelised, and the code uses just-in-time compilation using Numba [1] to speed up the dose calculation.

2.7 Integration with existing planning pathways

Once a satisfactory dose distribution is achieved, the modified spot weights can be exported to a file. This file is then read by a script in the TPS which sets the spot weights in the plan to the exported values. Plan specific header information is provided to ensure that the data is correctly associated. From this point, the plan in the TPS is indistinguishable from one produced through conventional optimisation approaches and can proceed to treatment using existing planning pathways.

2.8 Clinical example cases

Proof of principal has been demonstrated using 6 patient cases covering a range of treatment indications. Details are shown in table 2. Patient data were anonymised and used with consent.

3 Results

The response time, measured as the time from registering a click on a point in the dose distribution to displaying the updated dose distribution for each plan is shown in table 2. For the 6 cases evaluated, response times of between 118-364 ms were measured. In all but one case (case 5) the response time is <175 ms such that the interaction to the user is perceived as being near instantaneous.

DVH calculation, which is implemented with the calculation of dose to all voxels that are contained within the selected structures takes longer and is dependent on the total volume of the selected structures.

RAM usage is considerably reduced using sparse arrays. This additionally enables larger dose calculation volumes to be considered with fixed resources.

The software supported fast and intuitive interaction for all cases and modified spot weights were successfully reimported back to the TPS.

4 Discussion

The tool presented here proposes a method of improving PBS proton treatment plans that is both fast and intuitive.

There remain a number of options to improve calculation times. In this proof of principle, calculation is done using CPU and does not exploit GPU acceleration. Implementation in an alternative programming language may also provide some performance benefits.

In this implementation, the dose resolution is matched to the CT resolution, but this could be lowered, reducing the size of the influence matrix, and decreasing calculation times.

The influence matrix used here was derived from an analytical dose calculation in Eclipse. However, this could be provided from alternative sources. Direct access to the influence matrix would also provide important workflow

benefits as its reconstruction through scripting can be a time-consuming process. The dose calculation used for the influence matrix determines the accuracy of the resultant dose distribution. For example, if Monte Carlo was used, the interactive dose modification would operate with equivalent accuracy.

The use of sparse arrays has an impact on response time but significantly reduces memory and loading time. The largest impact was seen in case 5 where the response time increased from 200±28 ms to 364±4 ms with the use of sparse arrays.

Some optimisation approaches, such as the use of deep learning models, can produce treatment plans without the need for objective functions [2]. However, if clinical requirements are not fully met additional postprocessing is required to modify them. Further optimisation approaches that do not use objective functions could also be envisioned.

Other interactive approaches to planning have been demonstrated in clinical practice. Graphical optimisation has been demonstrated in brachytherapy treatment planning where users can drag isodose lines and the required dwell times for brachytherapy sources is calculated [3]. Compared to PBS, where there may be several thousand spots, there are typically a more limited number of dwell positions in this context as well as there being a simpler description of dose distribution making the problem for brachytherapy more tractable than in proton therapy.

Multi-criteria optimisation (MCO) approaches have also been demonstrated [4] with the use of sliders to adjust plans and explore planning trade-offs. In contrast to MCO, the approach proposed here does not require specific structures or objectives to be defined up front and does not require calculation of a Pareto surface. It allows for more direct control over how and where a plan is changed.

By returning the modified spot weights back to the treatment planning system, the existing treatment planning framework including critical safety checks, plan evaluation, robustness analysis, and treatment preparation can be used.

Future development will focus on: evaluating and quantifying potential time savings or improvements in plan quality; assessing user experience; exploring at what stage in the planning process it may be most effective to employ such a tool; and combination with automated planning approaches to enable such technologies to be clinically implemented more widely.

5 Conclusion

A proof of principle implementation of an interactive dose modification tool has been presented. It is capable of changing existing PBS proton treatment plans both quickly and intuitively.

This approach may complement existing automated planning approaches to simplify treatment planning as well as enabling the introduction of automation approaches that do not yet exceed the capabilities of human generated plans and require some modification.

Table 2. Patient cases. Response time reflects the time from registering a click in the dose distribution to displaying the updated dose. Transverse slices from the treatment planning system are shown. RAM usage reflects the peak value during use of the software.

ID			Appearance
1	Indication	Base of skull chondrosarcoma		Number of spots	1225	
	Response time	118 ± 1 ms	
	Sparse array size	250 Mb	
	RAM usage	1720 Mb	
	No. of voxels	111(x)×96(y)×76(slices)	
2	Indication	Posterior fossa ependymoma		Number of spots	2335	
	Response time	134 ± 4 ms	
	Sparse array size	791 Mb	
	RAM usage	4600 Mb	
	No. of voxels	131×115×120	
3	Indication	Embryonal rhabdomyosarcoma of the maxillary sinus		Number of spots	4076	
	Response time	157 ± 3 ms	
	Sparse array size	793 Mb	
	RAM usage	5320 Mb	
	No. of voxels	132×137×57	
4	Indication	Adenocarcinoma of the sphenoid sinus		Number of spots	2444	
	Response time	122 ± 1 ms	
	Sparse array size	526 Mb	
	RAM usage	2210 Mb	
	No. of voxels	106×106×38	
5	Indication	Nasopharyngeal carcinoma		Number of spots	16942	
	Response time	364 ± 4 ms	
	Sparse array size	2070 Mb	
	RAM usage	21770 Mb	
	No. of voxels	168×129×88	
6	Indication	Mediastinal Rhabdomyosarcoma		Number of spots	6109	
	Response time	172 ± 2 ms	
	Sparse array size	1210 Mb	
	RAM usage	8620 Mb	
	No. of voxels	121×139×64

Abstract Reducing proton therapy delivery time can improve patient comfort, but must be balanced against clinical goals and treatment plan quality. We propose a method to improve the delivery efficiency of proton therapy by simultaneously reducing the number of spots and energy layers using reweighted l_1 regularization. We formulate the treatment planning problem as a convex optimization problem with an objective consisting of a dosimetric plan quality term plus a weighted l_1 regularization term. We then iteratively solve this problem and adaptively update the regularization weights to promote sparsity of the spots and layers. To assess our method's effectiveness, we compare its performance on four head-and-neck cancer patients against standard l_1 and group l_2 regularization methods. Reweighted l_1 regularization reduces the number of spots and energy layers by 40% and 35%, respectively, with minimal cost to dosimetric plan quality. In addition, it provides a better trade-off between plan delivery efficiency and plan quality than standard l_1 or group l_2 regularization, requiring the lowest cost to quality to achieve a given level of efficiency.

1 Introduction

During intensity modulated proton therapy (IMPT), protons are delivered spot-by-spot within each energy layer and layer-by-layer with each beam. The total plan delivery time is approximately equal to the total energy layer switching time, spot travel time, and dose delivery time [1, 2]. We seek to reduce IMPT delivery time by reducing the number of spots and energy layers. A shorter treatment time improves patient comfort, increases patient throughput, and decreases the risk of error due to intra-fractional motion. At the same time, we want to ensure the quality of the treatment plan remains uncompromised.

One approach to this problem is to solve the proton treatment planning problem with a regularization function that encourages sparsity (i.e., zero values) in the spot intensities and energy layers. Common sparsity-inducing regularizers include the l_1 norm [3–5] and the group l_2 norm [1, 6–8]. However, l_1 regularization only promotes sparsity of the spots, but not the energy layers, while group l_2 regularization promotes sparsity of the layers, but results in a denser spot vector. In this study, we propose a reweighted l_1 regularization method that *simultaneously* reduces the number of nonzero spots and energy layers, while upholding dosimetric plan quality and providing a better trade-off between plan quality and delivery efficiency than either l_1 or group l_2 regularization.

2 Materials and Methods

2.1 Problem Formulation

Let m be the number of voxels in the patient's body, n the number of spots, and G the number of energy layers. For a given spot intensity vector $x \in \mathbf{R}^n$, the dose delivered per voxel is $d = Ax$, where $A \in \mathbf{R}_+^{m\times n}$ is the dose influence matrix. We want to choose x so the deviation between d and a prescribed dose $p \in \mathbf{R}_+^m$ is low; this deviation is represented by the plan *cost function*

$$f(\overline{d},\underline{d}) = \overline{w}\|\overline{d}\|_2^2 + \underline{w}\|\underline{d}\|_2^2, \tag{1}$$

where $\overline{d} := (d-p)_+$ is the overdose, $\underline{d} = (d-p)_-$ is the underdose, and $\overline{w}, \underline{w} \in \mathbf{R}_+^n$ are weight parameters.
Simultaneously, we wish to reduce the plan delivery time (i.e., increase delivery efficiency), which is positively correlated with the number of nonzero spots and energy layers in the treatment plan [1, 9]. Thus, we introduce a *regularization function* $r : \mathbf{R}^n \to \mathbf{R}$ that penalizes x in a way that decreases the number of nonzero spots/layers, and define the proton treatment planning problem to be

$$\begin{aligned} \text{minimize} \quad & f(\overline{d},\underline{d}) + \lambda r(x) \\ \text{subject to} \quad & Ax - \overline{d} + \underline{d} = p, \quad Bx \le c \\ & x \ge 0, \quad \overline{d} \ge 0, \quad \underline{d} \ge 0 \end{aligned} \tag{2}$$

with respect to $x, \overline{d}$, and $\underline{d}$, where B and c are constants used to express linear dose constraints (e.g., mean/max dose upper bounds). The regularization parameter $\lambda \ge 0$ controls the trade-off between dosimetric plan quality, represented by plan cost $f(\overline{d},\underline{d})$, and delivery efficiency, captured by the regularization term $r(x)$. A larger value of λ places more importance on efficiency.

2.2 Reweighted l_1 Method

An ideal choice of r would be the l_0 norm, or cardinality function, which directly penalizes the number of nonzero spots or energy layers. Unfortunately, the cardinality is nonconvex and computationally expensive to evaluate. Popular convex approximations also have flaws: the l_1 norm promotes sparsity of the spots, but not the energy layers, while the group l_2 norm promotes sparsity of the layers, but encourages even denser spots.

In this section, we introduce the reweighted l_1 regularization method [10], which simultaneously promotes sparsity in both the spots and the energy layers. Let $\mathscr{I}_g$ be the set of indices of the spots in layer g. Define the *weighted group l_1 regularizer*

$$r_3(x;\beta) = \sum_{g=1}^{G} \beta_g \sum_{i\in\mathscr{I}_g} |x_i| \tag{3}$$

with weight parameters $\beta_g \in \mathbf{R}_+ \cup \{+\infty\}$ for $g = 1,\ldots,G$. An intuitive way to set β_g is to make it inversely proportional to the optimal intensity of energy layer g, so that each spot contributes about equally to the total regularization penalty, similar to the cardinality regularizer. However, since we do not know the optimal layer intensity, we will approximate this weighting scheme via an iterative method.
Let the initial weights $\beta^{(1)} = \mathbf{1}$. At each iteration $k = 1,2,\ldots,$

1. Set $x^{(k)}$ equal to a solution of Problem 2 with $r(x) := r_3(x;\beta^{(k)})$.

2. Calculate the total intensity of each energy layer $e_g^{(k)} = \sum_{i\in\mathscr{I}_g} x_i^{(k)}$, where $\mathscr{I}_g$ is the set of indices of the spots in layer g.

3. Apply a lower threshold to the energy layer intensities to get

$$\tilde{e}_g^{(k)} = \max(e_g^{(k)}, \varepsilon^{(k)}), \quad g = 1,\ldots,G,$$

where $\varepsilon^{(k)} = \delta \cdot \max_{g'} e_{g'}^{(k)}$ for some small $\delta \in (0,1)$.

4. Update the weights. First, compute the standardized reciprocals

$$\alpha_g^{(k)} = \left(\frac{1}{\tilde{e}_g^{(k)}}\right) \Bigg/ \left(\sum_{g'=1}^{G} \frac{1}{\tilde{e}_{g'}^{(k)}}\right), \quad g = 1,\ldots,G. \tag{4}$$

Then, calculate the scaling term

$$\lambda^{(k)} = \sum_{g=1}^{G} \tilde{e}_g^{(k)} \Bigg/ \left(\sum_{g=1}^{G} \alpha_g^{(k)} \tilde{e}_g^{(k)}\right). \tag{5}$$

The new weights are $\beta_g^{(k+1)} = \lambda^{(k)} \alpha_g^{(k)}$.

5. Terminate on convergence of the objective, or when k reaches a maximum number of iterations.

In practice, the number of reweighting iterations needed is typically very low, with most of the improvement coming from the first $k = 2$ to 3 iterations.

2.3 Computational Framework

We implemented the l_1, group l_2, and reweighted l_1 treatment planning methods in Python using CVXPY [11–13] and solved the optimization problems with MOSEK [14]. Then, we compared the performance of the methods on four head-and-neck patients from The Cancer Imaging Archive (TCIA) [15, 16]. For the sake of brevity, we present detailed figures for a single representative patient (2) below, and summarize results for all patients in Tables 1 and 2 at the end of the paper.

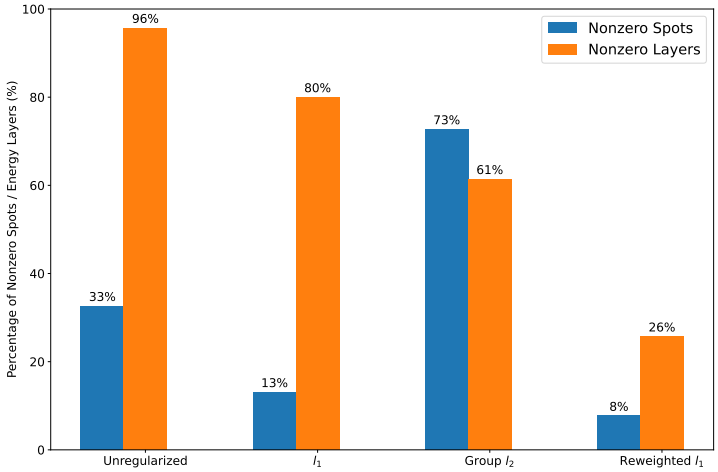

Figure 1: Percentage of nonzero spots/energy layers (relative to the total) for the unregularized model and the l_1, group l_2, and reweighted l_1 regularized models ($\lambda = 5$).

3 Results

3.1 Reduction in Spots and Energy Layers

Figure 1 summarizes the results from the different regularization methods using $\lambda = 5$. Without regularization, one-third of the total 7011 spots and nearly all of the 70 energy layers are nonzero. Standard l_1 regularization drastically sparsifies the spot intensity vector, but the percentage of nonzero layers remains high at 80%, while group l_2 regularization does the opposite, decreasing the number of nonzero energy layers, while significantly *increasing* the number of nonzero spots to 73%. Only reweighted l_1 regularization reduces both the number of nonzero spots and energy layers, resulting in a treatment plan with just $541(8\%)$ nonzero spots and $18(26\%)$ nonzero layers – significantly lower than all the other methods.

3.2 Delivery Efficiency versus Plan Quality

To analyze the trade-off between delivery efficiency and treatment plan quality, we plot the relative (percentage-wise) change in the number of nonzero spots/energy layers versus the relative change in plan cost (Equation 1) with respect to the unregularized solution. These Pareto optimal trade-off curves are shown in Figures 2 and 3 for l_1, group l_2, and reweighted l_1 regularization. In Figure 2, both l_1 and reweighted l_1 curves drop sharply from the origin, attaining a $> 45\%$ decrease in nonzero spots for a $< 10\%$ increase in plan cost, with reweighted l_1 outperforming l_1 by about 5 percentage points. Group l_2 regularization performs worst

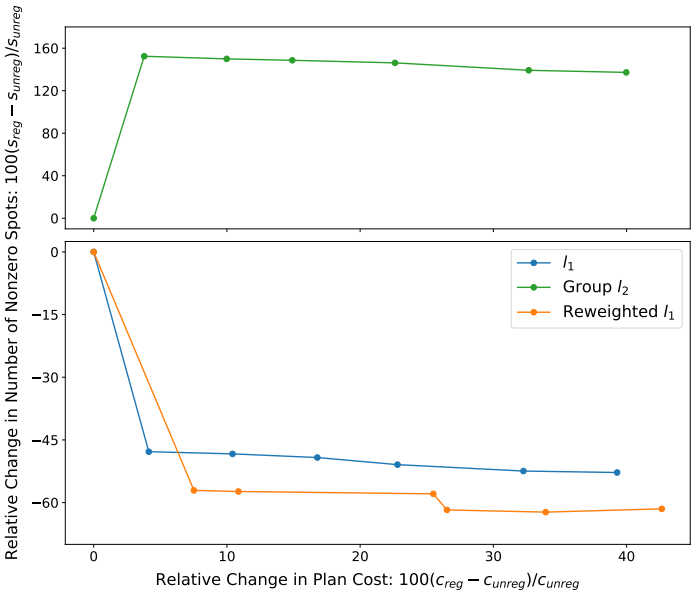

Figure 2: Relative change in number of nonzero spots versus relative cost to plan quality with respect to the unregularized plan. Each point corresponds to a different value of λ for the specified regularization method; the origin is $\lambda = 0$.

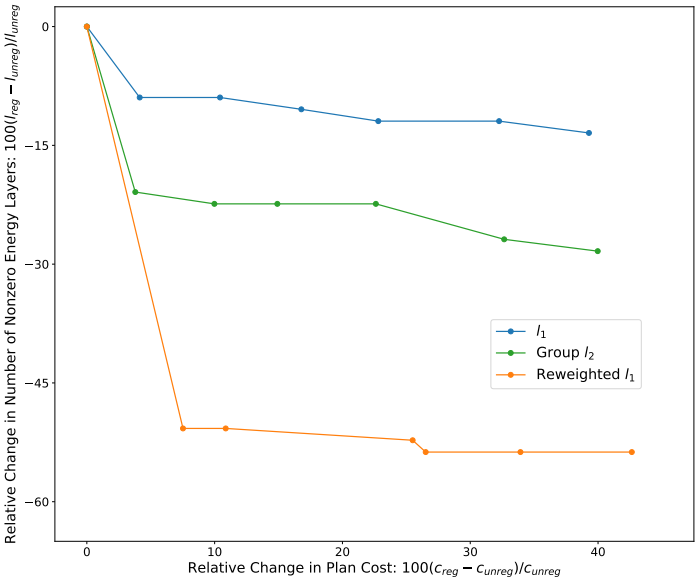

Figure 3: Relative change in number of nonzero energy layers versus relative cost to plan quality with respect to the unregularized plan.

of all, increasing both the number of nonzero spots and plan cost, as indicated by the inverted trade-off curve.

All three regularization methods reduce the number of nonzero energy layers with modest cost to plan quality, as depicted in Figure 3. For an 8% to 10% increase in plan cost, l_1 obtains a roughly 8% drop and group l_2 a 20% drop in nonzero layers. However, reweighted l_1 significantly outperforms both these regularizers, achieving a $> 50\%$ decrease in the number of nonzero layers for a $< 10\%$ increase in plan cost. Overall, it is clear the reweighted l_1 method provides the best trade-off between delivery efficiency and treatment plan quality. The resulting dose-volume histogram (DVH) curves (Figure 4) are similar to the unregularized plan, obtained with only a fraction of the number of nonzero spots and energy layers.

4 Discussion

In this brief paper, we have not presented calculations of the plan delivery time because it requires machine-specific parameters such as dose rate, energy layer switching time, and spot travel time. We have also not enforced the minimum-monitor-unit constraint, although this can be done by combining reweighted l_1 regularization with the two-step optimization method described in [8]. In general, our reweighted l_1 method is agnostic to the optimization framework and can be used in conjunction with an automation tool (e.g., hierarchical optimization [17]). It can also be integrated into existing techniques in the literature to handle DVH constraints [18–20] and plan robustness requirements [21, 22], making it a highly flexible algorithm.

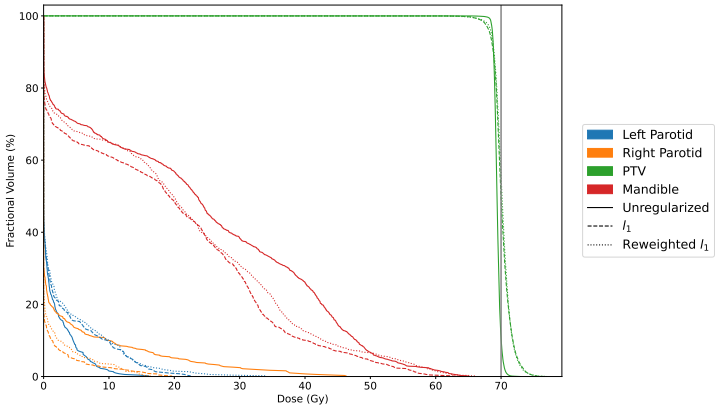

Figure 4: DVH curves obtained from the unregularized model (solid), and the standard l_1 (dashed) and reweighted l_1 (dotted) models regularized to 10% relative cost to plan quality (with $\lambda = 1.325$ and $\lambda = 0.3$, respectively). The vertical gray line indicates the prescription $p = 70$ Gy. Group l_2 curves were omitted because they largely overlap with l_1, but the corresponding plan demands a $> 55\%$ increase in the number of nonzero spots.

5 Conclusion

The reweighted l_1 regularization method is capable of simultaneously reducing the number of spots and energy layers in a proton treatment plan, while imposing minimal cost to dosimetric plan quality and achieving a better trade-off between delivery efficiency and plan quality than standard l_1 and group l_2 regularization.

Supplemental Data

Patient	l_1	Group l_2	Reweighted l_1
1	−38%	40%	−41%
2	−49%	150%	−57%
3	−30%	80%	−33%
4	−24%	91%	−27%

Table 1: Relative change in number of nonzero spots at a relative change in plan cost of 10% with respect to the unregularized plan.

Patient	l_1	Group l_2	Reweighted l_1
1	−5%	−5%	−37%
2	−8%	−23%	−50%
3	−6%	−9%	−31%
4	−7%	−5%	−25%

Table 2: Relative change in number of nonzero energy layers at a relative change in plan cost of 10% with respect to the unregularized plan.

Abstract

Purpose

Radiation Therapy (RT) is known to modulate the immune system and contribute to the generation of anti-tumor T cells stimulating T cell infiltration into tumors. However, this anti-tumor activity is offset by radiation-induced immunosuppression (RIIS). Lymphocytes, (80% are T cells) are highly radiosensitive and RIIS means destroying existing as well as newly created T lymphocytes. Optimizing RT treatment planning by considering circulating blood and lymphatics as a critical organ at risk may mitigate RIIS and lead to the preservation of cytotoxic T lymphocytes converting the tumor from an immunologically cold to a hot environment increasing the efficacy of immunotherapy. In this paper, we present an algorithm to predict RIIS based on a model of circulating blood and lymphatics using advanced stage lung cancer patients treated with radiation therapy and its utilization in ameliorating immune suppression.

Methods

We have developed a Python-based algorithm that uses DICOM data for radiation therapy treatment plans, dose maps, patient CT data sets, and organ delineations to stochastically simulate blood flow and lymphatic flow and predict the doses absorbed by circulating lymphocytes. These absorbed doses are used to predict the fraction of lymphocytes killed by a given treatment plan. This predictive model was used on a cohort of 35 retrospective advanced-stage NSCLC patients to reduce immune suppression via treatment planning. Clinical Goals were created per LU 001.

Results

The RIIS predictive model had 78% of the patients having a immune cell kill difference between the prediction and the measurement less than $0.2x10^9$ cells/L.

Reduction of immune suppression via re-planning with the aid of the predictive algorithm showed varying amounts of immune system sparing and as much as 21.4% (kill % decreases from 78.2% to 56.8%).

Conclusions

Our model performed well in predicting RIIS in patients treated using standard fractionation to lung. It has the capability to be interfaced with treatment planning systems to prospectively reduce immune cell toxicity while maintaining national LU001 conformity and plan quality criteria.

1 Introduction

Approximately one third of patients with non–small-cell lung cancer (NSCLC) have stage III, locally advanced disease at diagnosis (1). The standard of care for patients with a good performance status and unresectable stage III NSCLC is platinum-based doublet chemotherapy concurrent with radiotherapy (CRT)(2). However, the median progression-free survival among patients who have received CRT is poor (approximately 6 months), and only 15% of patients are alive at 5 years (1)(3). PACIFIC trial (4)(5) was a phase 3 study which looked at the efficacy of immunotherapy (Durvalumab), an anti-PDL1 antibody, after CRT in Stage III non-small-cell lung cancer. With 709 patients enrolled in the trial, they observed a markedly increase in progression-free survival with Durvalumab compared to placebo with a median survival of (16.8 months (95% confidence interval [CI], 13.0 to 18.1) with Durvalumab versus 5.6 months (95% CI, 4.6 to 7.8) with placebo) changing the standard of care from CRT alone to immunotherapy following CRT. The PACIFIC trial demonstrated an OS advantage for all patients, regardless of PD-L1 status, with the addition of durvalumab (6).

Ionizing radiation (IR) has a variety of acute and long-lasting adverse effects on the immune system. Lymphocytes are among the cell types most sensitive to radiation-induced injury. It is well known that T cell death occurs within hours after irradiation (interphase death) (7)(8), and that IR also has long-term adverse effects on T cell immunity (9)(10)(11)(12).

The purpose of this work was to develop a model that predicts RIIS for advanced stage lung cancer treated with radiation therapy by estimating the dose delivered to circulating blood lymphocytes. We aimed to develop this model to interface with treatment planning systems (based on DICOM format) and generate fast predictions to augment decision making during treatment planning. Reduction of immune suppression via a predictive algorithm will benefit the treatments of immunotherapy in combination with radiotherapy.

2 Materials and Methods

Simulation Study: We have developed a comprehensive model, using Python software, to predict the immune suppression from lung SBRT on a patient specific manner. This predictive model is dynamic with the blood circulation intertwined with the lymphatic flow for all organs encompassing a region of interest up to a very low threshold dose of 40 cGy per fraction. It has been reported that 50 cGy is a threshold for lymphocyte kill (13) The interplay between time dependent RT delivery and the movement of blood and lymphatics, and lymphocyte osmosis between the blood flow, primary (bone marrow, thymus)/secondary lymphoid organs (lymph nodes, spleen, lymphatic vessels) as well as non-lymphoid organs (liver, lung, etc) were modeled as discussed below based on literature (14 – 19). After each radiation fraction, dose accumulation to lymphocytes in all above organs including circulating blood is modeled as follows. For each patient

included in the study, radiation therapy treatment plans, CT planning image sets, dose maps per each treatment field, delivery times, and the structure sets were accessed and imported into the simulation model via DICOM import to obtain the organ specific doses for each voxel of that organ. The dose delivered to the organs was obtained by applying a logical mask to the delivered dose map, the dose for each of these structures was applied while avoiding leakage into other organs. Blood circulation in the human body is a much faster process than lymphatic flow with very different cardiac outputs (20) and flow velocities for organs such as heart, aorta, vena cava, pulmonary artery, lung, liver, and other organs. This was simulated using the following: (i) varying blood flow levels to organs (20), great vessels, and heart (21), total blood volume of 5L (22) were taken from published literature. (ii) each treatment field was delivered within a variable time depending on the total delivered beam on time for that field and the dose rate of the energy used. In the model the dose was applied in time steps to the blood matrix and the blood matrix was rotated to simulate blood flow through the body. Following each treatment field blood was randomly mixed with the remaining blood. The circular shifting of the blood matrix using cross sectional area provided a method to simulate blood flow through complex organ shapes while ensuring accuracy over the course of an entire treatment. We have modeled the lymphocyte osmosis from organs to blood in the non-equilibrium state by a set of equations that is updated every 6 hrs. The flow rates (k_(blood,) k_s, k_BM,k_LN) are fractional flow rates of lymphocytes going away from the organs: blood, spleen, bone marrow, other organs, and lymph nodes. Since these are fractional flow rates the actual flow rates depend on the number of lymphocytes residing in a given organ at any given time. Therefore, this defines the time dependence on lymphocytes following RT. Depending on the organs that receive lymphotoxic doses, other organ's flow rates will try to establish equilibrium conditions. We used a linear-quadratic model (LQ model), of the form: K(D)=1-exp (-α D-β D^2) for lymphocyte kill with radiation. The two parameters, α and β, were fixed using the invitro measurements by Nakamura (23). This model predicts 15% kill for a dose of 0.5 Gy, 67% kill for a dose of 2 Gy, and 90% kill for a dose of 3 Gy. Taking into account all the radiation losses of lymphocytes, and the rate of addition of new lymphocytes into the blood stream, the model calculates a prediction for the number of lymphocytes left in the blood stream at any given time. Finally, a X^2 minimization was performed on the difference between the simulated and measured percent lymph kill to tune the model.

Replanning to Reduce RIIS Study: For the above advanced-stage NSCLC patients, new radiation therapy plans were created to spare the dose to aorta, thoracic spine, vena cava, pulmonary arteries, heart, and lymph nodes with the aid of the predictive algorithm. Dosimetric comparisons were made between the 3D, IMRT, VMAT plans that were delivered without consideration to the blood rich and immune rich organs, and the plans we designed to intentionally reduce dose to organs at risk that are important in reducing radiation induced immune suppression. Clinical Goals were created per NRG LU 001. RIIS reduction comparisons were quantified using the predictive algorithm.

3 Results

Simulation Study: Two examples of RIIS prediction to measurement in advanced stage lung cancer are given below. i) Top Figure 1 is a PTV of 274 cc with 200 cGy x 33 fractions leading to a post treatment absolute lymphocyte count (ALC) of 0. 37x10^9 cells/L, while the prediction was for a 0.53x10^9 cells/L. ii) Bottom Figure 1 is a PTV of 818 cc with 250 cGy x 15 fractions leading to a post treatment absolute lymphocyte count (ALC) of 0. 93x10^9 cells/L, while the prediction was for a 0.81x10^9 cells/L.

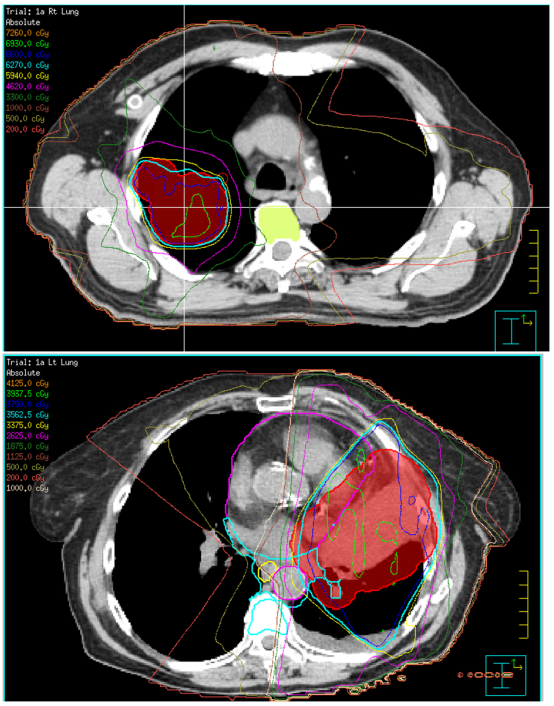

Figure 1: PTV comparison between two advanced-stage lung cancer patients.

Replanning to Reduce RIIS Study: In all cases, whether it is 3D dosimetry or IMRT, there is significant sparing of blood rich organs such as heart (in pink), lymph rich organ such as lymph nodes (in purple), and bone marrow rich thoracic spine (in green). In Figure 2 below, new optimized plan is in the left hand side (and squares in DVH), and the original plan is in the right hand side (triangles in DVH).

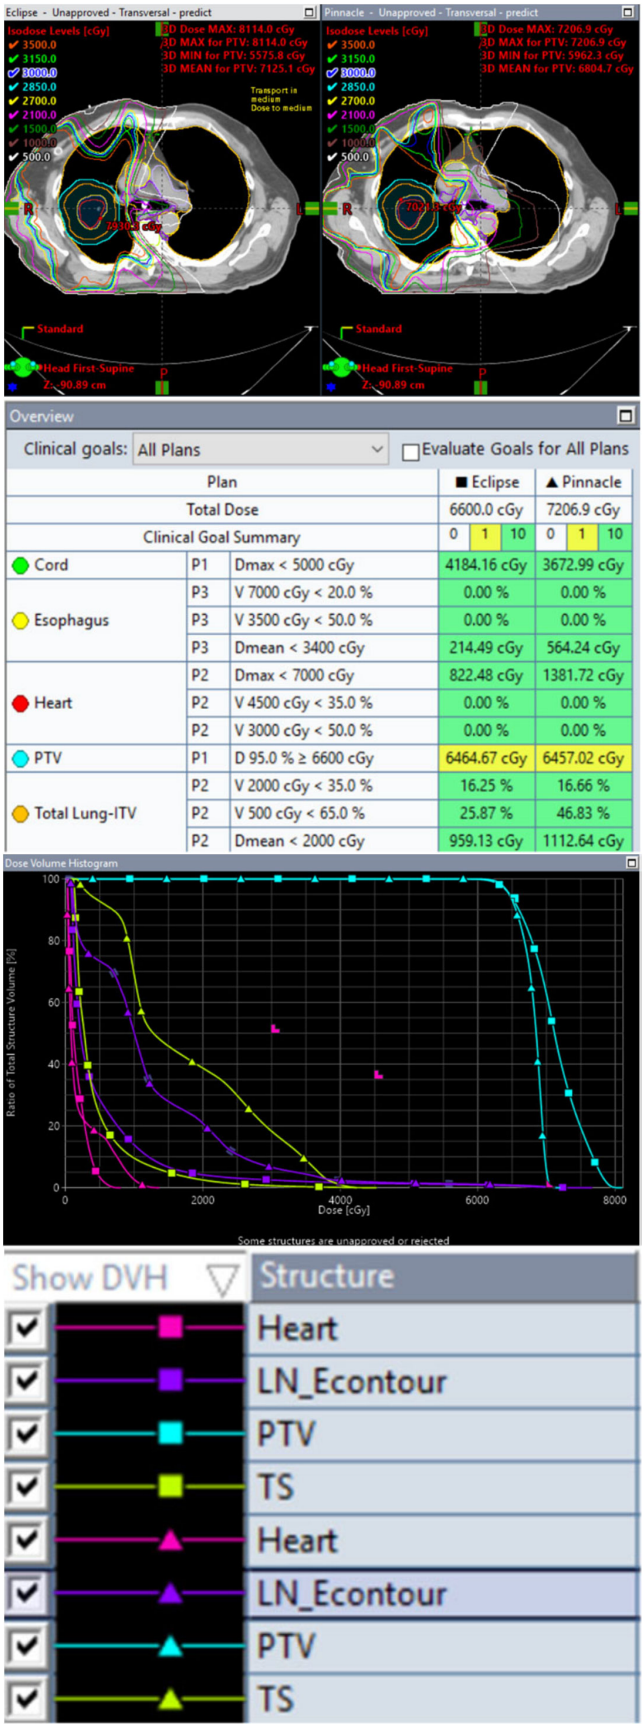

Figure 2: Dosimetric sparing of immune rich OAR in advanced stage lung cancer

Reduction of immune suppression via re-planning with OAR optimization criteria lead to varying amounts of immune system sparing according to the predictive algorithm. In some cases as much as 21.4% decrease was observed (kill % decrease from 78.2% to 56.8%) (Figure 3).

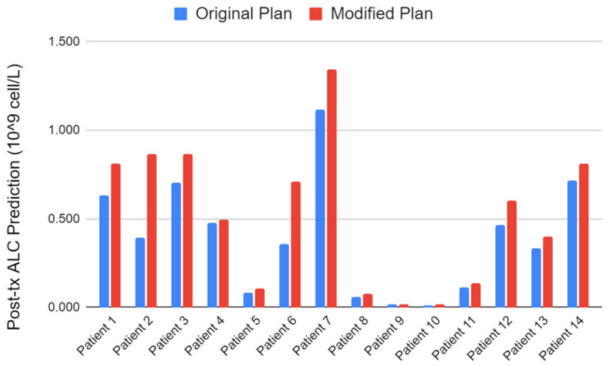

Figure 3: Reduction of immune suppression via re-planning

4 Discussion

In this work, we have presented a model which predicts radiation-induced lymphocyte reduction following radiation therapy to lung by simulating the dose delivered to circulating lymphocytes in the bloodstream and lymphatics. This approach is patient-specific, using three-dimensional dose maps from treatment planning software, varied treatment times, and organ-specific blood flows. Our model predicts initial lymphocyte death using a linear-quadratic survival curve from literature The model could accurately predict post-treatment ALC with 78% of patients having an error below 0.2×10^9 cells/L.

5 Conclusion

We present a model that accurately predicts lymphocyte depletion following RT to Lung as well as the onset of lymphopenia in a cohort of 35 patients under ten-fold cross validation. This model has the capability to be interfaced with treatment planning systems to prospectively reduce immune cell toxicity without compromising treatment efficacy during treatment planning.

Abstract: Voxel-based analysis (VBA), such as radiotherapy dose-response maps (DRM) derived by combining dose-surface maps (DSM) and toxicity outcomes, aims to identify high-risk sub-regions in organs at risk (OARs). The study aims to assess the differences between two different methods of using late toxicities, namely, with and without baseline normalization, for identifying high-risk sub-regions on DRM of the bladder and rectum in prostate cancer (PCa) patients undergoing radiotherapy. The selection of the toxicity analysis method, whether with or without baseline normalization, influences the identification of high-risk sub-regions in DRMs of OARs. Subtracting baseline from post-treatment toxicity grades reduces the effectiveness of the dose-response relationship of bladder and rectum in prostate cancer patients undergoing radiotherapy. This influence is primarily attributed to variations in the number of events available for the analysis of each toxicity as other variables were fixed within the DRM methodology. Further efforts are required to enhance the robustness of the methodology, ensuring the generation of more reliable and reproducible results. These results may have implications for other OARs in other cancer types.

1. Introduction

Different spatial dose patterns are associated with different toxicity outcomes for organs at risk (OARs) post-radiotherapy. Various methods exist to study the dose-toxicity relationship in patients undergoing radiotherapy. Dose constraints based on dose-volume histograms (DVH) **[1]** are commonly employed to strike a balance between effectively treating the tumor while preserving surrounding healthy organs. The DVH analysis is constrained by several assumptions, including but not limited to, the following: consistent dose delivery (implying that the dose is uniformly distributed throughout the target volume), homogeneity of tissue composition (implying uniform radiation absorption within the specified volume), uniform tissue response (implying consistent sensitivity and uniform reaction across all regions within the treated volume to the delivered dose), dose linearity (implying larger doses result in greater tissue response, and vice versa) and volume-effect independence (implying the effects of radiation on distinct tissue volumes are independent).

Voxel-based techniques, such as dose-response maps (DRM) derived from associating dose-surface maps (DSM) and toxicity outcomes **[2]**, aim to identify high-risk sub-regions in OARs, with the future possibility of minimizing dose to such sub-regions during treatment plan optimization **[3-4]**. However, we know that DRM results are affected by the choice of parameter value within the DRM pipeline and the number of events included within the analysis for each toxicity **[5-6]**. However, it is unclear if using different methods of toxicity analysis will change the number of events included in the analysis, affecting the identification of high-risk sub-regions in OARs using DRMs. Therefore, this study aimed to assess the differences between two different methods of analyzing late toxicities, namely, with and without baseline normalization, for identifying high-risk sub-regions on the DRM of the bladder and rectum in prostate cancer (PCa) patients undergoing radiotherapy.

2. Materials and Methods

We analyzed data from 1808 PCa patients enrolled in the REQUITE trial **[7]** who underwent radical radiotherapy and salvage/adjuvant radiotherapy post-prostatectomy. REQUITE stands for validating pREdictive models and biomarkers of radiotherapy toxicity to reduce side effects and improve QUalITy of lifE in cancer survivors. REQUITE was a prospective multicenter cohort study conducted across 26 hospitals in 8 countries between April 2014 and March 2017, with the primary objective of validating predictive models or biomarkers for assessing the likelihood of post-radiotherapy toxicities in cancer patients.

The rectum and bladder were segmented on planning computed tomography (CT) scans using ADMIRE software (ELEKTA, Sweden). Bladder and rectum DSMs were unwrapped using spherical and cylindrical coordinates, respectively **[6]**, and spatially normalized with a fixed-sized voxel grid of 91 rows and 90 columns. Doses were converted to equivalent doses in 2 Gy fractions (EQD2) with α/β ratios of 1 Gy **[6, 8]**.

We assessed 17 Clinician-rated Common Terminology Criteria for Adverse Events (CTCAE) late toxicities (including proctitis, perforation, bowel obstruction, fistula, bowel stenosis, bowel ulceration, diarrhoea, flatus, rectal bleeding, management of sphincter, haematuria, urinary

tract obstruction, urinary incontinence, urinary frequency, urinary urgency, urinary retention, and bowel fistula) and 21 patient-reported scores through prostate-specific pelvic symptoms (including pain lower tummy, pain open bowels, pain urine, urgency bowels, urgency bowels unable, bowel control, bladder control, urgency urine, urinary frequency, urinary flow, diarrhoea, constipation, urine night (i.e., Nocturea - frequently having to get up in the night to pass urine), blood urine, blood bowels, sticky slimy motions, medication for blood urine, medication for blood bowel, medication for diarrhoea, medication for constipation and medication for bladder (i.e., to control overactive bladder)) obtained at 12 or 24 months.

Two methods were used for the toxicity analysis. In the first method, the maximum of the 12- and 24-month toxicities was normalized by subtracting the baseline toxicity value and then dichotomized at grade 1 to obtain binary toxicity outcomes (0's & 1's). In the second method, the maximum of the 12- and 24-month toxicities was used (without normalization) and dichotomized at grade 1 to obtain binary toxicity outcomes (0's & 1's).

We categorized the DSMs into two groups based on dichotomized toxicity values. Welch's T-test was conducted voxel-wise across the 8190-voxels locations over two stacks of images to obtain a 2D-image of t-values (i.e., a T-map), assuming a normal distribution and based on the null hypothesis that the two populations have equal means, even when the two samples exhibit unequal variances and sample sizes. To address multiple comparisons, permutation testing was performed with 1000 iterations. The maximum T-value over the entire image (called Tmax) was obtained for each of the 1000 iterations. These Tmax values were then thresholded at the 95th percentile (corresponding to an adjusted *P*-value=0.05). This threshold was utilized to threshold T-map for true labels to identify statistically significant voxels to obtain a DRM. Figure 1 illustrates the DRM generation pipeline.

Datasets were excluded if the baseline or 12- and 24-month toxicities were missing, the dose or CT files were absent, the ADMIRE failed to segment rectum or bladder regions, the DSM visually appeared incorrect, the patient received brachytherapy, the difference between the prescribed dose and image-based mean prostate dose was more than ±10%, or the fractionation data was missing.

3. Results

3.1. The results presented here are only for CTCAE-based late toxicities due to space limitations. Bladder and rectum DRMs showed associations with CTCAE-based bladder-related toxicities but not with rectum-related toxicities.

For the bladder, toxicities such as urinary incontinence (Figure 2), urinary tract obstruction (Figure 3), urinary retention (Figure 4) and urinary urgency (Figure 5) showed significant regions highlighted on the DRMs (as shown by the blue color contour in these images). All four DRMs showed significant regions without baseline toxicity normalization, but only the former two showed significant regions with normalization. For the rectum, toxicities such as urinary incontinence (Figure 6), urinary tract obstruction (Figure 7) showed significant regions highlighted on the DRMs. The former only showed significant regions only without baseline toxicity normalization, but the latter showed significant regions for both types of toxicity analyses, with and without normalization.

3.2. Urinary incontinence (Figure 2) and urinary tract obstruction (Figure 3) toxicities for bladder DRMs and urinary tract obstruction (Figure 7) for rectum DRMs, highlighted statistically significant regions that were approximately concentric (but of different sizes) for the two different methods of toxicity analyses, suggesting that the difference in the highlighted regions may be due to the number of events included in the analyses, as other parameters were kept fixed. The toxicity analysis methods without baseline normalization led to an increase in the number of events compared to the other methods with baseline normalization, and therefore larger significant regions were identified without baseline toxicity normalization compared to the other method, as previously reported **[5-6]**.

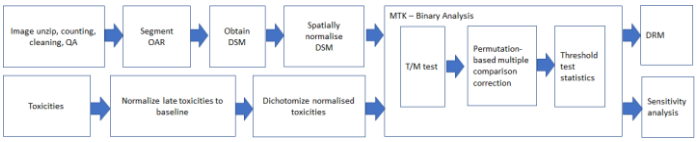

Figure 1. Dose-response maps (DRMs) methodology. Arrows describe the direction of operation. QA=quality assurance; OAR=organs-at-risk; DSM=dose-surface maps; MTK=Manchester tool kit; T/M=Welch t-test.

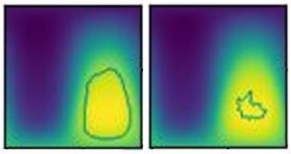

Figure 2. Urinary incontinence: **spherical** unwrapping for **bladder** dose-surface maps, α/β=1, 91x90 voxel grid, t-test, 1000 iterations, and 95th percentile. Without (left: **361** events) and with (right: **226** events) baseline normalization. Colors represent mean radiation dose over all patients included in the analysis for this toxicity type, with yellow indicating the highest dose, followed by green, blue, and black for decreasing dose magnitudes. Significant values are within the drawn contour on these images.

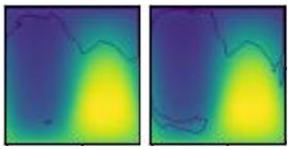

Figure 3. Urinary tract obstruction: **spherical** unwrapping for **bladder** dose-surface maps, α/β=1, 91x90 voxel grid, t-test, 1000 iterations, and 95th percentile. Without (left: **93** events) and with (right: **82** events) baseline normalization.

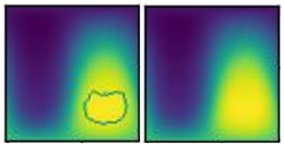

Figure 4. Urinary retention: **spherical** unwrapping for **bladder** dose-surface maps, α/β=1, 91x90 voxel grid, t-test, 1000 iterations, and 95th percentile. Without (left: **104** events) and with (right: **82** events) baseline normalization.

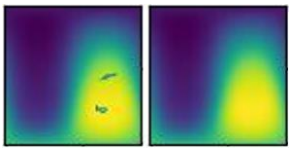

Figure 5. Urinary urgency: **spherical** unwrapping for **bladder** dose-surface maps, α/β=1, 91x90 voxel grid, t-test, 1000 iterations, and 95th percentile. Without (left: **465** events) and with (right: **286** events) baseline normalization.

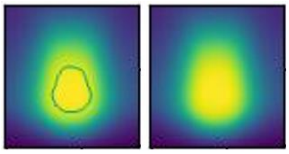

Figure 6. Urinary incontinence: **cylindrical** unwrapping for **rectum** dose-surface maps, α/β=1, 91x90 voxel grid, t-test, 1000 iterations, and 95th percentile. Without (left: **361** events) and with (right: **226** events) baseline normalization.

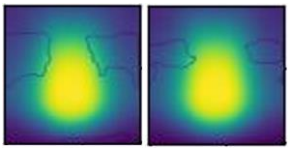

Figure 7. Urinary tract obstruction: **cylindrical** unwrapping for **rectum** dose-surface maps, α/β=1, 91x90 voxel grid, t-test, 1000 iterations, and 95th percentile. Without (left: **93** events) and with (right: **82** events) baseline normalization.

4. Discussion

4.1. Urinary incontinence and urinary tract obstruction toxicities highlighted significant regions on the DRMs of both the bladder and rectum. Urinary retention and urinary urgency toxicities only highlighted significant regions on the bladder's DSM. Therefore, it currently remains unclear if toxicities such as urinary incontinence and urinary tract obstruction occur as a result of the combined effect of radiation damage to both the rectum and bladder, or whether the regions identified on the rectum for urinary incontinence (which only showed significant regions without normalization) and for urinary tract obstruction (which showed significant regions for without and with normalization) are false positives, as the bladder-related toxicities are identified on rectum DRMs.

Test statistics, Tmax, is just a single extreme value property obtained from 8190 T-values from the image that we subject to further testing by applying 1000 permutations. Only the 1000 permutations count as multiple comparisons. Therefore, it was considered appropriate to call the 95th percentile as *P*-value=0.05 in the sense that 5% of the highest value permutations in the histogram of all 1000 permutations. The motivation for performing permutation testing on Tmax was to lower the *P*-value threshold (to minimise false positives) below the commonly chosen 0.05 level, aiming to account for multiple comparisons by considering the proportion of permutation samples producing a higher Tmax value than the one observed with true labels. However, this adjustment results in a stringent threshold, rendering it inadequate for identifying any significant regions on DRM. For instance, the bladder DSM with normalized urinary tract obstruction toxicity (Figure 3) yielded an adjusted *P*-value << 0.05 (i.e., close to zero) after correcting for 1000 multiple comparisons. This led to the failure to identify any significant region on the DRMs. Therefore, the threshold was adjusted to the 95th percentile to identify the significant voxels on DRMs, raising questions about the need for implementing and using permutation testing in the first place. Moreover, this choice of using a *P*-value threshold of 0.05 may have contributed to the identification of regions on the rectum's DRM for bladder-related toxicities (in figures 6-7), potentially resulting in false positives. Consequently, future studies employing VBA should, with caution **[9]**, consider adopting *P*-value thresholds < 0.05 (i.e., higher than 95th percentile) to minimize the occurrence of false positives when identifying significant regions on DRMs.

These results raise a further question about the validity of VBA applied to the combined datasets from radical radiotherapy and salvage/adjuvant radiotherapy post-prostatectomy and provide a compelling case for re-analysing the data in these two cohorts separately. It is because the two treatment approaches are given with different intent. Radical radiotherapy is given with curative intent and involves delivering targeted doses to the prostate gland to eliminate or shrink cancerous cells and, in some cases, the surrounding tissues. Salvage/adjuvant radiotherapy is given after a prostatectomy, with/without signs of recurrence or persistent cancer cell, intended to treat the remaining cancer cells in the prostate bed to prevent the cancer from spreading/returning. Plausibly, prostatectomy may have had a cascading impact on neural bundles around the prostate, potentially resulting in sexual health-related toxicities, which were excluded from the analysis.

4.2. Bladder DRM for urinary retention (104 events) and urinary urgency (465 events) showed statistically significant regions only for the toxicity analysis without baseline normalization. However, these cases may not be considered false positives as these toxicities are bladder-related toxicities and include a larger number of events. The lack of significant regions in the other analysis with baseline normalization could be due to the lack of events for these toxicities (82 and 286 events for urinary retention and urinary urgency, respectively). Possibly, some toxicity types may need more events to show significant regions on DRMs than other toxicity types, based on the strength of relationship between DSM and the toxicity type under investigation.

Moreover, the fact that there is such a good match among Figures 2, 4 and 5 in the significant regions highlighted near the high dose regions provides independent support that the observed statistically significant relationship between the dose and toxicity is not unrealistic.

Even though the reason for the differences in significant regions identified on OARs between the two methods, without and with normalization, appeared to be due to the number of events involved in the analysis, the minimum number of events required for toxicity to start showing significant regions on the DRMs and well as the maximum number of events required beyond which the identified significant regions on DRM show insignificant differences with the increasing number of events is unknown. Answering such questions requires further research.

4.3. The assumptions behind toxicity normalization were (i) that the DSM will only be associated with the post-radiotherapy toxicities due to radiation damage and that the toxicity at baseline (i.e., pre-radiotherapy) will be excluded from the analysis in identifying the high-risk sub-regions within OARs, and (ii) that the toxicity severity grades are linear in nature, such that the difference between two toxicity grades will produce the same effect; for example, grade 3 minus grade 2 is considered to have the same clinical effect as grade 1 minus grade 0, which may not be true. On the other hand, the toxicity analysis without baseline normalization assumes an exponential characteristic of toxicity grades, such that grade 3 minus grade 2 is considered to have a greater clinical effect than grade 2 minus grade 1, which his considered to have greater clinical effect than grade 1 minus grade 0, representing a more realistic clinical scenario. For further studies, since baseline toxicities are expected to be an important factor for toxicity outcomes post-radiotherapy, for the toxicity analysis without normalization (a more realistic clinical scenario), it may be worth using a toxicity prediction model that includes the baseline toxicities *a priori* within the model (e.g., using multivariable VBA).

4.4. Even though parameter values (such as α/β=1, voxel grid size=91x90, statistical test=Welch T-test, test statistics=Tmax, number of iterations=1000 and threshold=95th percentile used to obtain the DRMs were fixed in the present study, whether the choice of these parameter values is valid for each individual toxicity is a separate question that requires further investigation.

5. Conclusion

The choice of toxicity method (without or with normalization) impacts the identification of high-risk sub-regions on DRMs of OARs. Subtracting baseline from post-treatment toxicity grades reduces the effectiveness of dose-response relationship of bladder and rectum in prostate cancer patients undergoing radiotherapy. Therefore, the details of toxicity utilization as well as the number of events included in VBA for each toxicity type should be reported in the manuscripts for external validation. These results may have implications for other OARs in other cancer types (e.g., heart OAR in lung cancer). More work is needed to achieve a more robust methodology to produce reliable and reproducible results. Future work could combine genomics and dose data for toxicity prediction modelling.

Abstract The heart is believed to be the most critical normal structure responsible for competing events after RT in locally advanced lung cancer patients. A better knowledge of heart substructures' tolerance to RT is essential to define a safe dose escalation protocol and improve patients' overall survival.
Here, we combine a retrospective study to determine dose tolerances for the heart substructures through a prediction model of survival limiting toxicity and a prospective analysis to investigate the pathophysiological process leading to chronic symptoms and major adverse cardiac events.
In silico applications will be adopted to (i) design a decision-making tool for advanced RT patient selection and (ii) test the mechanisms of cardiac dysfunctions.

1 Introduction

Radiation therapy (RT) represents an option for treating lung, lymphoma, oesophagus and breast cancer. For these districts, the partial inclusion of the heart into the medium-high dose region limits the level of curative RT doses and, thus, the treatment success rate [1, 2]. The most robust evidence was reported by the phase 3 trial of RT dose-escalation RTOG 0617 [3], where the median survival for the enrolled lung patients was significantly worse in the higher dose arm. One contributing factor was the dose delivered to the heart.
Along the same line, a mathematical model on 7000 lung patients by Nix [4] showed that up to 20% in 2-year Overall Survival (OS2) gain could be obtained "if normal critical structures in which survival limiting toxicities arise can be identified and selectively spared without compromising the tumour coverage".
The heart is believed to be the most critical normal structure responsible for these competing events, and a better knowledge of its substructures' tolerance to RT is essential. The pathophysiology of radiation-induced heart disease has become more evident in the last decade. However, studies defining the biology that drives the dose-response relationships have been limited, and the results are controversial [5], even when considering the mean dose to the heart (MHD).
A reasonable option is a needful shift to the heart substructures (HSs) to understand better the causality of major adverse cardiac events (MACEs) after RT.
Moreover, robust subclinical warnings linked to the substructure dosimetry must be identified to comprehend cardiac disease pathophysiology better. Indeed, acute radiation-induced damage is usually considered an exclusive inflammatory process. For this organ, such a view is reductive, with chronic consequences of inflammation that can substantially alter the equilibrium in the electrophysiology and the fluid dynamics of the heart. An improvement in describing the detrimental mechanisms of the cardiac tissues can open specific interventions and prevent patient symptoms independently from the model predictions.
In this manuscript, we explained the methodological workflow and the role of technological innovations within the study "Location Matters".

2 Materials and Methods

The study is based on a well-structured research path that begins with a retrospective analysis aimed at identifying statistical associations in a large patient population to establish dose limits for a new set of at-risk structures, namely cardiac substructures. The prospective population will allow for a detailed estimation of the acute impact of radiotherapy on the functional and morphological parameters of the heart and lungs, thus identifying radiation-induced damages. A complex 3D model capable of mimicking cardiac function will enable the investigation of stress areas caused by parameters damaged by radiation therapy to determine potential mechanisms leading to the development of Major Adverse Cardiovascular Events (MACE).
In this process, innovative AI-based software, research machinery capable of determining parameters not yet in use in clinical practice, and everyday devices enabling longitudinal tracking of simple and precise functionalities play a crucial role.

2.1 The retrospective study cohort

A dataset of 1300 European LA-NSCLS patients treated between 2013 and 2020 will be shared and centralized at Fondazione IRCCS Istituto Nazionale dei Tumori. The clinical outcome, the Dicom RT, patient factors, tumour and treatment characteristics will be collected.

Using MVISION, an AI automatic contour software for CT scans, the delineation of the HSs will be obtained for all the patients. The central core of structures is characterized by the aorta, left atrium, right atrium, left ventricular, right ventricular, inferior ventricular cava, superior ventricular cava, and pulmonary artery. Dosimetric variables will be computed for the new structures, overcoming the whole heart dosimetry limitation.
In addition, patients' coronary artery calcifications (CAC) will be automatically contoured on the same imaging modality, and the Agatston calcium score will be computed through AVIEW (Coreline Soft, Seoul, Korea). This baseline parameter has been massively associated with a higher risk of developing heart dysfunctions [6] and will be included in the model with dose descriptors for HSs. Also, CAC location will be registered to understand if calcium deposits are more likely to induce cardiac diseases when localized at a specific point.

The study endpoint will be the OS2 for LA-NSCLC patients. A novel combined approach will be performed to analyse this endpoint. We will start with the mathematical model proposed by Nix et al. to describe positive and negative contributions to the OS2 in LA-NSCLC patients. It considered three components for describing the OS2: the equivalent dose (EQD2) to the tumour to take into account the loco-regional response, the chemotherapy's impact on distant relapse and a last parameter defining the survival limiting toxicity (SLT), i.e. the reduced survival when higher doses to the tumour were prescribed. Unlike Nix et al., where this part is only considered as a mathematical function of the prescribed dose for the tumour, we propose a description of causality for the SLT, as depicted in Fig. 1.
The description will be performed in three progressive methods: (i) substituting the dose to the tumour with the dose to the HSs, (ii) as in (i) + the Agatston calcium score, (iii) as in (ii) + the dose to the normal lung tissue (i.e., lungs – PTV). The reason for choices (ii) and (iii) comes from the previously introduced impact of the CAC on heart disease and the well-described cooperation between the heart and lung, which shows how the loss of cardiopulmonary performance is intensified when the heart and lung are co-irradiated. Through this process, we will complete the findings by Sheperd et al. [7] on the reduction of survival with the increase in the MHD modelling this competing part through the dose to the HSs. Reasonably, we could move from one dosimetric constraint for the whole heart to a set of rules for more substructures involved singularly or in a couple according to the anatomical location of the tumour or to the dose gradient for that treatment technique.
Moreover, the model component on the distant relapse will be enriched, including the impact of immunotherapy on the OS2 for patients with PDL-1 expression.

2.2 A decision-making tool for advance RT patient selections

The derived set of dosimetric constraints for safely sparing the heart substructures and their functionality will guide an in-silico comparison of different treatment modalities. Indeed, when a treatment plan for a patient does not satisfy these limits, the clinician could address the patient toward RT techniques that are more capable of satisfying the dose distribution requirements. Notably, in this study, we could test the clinical gain derived from the use of Tomotherapy (San Raffaele Hospital), hadron-therapy (CNAO Foundation) and MRI-Linac (Policlinico Gemelli of Rome). The differences in the dose distribution will be converted through the model (specifically to the part for SLT) to estimate the risk reduction of radiation-induced heart disease caused by such more conforming treatment modalities. The model developed could allow us to determine if such dose differences are clinically relevant more than statistically significant.

2.3 The prospective study cohort

A cohort of LA-NSCLC patients treated with RT will be enrolled at Fondazione IRCCS Istituto dei Tumori. Comorbidities and cardiovascular risk factors will be recorded for all the patients. We will plan an extensive set of cardiac tests before, at the end of RT, and 8 months after treatment (to assess cardiac remodelling and patient recovery). It will include electrocardiogram, echo cardio, spirometry, blood circulating biomarkers (Troponin and Natriuretic peptide tests) and cardiac calcium score from CT scan (including Follow-up acquisitions). In addition, we will include a set of measures using the cardiovascular ultrasound machine MyLab X8 (Esaote). This machine will allow us to investigate subclinical vascular organ damage indicators, including carotid distention and intima-media thickness (descriptor of the carotid inflammatory state), through a simultaneous and automatic procedure from raw imaging data. This guarantees the extraction of highly reproducible and operator-independent features.
Finally, patients will be equipped with a wearable device (Garmin Venu 3) to collect longitudinal information on heart rate, oxygen saturation, respiration rate, aerobic power and maximal oxygen uptake, and training status, including the recovery time after customised exercise based on the patient status.
The prospective analysis aims to associate the most "radiosensitive" functional parameters or biomarkers (i.e. the more prone to variate after RT) with the dosimetric indications for HSs from the retrospective study. First, we will analyze the variations of the parameters in patients with doses above and below the identified constraints for HSs. Secondly, we will test whether a dose relationship model can continuously describe the changes for the parameters with statistically significant differences. The primary focus will be the comprehension of the dose response for morphologi-

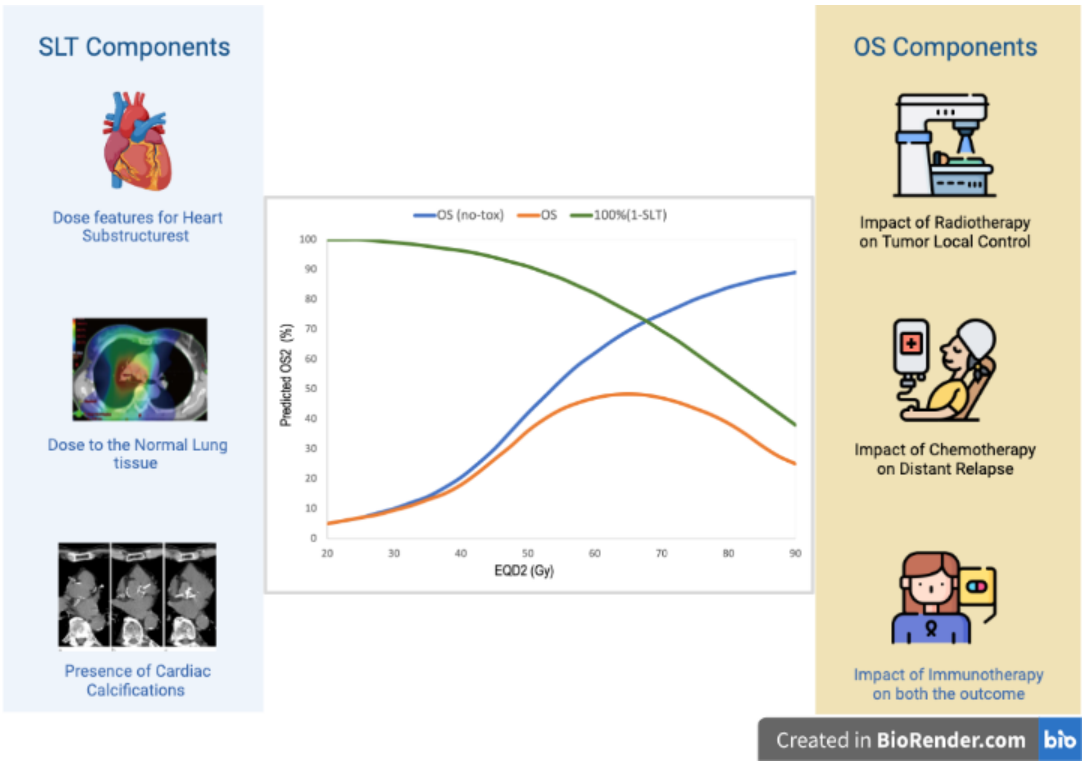

Figure 1: Graphical representation of the two components contributing to the Overall Survival at 2-year post-RT curve (orange line). Blue is the theoretical curve of overall survival caused by the benefits of RT on tumour volume, chemotherapy, and immunotherapy. In green is the complementary of the surviving limiting toxicity components, which includes the dose to the heart substructures, the dose to the normal lung and the presence of cardiac calcification before the start of the RT (impacting on the green line

cal and functional parameters that are altered chronically (8 months after RT). For this study, we estimate to enrol 150 LA-NSCLS patients in 3 years.

2.4 The 3D computational model

In collaboration with Politecnico of Milan, a mathematical approach will use the available patient data of the study to formulate an in-silico mechanistic model for blood flow in large vessels and the heart. The simulation will consider risk factors due to fluid mechanics and the mechanical alteration caused by the radiation on the endothelium and the surrounding tissue. The model could quantitatively describe the differences in the output parameters due to the inclusion of input values from patients below and above the subclinical warnings identified in the prospective study. To summarise, the real-world data coming from the clinical setting will inform an already available computational model for numerical simulations of the cardiac functions to describe in a mechanistic way the impact of such altered parameters on the natural physiology of the heart.

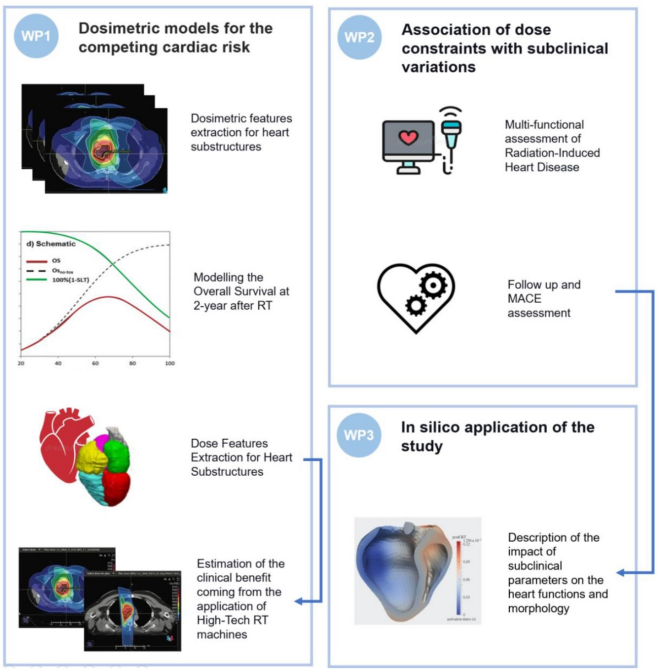

Figure 2: The study workflow: 1) the analysis of heart substructures dose tolerances, 2) the association of dose variables and alteration of functional parameters, 3) the in-silico mechanistic description through a 3D heart model. Arrows indicated the origin of the input parameters for the decision-making tool and the in silico application.

3 Discussion

The identification of the dose tolerance for the most radiosensitive HS, i.e., the one more prone to produce a critical dysfunction in a short period after cancer treatment, could impact the average overall survival time for LA-NSCLC patients,

improving the success rate of CH-RT, which is currently limited by the adverse events. The development of a survival model, including the dosimetric information from HSs, can drive the clinical practice toward a safe dose escalation protocol, exploiting the current technological level of the RT at best. For example, it could allow the performance of a safer and more effective stereotactic body radiation therapy (SBRT). There is considerable interest in combining SBRT with Immunotherapy without any concern about the possible detrimental effects of high doses on small heart substructures. This could lead to an apparent low efficacy of this treatment combination due to the neglect of survival-limiting toxicity. The model could also provide quantitative information for selecting patients who could benefit from using high-tech machines such as the hadron therapy. Indeed, a practical estimate for the risk of cardiac events should be included in the eligibility criteria for the mentioned machines and should not only be based on patient status (presence of cardiovascular comorbidities), taking into account even healthy cardiac patients subjected to doses that the HSs could not tolerate. The definition of subclinical warnings coming from the functional and morphological in-vivo test on patients during the treatment and the follow-up could improve the knowledge of Radiation-Induced Heart Disease (RIHD) and the tissue alteration regarding parenchymal cell composition, structure functionality and electrophysiology. Early identification of deficit values for some parameters that do not manifest into symptoms before inducing MACEs could allow a preventive intervention by cardiologists. The comprehension of such critical parameters is even of help for all the patients who received a safe dose of radiation to the heart but even started to degenerate. Patients with unfavourable genetic characteristics represent some examples of tolerating the RT damage or with already impaired tissue and comorbidities. Finally, the answer to all of these questions is not limited to lung cancer but could give advantages to other thoracic cancer treatments.

4 Conclusion

Establishing dosimetric constraints for heart substructures will provide an instrument for safe dose escalation in thoracic cancer patients, improving the success rate of radiotherapy alone or in combination with other cancer treatments. The estimated gain in terms of Overall Survival for lung cancer patients is 15-20%. A longer life expectancy for these patients could show the real benefit of the combination of RT, Chemotherapy and Immunotherapy. Indeed, Artificial Intelligence (AI) -based automatic contouring and segmentation of the HS can lead to more reliable dosimetric models for RIHD for cancer patients treated with RT in the thoracic region. Moreover, clinicians can exploit these dosimetric models to address patients at risk, i.e., patients with critical tumour location or needing cancer retreatment toward a better-sparing treatment technique or radiation source. The project results can be exploited for other cancer districts where RT is part of the oncological path, and the heart could be included in the medium-high dose region.

Abstract: Intensity-modulated radiotherapy (IMRT), while effective for conformal dose irradiation, may inadvertently expose out-of-field areas to radiation due to scattering and leakage doses from the treatment head, potentially leading to secondary cancer. In this study, we evaluated whole-body organ doses to predict the risk of secondary cancer using body-size-dependent tetrahedral mesh-based computational phantoms (TM phantoms) with our developed TET2DICOM software. TET2DICOM software converts TM phantoms into DICOM format, enabling their integration into commercial treatment planning systems (TPS). We utilized MONACO TPS for whole-body organ dose assessment. All selected TM phantoms, with similar BMI to the patients, were successfully transformed into DICOM format. A comparison of average doses at the target volume between patient CT images and TM phantom CT images revealed an error rate of 1.2% to 2.6%. After verifying this method through this comparative analysis, it was finally possible to quantitatively calculate the whole-body organ dose.

1 Introduction

Modern radiation therapy (RT) technology has progressed toward the aim of administering the most optimal dose to the tumor while simultaneously reducing the dose to the organ-at-risk. Intensity-modulated radiotherapy (IMRT) is one of the widely used advanced RT techniques in oncology, it allows the conformal dose delivery to the tumor by dividing a number of beam fractions.

Nevertheless, such hyper-fraction RT technique is reported in an increase of about 3-5 times in the out-of-field dose, attributed to either leakage dose or the scatter radiation than conventional RT technique [1-2]. The TG-158 report from the American Association of Physicists in Medicine (AAPM) suggests that a low dose of out-of-field can give rise to adverse consequences, including skin-related side effects, cardiac toxicity, or secondary cancers in normal tissues [3].

Treatment planning systems (TPS), presently utilized in clinical practice, may exhibit diminished accuracy in dose assessment as the distance from the region of interest expands. Besides, due to the restricted nature of patient Computed tomography (CT) data to the local treatment area, accurate evaluation of the dose to organs outside of the field can be difficult [4].

Meanwhile, the International Commission on Radiological Protection (ICRP) has recently put forth the tetrahedral mesh-based computational human phantoms (TM phantoms) [5] that faithfully replicate the anatomical structures of the human body. Through this, it suggests the possibility of accurately evaluating the dose of whole organs exposed to radiation.

Integrating the TM phantoms into the TPS may be feasible to achieve a comprehensive dose assessment of the whole body. In addition, as it is feasible to predict the dose administered to major organs of individuals receiving therapeutic radiation, patient-specific metadata can be obtained to be employed in subsequent investigations, such as the forecasting study of secondary cancers.

In this study, our research team has developed a conversion software application, called TET2DICOM [6], from TM phantoms into a Digital Imaging and Communications in Medicine (DICOM) format for employment in TPS. Furthermore, the out-of-field dose delivered to major organs according to the treatment target organs was evaluated.

2 Materials and Methods

2.1 Conversion body-size-dependent TM phantoms to DICOM format of the whole-body CT images

In order to convert the TM phantoms into CT images, a total of 6 instances involving cancer patients undergoing radiotherapy were taken into account. As shown in Table 1, taking into consideration both gender and Body Mass Index (BMI), the TM phantom that bore the closest resemblance to the patient in terms of shape was utilized for the conversion process.

Table 1. BMI of candidate patients and TM phantoms.

			Patient		TM Phantom	
Patient case	Gender	Treatment area	Height (cm)	Weight (kg)	Height (cm)	Weight (kg)
PC 1	Male	Brain	163	69	165	70
PC 2	Male	Esophagus	173	67.5	175	70
PC 3	Male	Rectum	172.7	89.3	175	90
PC 4	Female	Cervix	162.8	46.5	165	45
PC 5	Female	Liver	145	42.7	150	40
PC 6	Female	Breast	148	43.7	150	45

This study employed the TET2DICOM software to transform TM phantoms into CT images, which were subsequently utilized in commercial TPS applications. It encompassed two distinct procedures: (1) the conversion of a mesh-type structure into a voxel-type structure, which represents the CT image; and (2) contouring the data about the location, shape, and volume of the organs.

The CT-to-Density curve was measured by acquiring CT images using a cheese phantom containing 12 non-homoge-

neous material rods. The average CT value within the circular region of 8 mm diameter in each distinct material area was taken into account, as shown in Figure 1. It was employed to establish the HU value within the voxel based on the material information derived from the TM phantom.

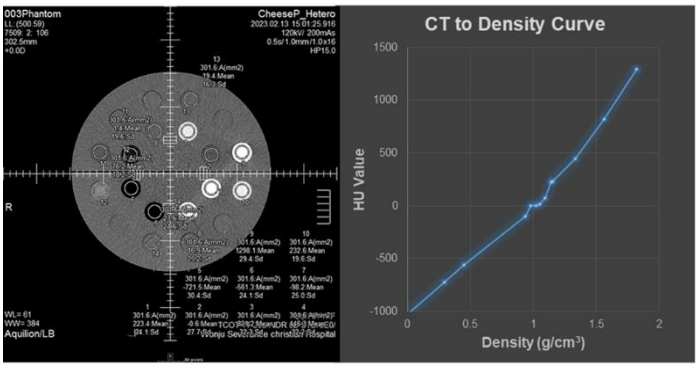

Figure 1. CT-to-Density curve data: the correlation between CT image intensity and material-specific density.

Contour data was defined for major organs in the body with relatively different probabilistic risks during radiation exposure specified in the ICRP 103 report to calculate the organ dose in commercial TPS.

Finally, in order to apply the converted CT image to a commercial TPS, the CT image and contour data were converted to Digital Imaging and Communication in Medicine (DICOM) format. The Grassroots DICOM Library (GDCM), which is a cross-platform library for DICOM medical files was used, and CT image data was converted to binary format according to specific tag rules.

2.2 Whole-body organ dose assessment by commercial TPS

Before performing the calculation of the dose for the entire body, an image registration process was carried out to align the converted DICOM data with the positions of the patient's CT image treatment site and the organs of the entire body, as illustrated in Figure 2. For the purpose of image registration, a commercially available RT plan check system (MIM, MIM Software Inc., Cleveland, USA, version 6.5.6) was utilized. This rigid registration method only includes the rotation and movement of the entire image, without form of distortion such as size or shape transformation of the CT images.

After that, the MONACO 6.1 version TPS software was utilized to calculate the whole-body organ dose using a CT image of the TM phantom. The dose assessment algorithm employed in this software is a simplified Monte Carlo algorithm, specifically designed to evaluate the whole-body organ dose through scattered radiation.

The contour data for each organ was generated as an RT-structure file so that the dose distribution was quantitatively evaluated using a dose volume histogram (DVH). The dose calculated in the Clinical Target Volume (CTV) or Planning Target Volume (PTV) of the radiotherapy plan established

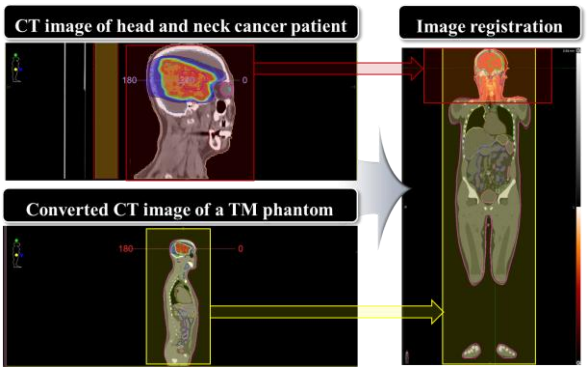

Figure 2. Rigid registration of the CT image of a cancer patient and the converted CT image from the TM phantom.

from each patient's CT image was compared and analyzed with the dose calculated in the CTV or PTV formed in the TM phantom.

3 Results

3.1 Conversion of TM phantoms with similar BMI to 6 patients

All 6 TM phantoms, which had similar BMI to the patients, were successfully transformed into DICOM CT images, as illustrated in Figure 3. For the conversion parameter, as outlined in Table 2, the field of view (FOV) was stated to be 500 mm, which was automatically adjusted to accommodate the size of the phantom. The resolution of the images was set at 512 × 512, and the voxel size was determined to be 1.281 × 1.281 × 3 mm^3, depending on the FOV. The number of slices produced for the phantoms varied from 532 to 590, depending on the height of each phantom.

Table 2. Parameters for conversion of CT image with TM phantoms.

	CT image parameters			
	Field of view (mm)	Pixel size (mm^2)	Pixel resolution	Number of slices
PC 1	500	1.281 ×1.281	512 × 512	564
PC 2	500	1.281 ×1.281	512 × 512	590
PC 3	500	1.281 ×1.281	512 × 512	590
PC 4	500	1.281 ×1.281	512 × 512	572
PC 5	500	1.281 ×1.281	512 × 512	532
PC 6	500	1.281 ×1.281	512 × 512	532

The generation of a DICOM dataset for 6 TM phantoms using TET2DICOM required a time range of 80 to 100 minutes, respectively, with a specific duration dependent on the size of the phantom. Moreover, it is worth noting that all converted CT images were found to be compatible with commercial TPS.

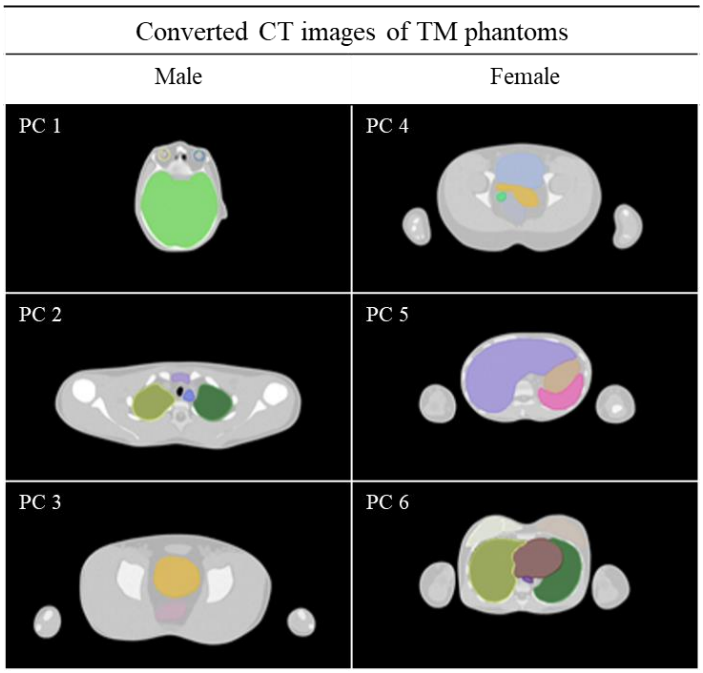

Figure 3. Converted CT images of TM phantoms with similar BMI for each patient case.

3.2 Whole-body organ dose assessment with the converted DICOM CT data

Figure 4 shows the rigid registration results between the CT images of the 6 patients and the TM phantoms which are similar in gender and BMI with 6 patients. Although the specific target volume is not explicitly defined in the converted CT image derived from the TM phantom, and there exists a slight disparity in the dimensions and placement of organs, the distribution of dose was calculated by aligning the patient-specific parameters of the skeletal attributes.

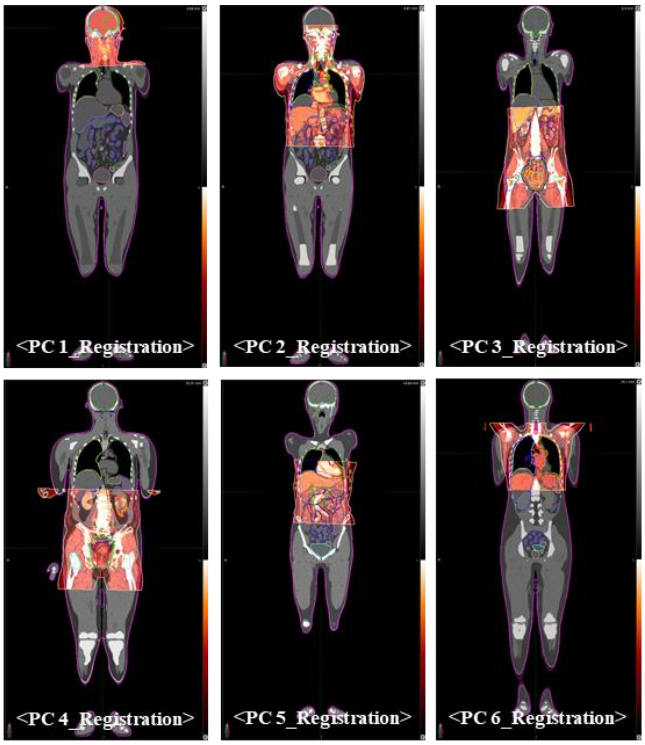

Figure 4. Registration of the patient's CT image and the TM phantom's CT image

By comparing the dose calculated on the CTV or PTV of the existing radiation treatment plan established from the patient's CT image with the dose calculated on the CTV or PTV calculated by converting and matching the TM phantom, the dose difference was confirmed as shown in Table 3. The maximum dose within the target volume in all patient cases except for the breast cancer patient case showed an error rate of 0.6% to 5.1%, and the average dose showed a difference of 1.2% to 2.6%.

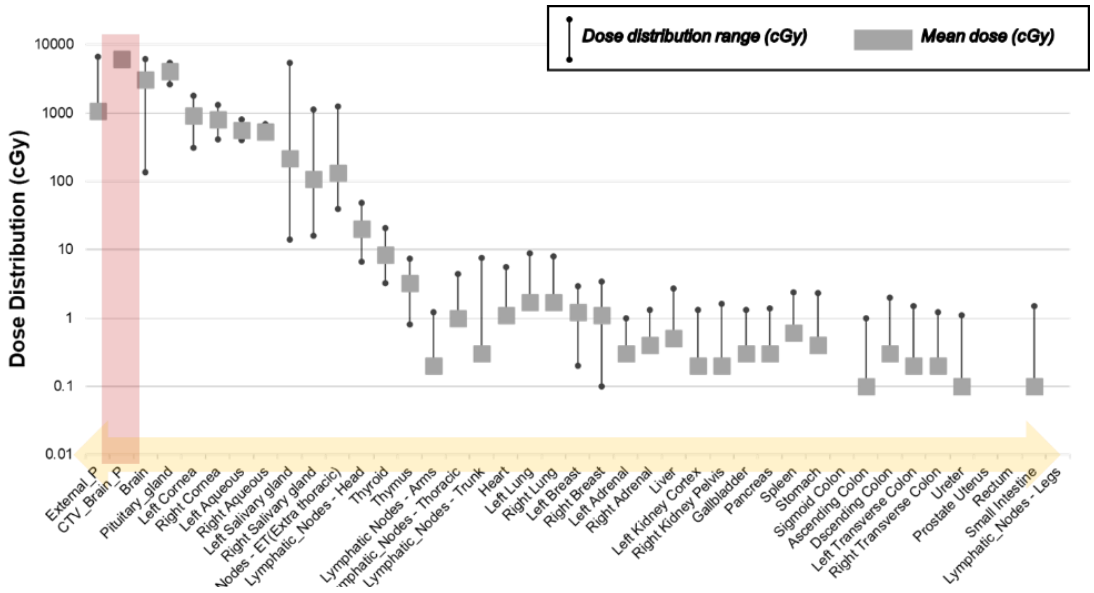

Figure 5. Dose distribution for each organ of the whole body for brain tumor patients.

Table 3. Comparison of calculated dose between the CTV or PTV of each patient's original CT image and the converted CT image in the TPS.

	Maximum dose within target volume (cGy)			Average dose within target volume (cGy)		
	CT image	TM Phantom	Error (%)	CT image	TM Phantom	Error (%)
PC 1	6381.4	6709.1	5.1	5973.7	6129.3	2.6

PC 6	4590.7	4689.6	2.2	4311.1	3728.5	13.5

After verifying the evaluation method by calculating the dose in the target volume, the delivered dose for organs of the whole-body was calculated and quantitatively evaluated based on the contour data, and the results as shown in Figure 5.

4 Discussion

In this study, we aimed to calculate the dose of whole-body organs by converting the body-size-dependent phantom library into DICOM format and applying it to the commercial treatment planning system. TET2DICOM software was developed and used to convert the tetrahedral-mesh computational phantom to DICOM format, and for calculating whole-body organ doses, MONACO treatment planning system was used.

TM phantoms that had a similar BMI to the chosen 6 patients were converted into DICOM format, as depicted in Figure 3. Subsequently, a dose calculation and comparison were conducted to validate the method used to assess the doses on whole-body organs. This involved comparing and analyzing the average dose and maximum dose on the clinical target volume (CTV) or planning target volume (PTV) within the converted DICOM CT data and the actual patient's CT image. In all cases, except for patient 6 whose treatment area was breast cancer, the average dose in the CTV or PTV for each patient demonstrated a tendency to be consistent within a range of 2.6%. However, for patient 6, the average dose error was evaluated to be 13.5%. This discrepancy was deemed relatively substantial due to the concentration of radiation irradiation on the body surface and the notable differences in breast volume and shape.

The graph displayed in Figure 5 exhibits the quantitatively calculated dose to the entirety of the patient's organs, resulting from radiotherapy administered for the treatment of a brain tumor. This graph effectively categorizes the organs of the entire body, including the target volume, in a hierarchical manner from the top to the bottom of the body. It has been verified that the dose in the target volume amounts to 6129.3cGy, while lower doses have been observed to be distributed below 100mGy in organs situated further away from this specific area. It has been ascertained that the quantification of the whole-body organ dose is not only applicable to the treatment of brain tumors but also encompasses all five patients involved in this study. Furthermore, it has been determined that the evaluation of the whole-body organ dose, which is the aim of this study, can indeed be accomplished.

5 Conclusion

The confirmation of the possibility to quantitatively assess the dose received by the patient's organs has been achieved through this study. Currently, there are limitations in calculating accurate organ dose due to distortion of the volume and organ shape between actual patient CT and converted CT data. However, in upcoming years, it is envisaged that the construction of an extensive database containing a multitude of patient cases, utilizing the approach employed in this study, will allow for the provision of factors for referencing secondary carcinogenic risk. Furthermore, the establishment of a framework for the presentation of globally standardized guidelines aimed at optimizing novel radiation treatment plans can be expected.

Abstract: Survivors of childhood cancer need life-long monitoring for side-effects from radiotherapy. However, longitudinal data from routine monitoring is often infrequently and irregularly sampled, and subject to inaccuracies. Due to this, measurements are often studied in isolation, or simple relationships (e.g., linear) are used to impute missing timepoints. In this study, we investigated the potential role of Gaussian Processes (GP) modelling to make population-based and individual predictions, using insulin-like growth factor 1 (IGF-1) measurements as a test case. With training data of 23 patients with a median (range) of 4 (1-16) timepoints we identified a trend within the range of literature reported values. In addition, with 8 test cases, individual predictions were made with an average root mean squared error of 31.9 (10.1 – 62.3) ng/ml and 27.4 (0.02 – 66.1) ng/ml for two approaches. GP modelling may overcome limitations of routine longitudinal data and facilitate analysis of late effects of radiotherapy.

1 Introduction

Each year an estimated 400,000 children are diagnosed with cancer worldwide [1]. Radiotherapy plays a main role in curative-intent treatment with more than 75% of children now surviving more than 5 years [2]. Despite modern radiotherapy techniques, brain tumour survivors have the highest incidence of severe chronic health conditions compared to other childhood cancers, in part due to the impact of radiation on the developing brain [3]. There is a need to study the relationship between radiation to brain substructures and late outcomes so we can plan 'gentler' radiation treatments and ultimately improve patient outcomes.

A common outcome post-radiotherapy in survivors of childhood brain tumours is growth hormone deficiency (GHD), which, if it goes untreated, can lead to short-stature, fatigue and increased risk of diabetes and heart disease among others [4,5]. Routine blood tests are used as follow-up for brain tumour survivors, which include a specific test for Insulin-like growth factor 1 (IGF-1), a primary index for diagnosis of GHD.

To enable the study of the association between dose to brain substructures and GHD, we have so far dichotomised the outcome as the likelihood a child is placed on treatment for GHD (yes vs no). A dichotomous outcome could lead to loss of valuable information on patterns of change for those within each group. In future, we plan to make use of longitudinal measurements of IGF-1 for a more granular study of outcome. Follow-up routine blood rests are typically recorded for children many years post-treatment. However, these tests are infrequent, sampled at irregular timepoints, and subject to inaccuracies. To move towards dose-response modelling with longitudinal data, we need to understand population trends with age and make predictions of an individual's trajectory to provide outcomes at interpolated standardised time-points such that patients can be compared. Gaussian processes (GP) modelling has the potential to enable this.

GP modelling is a machine learning approach that can be used to capture the function that maps any input variable (i.e., time) to any output variable (i.e., IGF-1) [6]. Fundamentally, it is non-parametric regression and more flexible in comparison with typical parametric approaches (e.g., linear and polynomial regression) that are somewhat limited in the spectrum of trends they are able to capture. Due to this flexibility, GPs are particularly powerful in situations where there is limited data and/or relationships are complex. GPs are probabilistic in nature and hence leverage prior information during training to provide uncertainty quantification for the output estimates of the model. Multi-task GPs encompass the situation where a GP may be trained on data from multiple individuals. In this case, one can take advantage of a latent mean process, common to all individuals, to share information across them and enhance modelling and prediction accuracy. This is useful for the situation where some individuals do not have many timepoints sampled or have large gaps in recording, as they can 'borrow' information from other individuals. This would allow us to impute data based on population trends. One package for performing this type of prediction is MAGMA (Multi tAsk GPs with common MeAn) developed by Leroy et al. [7]. MAGMA has proved advantageous in multiple simulated and realistic scenarios (e.g., predicting athletes swimming performance and modelling body mass index during childhood). However, the ability to use such techniques in routine follow-up data for childhood cancer survivors has not yet been explored.

Here, we train multi-task GPs with a common mean to measure how IGF-1 changes with age from routine measurements of children and young adults who received

radiotherapy for a brain tumour. We will test **1)** the ability to identify underlying population trends, and **2)** the ability to interpolate individual timepoint predictions in unseen data. By performing these tasks, we highlight the potential of using GPs to impute data at a given time, thereby enabling study of the late effects of radiotherapy.

2 Materials and Methods

Data

We collected data from a single institutional archive on blood tests for IGF-1 recorded after radiotherapy for 31 children and young adults with brain tumours. The dataset was divided quasi-randomly to ensure a 75% / 25% split for training and testing (23 training, 8 test). The quasi-random component was to make sure patients with one timepoint were only included in the training set (as there would not be enough points for testing).

Training

We trained a MAGMA model, which is defined as the sum of a shared mean GP and an individual specific GP. We test two variations model hyperparameters (HPs) in training: **1)** consider *common* mean and covariance HPs to be equal for all individuals, assuming individuals correspond to different trajectories of the same process, and **2)** individual-specific HPs to generate a more flexible model. Model training is performed via likelihood maximisation within an expectation-maximisation algorithm. To account for the influence of the HPs random initialisation, we repeat the training process 25 times per variation and select the GP models with the maximum log-likelihood. We compare the trained population GP to literature reported values.

Testing

We ensured that each individual the in the test set had at least two timepoints. Per test patient we randomly sample half of the timepoints for prediction, and half for evaluation. Using the prediction points for each patient, we can predict the entire curve of IGF-1 values with associated uncertainty, in particular at the location of the testing points for evaluation purposes. To evaluate the individual GP model, we calculate the root mean squared error (RMSE) and coverage of the 95% credible interval (CIC-95) for each of the evaluation timepoints. We report the average statistics across the evaluation points for each case. The evaluation is repeated for the common and individual-specific HPs models.

3 Results

Data

Longitudinal blood test data was available for 149 data points (114 for training, 35 for testing) across the 31 individuals. All patients had received photon radiotherapy for a brain tumour of mixed diagnosis. Patients were of median age 21.0 (3.79 – 25.5) years at radiotherapy. IGF-1 measurements were recorded at a median (range) of 4.82 (0 - 14.4) years after radiotherapy. All patients were on growth hormone replacement therapy and had begun this intervention treatment 7.19 (0.49 – 14.6) years after radiotherapy which should return IGF-1 to normative ranges. In terms of data availability, the median (range) number of recordings of IGF-1 for each patient was 4 (1-16). Six patients had only one recording and hence were included in the training dataset, and the rest of the data was randomly selected for training and testing.

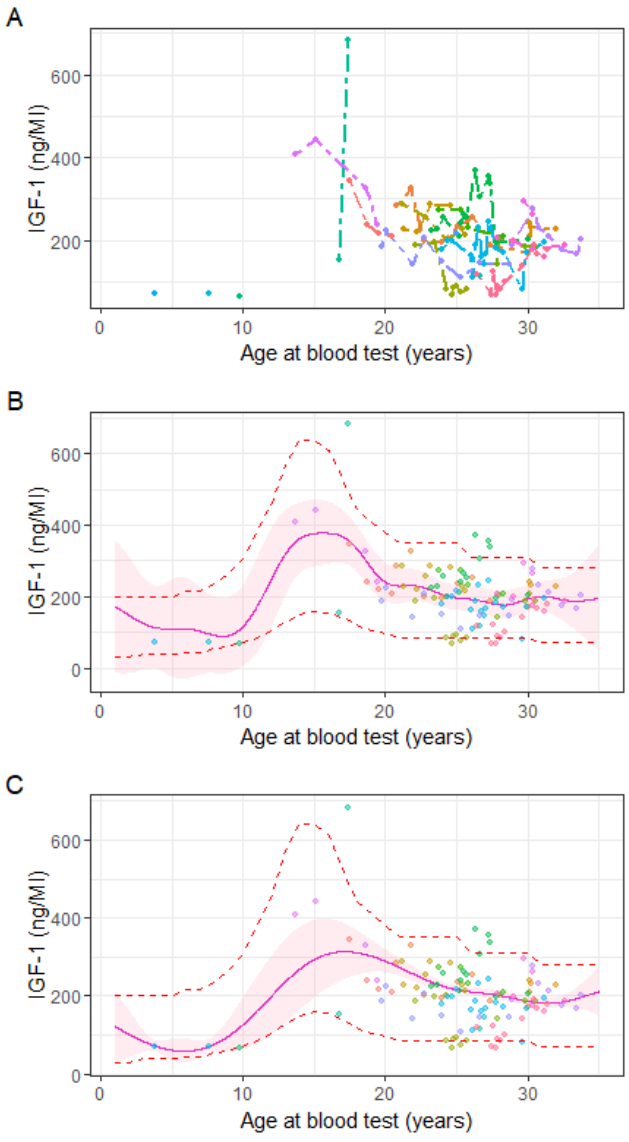

Figure 1. A) Individual trajectories for patients within the training dataset. Each colour represents a patient, with lines connecting time-points from the same individual. B) Fitting of a GP model with common hyperparameters, the light pink represents the 95% credible interval. C) Fitting GP model without individual-specific hyperparameters. The red dashed lines display normative trends for IGF-1.

Training

In Figure 1A an individual's 1GF-1 trajectory is mapped out over the age at which the test was taken. Figure 1B shows the GP model assuming common mean

hyperparameters. The maximum log-likelihood for this model fit was -804.56 with a minimum of -821.74 across the 25 training runs. In the GP model with individual-specific HPs (Figure 1C) the maximum log-likelihood was -744.88 within a minimum of -779.31. In comparison to normative reference values (red dashed lines on Figure 1 [8]), when there is a common HP most timepoints are within the ranges until very few data-points for training are available (i.e., <12 years old) and the GP follows the shape of the normative trajectory. For individual-specific HP, the credible interval is within the range for all timepoints, but the shape is smoother with a smaller peak. The models trained in 64 and 76 seconds respectively.

Testing

The results of the 8 test cases for individual-specific GPs are reported in Table 1.

Case	Prediction	Evaluation	RMSE (common HP)	RMSE (individual-specific HP)
1	2	3	24.96	31.94
2	2	2	38.24	92.55
3	2	3	25.56	41.24
4	1	1	10.12	18.74
5	4	5	62.29	66.06
6	1	1	46.07	0.02
7	3	3	10.89	22.78
8	1	1	56.65	5.53
			31.90	***27.36***

Table 1. A table of the test results for the GP models with common and individual-specific HPs. The case is an individual patient, prediction gives the number of timepoints included for prediction, and evaluation is the number of timepoints included for evaluation. The RMSE represents the average across the evaluation timepoints (ideal value is 0), and overall means are included in the bottom row.

On average, the lowest RMSE is observed in the individual-specific HP model, however, not all evaluation points were covered by the 95% credible interval suggesting a slight underestimation of the uncertainty. There was 100% CIC-95 in all cases apart from case 5 who had 50% coverage. For the common HP setting all evaluation points had 100% CIC-95. Considering individuals, in 6 out of 8 cases, the common HP approach has an improved model fit for prediction. But the overall average RMSE is skewed by the predictions where only one timepoint is available. For cases with one timepoint it appears there is an advantage to the more flexible model.

Model fit examples are displayed in Figure 2. In case one (A and B) the datapoints show fluctuations around the common mean, so, in both cases the error is small. In case 5 (C and D) an uncharacteristic peak is observed in the years post-treatment, and here the population mean process does not fit well in either case. In case 6 and 8 only one timepoint is available for fitting the individual prediction (and one for testing), so the individual-specific HP performs better (E-F and G-H respectively).

4 Discussion

We have studied the use of MAGMA to perform Gaussian Processes modelling on the dependency between IGF-1 and age in a dataset of children treated with radiotherapy for brain tumours and under growth hormone treatment. We have shown the GPs can correctly model the underlying expected trends from normative samples.

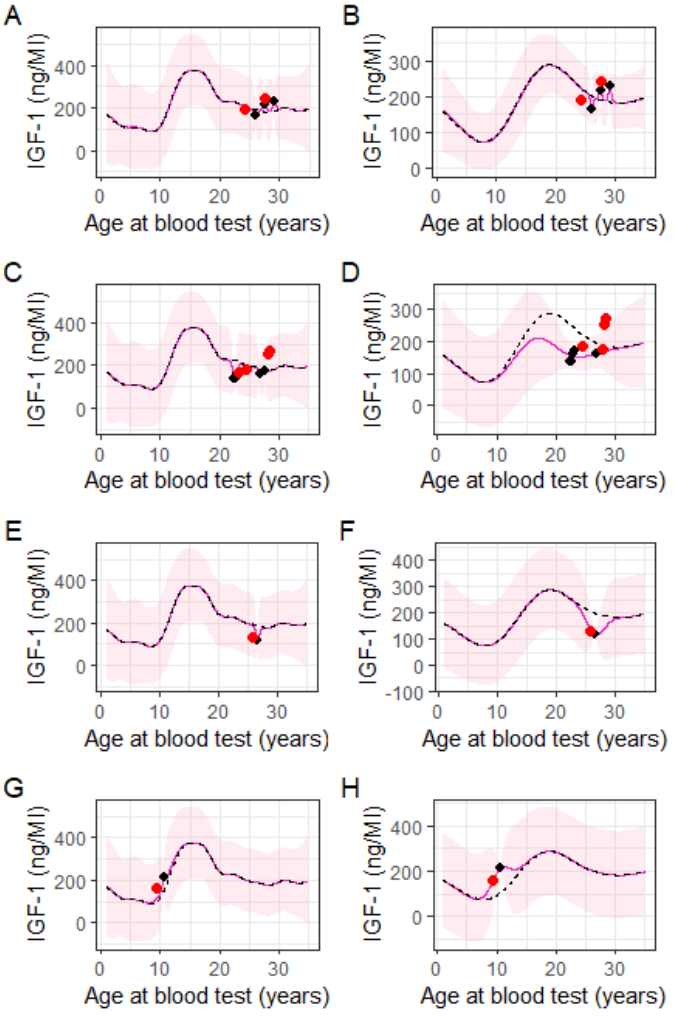

Figure 2. Examples of individual GP models (pink line) for 4 out of 8 example cases using the common mean process (dotted line) trained using common HPs (left) and individual-specific HPs (right). The prediction points for that case are in black, and evaluation points (unseen in training and prediction) are in red.

Individual predictions were performed with an ~30ng/ml root mean squared error, and in all but one case (94%) evaluation points were covered by the 95% credible

interval. In future work, we aim to incorporate the longitudinal predictions modelled by GPs into our existing image-based data-mining pipeline [9].

Gaussian processes have previously been explored in radiotherapy for motion-modelling for image-guided treatment [11] and motion compensation in robotics treatment [12]. However, as far as the authors are aware they have not yet been utilized for dose-response outcome modelling.

The large credible intervals displayed by the model are unsurprising given the noise in the dataset. It is known that IGF-1 scores are also influenced by the time after radiotherapy, the age at radiotherapy, puberty status, weight, diet, and day-to-day variations in recording [13,14]. In addition, we are typically interested in measuring what is 'abnormal' so the ability to model normative ranges may appear a redundant test. However, all these patients were administered growth hormone therapy at some point post-radiotherapy. The potential confounding variables and external factors influencing this data raises concern for its use for showcasing the advantages of GPs in dose-response modelling. Incorporating extra covariates including time-varying ones, using MAGMA will be explored to overcome some of the issues presented here for future work with this cohort.

5 Conclusion

We demonstrated how multi-task GPs with a common mean process (MAGMA) can be used in routine and 'inadequately sampled' outcome data. The model was able to identify population-level trends that match known values and make individual predictions on 'missing' data-points where the true values were within the 95% credible interval for 94% of cases. This tool will aid the analysis of late effects of radiotherapy in childhood cancer as we could interpolate missing timepoints in routine follow-up data, and eventually study patterns of development across different treatment groups or dose levels. This will also complement our ongoing image-based data mining work for endocrine outcomes.

Abstract Despite careful radiotherapy treatment planning, recurrence may occur in patients with non-small cell lung carcinoma (NSCLC). If clinicians can identify patients at high risk of recurrence, treatment plans could be tailored with risk-adapted approaches. Although artificial intelligence (AI) can predict patient outcomes, it often does not explain its underlying decision-making process and therefore is not widely adopted in clinical practice. In this retrospective study, we use explainable AI methods to predict post-stereotactic ablative radiotherapy NSCLC recurrence in 74 patients treated across a Canadian province and interpret the results. The eXtreme Gradient Boosting model outperformed the random forest and Explainable Boosting Machine models, achieving an accuracy of 0.73, F1-score of 0.5, and area under the curve of 0.65. Radiomic features were considered to be the most important features, whereas clinical features were not as important overall. This work shows the utility of explainable AI in the context of recurrence prediction.

1 Introduction

Stereotactic ablative radiotherapy (SABR) is recommended for patients with stage I and II non-small cell lung cancer (NSCLC) who are medically inoperable, or who are potentially operable but considered high-risk, elderly, or prefer not to undergo surgery [1]. While SABR for early-stage NSCLC reports over 90% local control, there remains a substantial risk of distant metastasis, with rates ranging between 10% and 20% [2]. A retrospective study reports that the median times to local and distant recurrence after SABR are 14.9 and 9.6 months respectively [3]. Currently, the integration of individualized recurrence risk estimation into the radiotherapy planning process is not a standard practice. If the recurrence risk of each patient could be precisely predicted, treatment strategies could be tailored with risk-adapted approaches, such as escalation or de-escalation, to potentially enhance treatment effectiveness and durability.

Recent strides in artificial intelligence (AI) have revolutionized many medical fields, including radiation oncology. AI models have been developed for tasks including image reconstruction, registration, segmentation, diagnosis, and outcomes prediction [4]. Despite their popularity and accuracy, their low interpretability prevents their widespread adoption in medicine. A clinician trusting a prediction without understanding its limitations or the underlying rationale may cause adverse consequences for the patient.

In response to the black-box nature of traditional AI, explainable artificial intelligence (XAI) has emerged to help the user better understand model predictions [5]. Among them, Shapley Additive exPlanations (SHAP) is a method based on game theory that determines the importance of each feature for a given prediction [6]. SHAP values can be used to identify the most important features on a global or individual basis. Another approach proposes the use of glass box models designed to be inherently more interpretable. Although XAI has generated increasingly interest in medicine, to our knowledge, its application to predicting NSCLC recurrence after SABR remains unexplored.

While traditional AI models have been developed for recurrence prediction, they have not gained enough trust of clinicians to be used broadly in practice. This work aims to explore the use of XAI to predict NSCLC recurrence in SABR patients treated across the Canadian province of British Columbia. XAI would provide clinicians with outcomes predictions that are interpretable and related to patient-based features, which would help clinicians to assess the prediction's reliability and to justify any treatment plan modifications. It has the potential to support clinical decision making and ultimately improve treatment outcomes in British Columbia.

2 Materials and Methods

This retrospective study was approved by the British Columbia Cancer Research Ethics Board (H21-02186). The patient dataset was collected retrospectively and consists of 74 NSCLC patients treated with SABR across British Columbia, Canada between 2010 and 2017. Patients receiving simultaneous treatment to multiple disjointed tumour sites, receiving atypical chemotherapy treatment, or lacking sufficient follow-up time (one year) were excluded. The dataset included medical records and radiotherapy planning computed tomography (CT) scans containing contours delineated by expert clinicians. Chart review was performed to determine the two-year recurrence status of each patient. Locoregional recurrence and distant metastasis were both considered disease recurrence in this study, and not distinguished. Patient data was anonymized.

Clinical features from medical records were one-hot encoded. Radiomic features were extracted from gross tumour volumes on CT scans using IBEX radiomic software [7]. Subsequent analysis was performed using Python 3.7. Transforms were performed on heavily skewed continuous features to achieve a more Gaussian-like distribution. Feature selection was performed using Pearson coefficient correlation with a cut-off threshold of 0.8, resulting in a total of 15 radiomic and 28 one-hot encoded clinical features.

The data set was split into training (80%) and testing (20%) sets with balanced classes. Random Forest (RF), eXtreme Gradient Boosting (XGBoost), and Explainable

Boosting Machine (EBM) classification models were trained using stratified ten-fold cross validation. RF and XGBoost are commonly used tree-based models that can be explained using SHAP values. EBM is a glass-box model designed to have comparable accuracy to RF and XGBoost, but with increased interpretability. Hyperparameters for RF and XGBoost were optimized using Bayesian optimization. Following EBM author recommendations [8], the default EBM hyperparameters were used. Model performance on the test set was evaluated using accuracy, F1-score, and area under the curve (AUC). Model explainability was investigated using SHAP values and EBM visualizations.

*Table 2: Optimum hyperparameters for the models. *Calculated as log2 of number of features*

3 Results

The dataset consists of 74 non-metastatic stage I–III NSCLC patients treated in five provincial health authorities across British Columbia, Canada. The majority of patients were in AJCC (7th edition) stage I and had adenocarcinoma. The mean age of patients was 75.6 years, with a 31% recurrence rate. Demographics of the study population are provided in Table 1.

Bayesian optimization was performed with 50 iterations. Optimized model hyperparameters are shown in Table 2.

Performance metrics of the models are summarized in Table 3. The best performing model was XGBoost with an accuracy of 0.73, F1-score of 0.5, and AUC of 0.65. Figure 1 shows AUC curves of all three models. The most important features based on XGBoost SHAP values are shown in Figure 2 and mostly consist of radiomic features.

Global feature importance of the models represented by SHAP values or EBM visualizations was compared. Radiomic features (Autocorrelation, ClusterShade, and LongRunLowGrayLevelEmpha) were identified within the top five important features of all three classifiers. Two clinical features ranked among the top ten important features overall by specific classifiers. Adenocarcinoma histology was the sixth most important feature for the XGBoost model, while age at diagnosis ranked tenth for the RF model.

Model	Accuracy	F1-score	AUC
RF	0.73	0.33	0.6
XGBoost	0.73	0.5	0.65
EBM	0.67	0.0	0.5

Table 3: Performance metrics for the models on the test set.

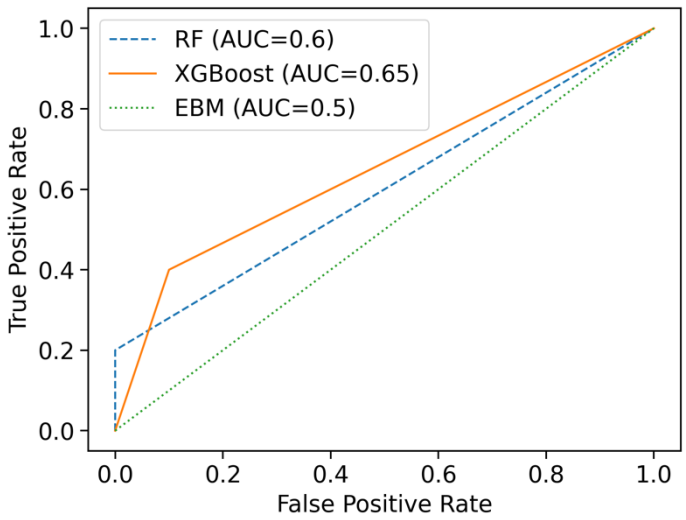

Figure 1: Area under the curve (AUC) of RF, XGBoost, and EBM models.

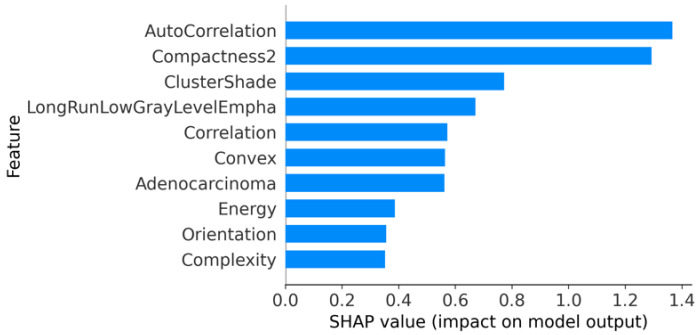

Figure 2: Features with the highest SHAP values identified by the XGBoost model.

4 Discussion

Although EBM models are often as accurate as black-box models, it was outperformed by XGBoost and RF models for our cohort. By incorporating the use of SHAP values, the RF and XGBoost models achieved similar interpretability as the glass box EBM model. Our best performing model achieved similar performance to a RF model in a previous radiomics-based study [9] despite being trained on a smaller dataset.

All models considered radiomic features to be most useful for recurrence prediction, while clinical features were not important. This may be because some clinical features were found to be correlated to radiomic features and therefore dropped during feature selection. A lower Pearson correlation coefficient cut-off threshold during the feature selection process may help decrease the influence of radiomic features. Note that the evaluation of SHAP values may be also performed for individual patients rather than at the level of the study population. A personalized SHAP assessment may place more weight on clinical features when making outcomes predictions. In addition, these features may not necessarily rank among the overall most important features due to patient variability.

Although the model explains the underlying 'motivation' behind predictions, it cannot recommend specific treatment plan modifications because it is based on radiomic and clinical features alone. An AI recommender system would involve specific features that can be modified by clinicians, such as details of the treatment plan. In our case, the model would support clinical decision making by indicating which patients may be at higher risk of recurrence and therefore justify an increased risk of toxicity in order to pursue a more aggressive treatment.

Patient data was acquired using standardized procedures in a provincial framework. The dataset is expected to be high quality, but is still likely to contain heterogeneity due to the inclusion of patients treated in different geographical regions. This study is limited by its use of a small subset of the available data. Future studies will leverage a larger provincial dataset and allow more efficient model training and robust analysis. A larger dataset will also provide a more complete assessment of the model's generalizability and better represent the five health authorities featured in this study.

Another limitation of the present work is the lack of recurrence examples present in the datasets, which is a common issue in medical studies. The percentage of recurrence cases in the training and testing datasets were balanced, but mild class imbalance was observed. To decrease this effect, resampling techniques may be warranted.

5 Conclusion

XAI methods were used to predict NSCLC recurrence in SABR patients across British Columbia and provide understandable explanations for its predictions. It was found that the XGBoost model architecture had the highest predictive performance. SHAP values showed that radiomic features were most informative for model predictions. Ultimately, XAI would provide outcomes recurrence predictions that can be trusted to support clinical decision making and potentially improve patient outcomes.

Abstract In cancer management, timely completion of radiotherapy (RT) is crucial, as interruptions impact overall survival. We investigated whether comorbidity burden is associated with RT completion in a cohort of 1,877 patients with head and neck squamous cell carcinoma (HNSCC) who underwent curative-intent RT with/without chemotherapy. Multinomial logistic regression explored associations between treatment completion categories, comorbidities, and overall comorbidity scores. Patients with moderate and severe overall comorbidity scores had a poorer survival than those with no comorbidity. Based on the ΔAIC analysis, accounting for each comorbidity category has the most pronounced effect on predicting treatment completion (ΔAI>4). The risk of not completing treatment increased for patients with moderate comorbidity score, and for patients with cardiovascular comorbidities. The risk of late treatment completion increased for patients with both respiratory and cardiovascular comorbidities. We found that comprehensive consideration of each comorbidity category significantly enhanced the accuracy of predicting treatment completion.

1 Introduction

Radiotherapy (RT) plays an important role in the management of patients with cancer. One of the key elements in radiation oncology is timely completion, which is associated with treatment outcome, including overall survival (OS) [1]. In addition, higher comorbidity scores are associated with poorer treatment outcomes and incomplete treatment [2] However, the degree to which comorbidity burden affects RT interruption is not fully understood. Therefore, in this study, we investigated the association between RT completion and OS and furthermore assessed whether overall score comorbidities and baseline comorbidities are associated with RT completion in a large cohort of patients with head and neck squamous cell carcinoma (HNSCC) cancer treated with RT.

2 Materials and Methods

Data were collected from 1,877 HNSCC patients treated at a single institute with curative-intent RT (60/63/66 Gy in 30 fractions, with/without concurrent or sequential chemotherapy) between January 2013 and February 2023 and for whom Adult Co-Morbidity Evaluation (ACE27) score were available. RT was given to patients on weekdays over six weeks. Overall treatment duration (days) was defined as the number of weekdays from treatment initiation to the last fraction received. ACE-27 comorbidity burden was collected at diagnosis and were considered as binary variables (with/without comorbidity) for twelve organ systems (3). Incidence of all comorbidities was calculated, but we only report on those exceeding a 5% occurrence to ensure the robustness of our outcome. Besides ACE-27 comorbidity burden, we also had overall comorbidity scores which were scored as none, mild, moderate, and severe based on the validate comorbidity instrument ACE-27 [3]. Treatment completion was categorized into three groups, patients who did not complete the treatment, those who completed the treatment in the scheduled 30 days, and those who completed the treatment after more than 30 days (late completion). The association of treatment completion and OS was assessed via a multivariable Cox regression model. The association of treatment completion category with different comorbidities and overall comorbidity score was assessed via individual multinomial logistic regression models. The goodness of fit of all multinomial models was evaluated using AICs. All models were adjusted for age, gender, performance status, log gross tumour volume, chemotherapy and multiple deprivation index (IMD). IMD deciles were calculated by ranking geographic areas of the UK from most to least deprived and dividing them into 10 equal groups (decile 1, most deprived 10%; decile 10, least deprived 10%).

3 Results

1,655 (88%) patients completed treatment in time, 180 (10%) patients had late completion and 42 (2%) patients did not complete their treatment. Cardiovascular (40%), respiratory (14%), and endocrine (11%) conditions were the most common comorbidities. Overall comorbidity scores showed almost half of patients had no diagnosed comorbidity (46%), and 35%, 14% and 5% of patients had mild, moderate, and severe comorbidity burdens, respectively. An adjusted multivariable cox regression model revealed that the survival of patients did not complete treatment was significantly worse than those who did complete treatment (HR (95% CI) = 3.32 (1.84, 5.99), P < 0001), Figure 1. Also, patients with moderate overall comorbidity scores (HR (95% CI) = 1.89 (1.27, 2.80), P = 002) and severe overall comorbidity scores (HR (95% CI) = 1.87 (1.11, 3.14), P = 0.019) had worse survival than those with no comorbidity. We fitted various

adjusted multinomial logistic regression models to assess the most influential predictor of comorbidity associated with the treatment completion category. The AIC for the model incorporating overall comorbidity score was 516.42, while including all comorbidities it was 513.53. The model with categorized comorbidities had an AIC of 515.82, and the lowest AIC among individual categories was observed for cardiovascular disease at 507.22. Considering the ΔAIC, there is strong evidence that factoring in all comorbidity categories would provide the most significant prediction of treatment completion (ΔAIC = 9.2). The adjusted multinomial logistic regression revealed the risk of not completing treatment increased for patients with moderate (OR (95%CI) = 9.93 (1.91, 51.62), P = 0.006) overall comorbidity. No significant association was found between the risk of late completion and overall comorbidity scores. The risk of not completing treatment increased for patients with cardiovascular conditions at baseline (OR (95%CI) = 6.70 (1.98, 22.63), P = 0.002), Figure 2. The risk of late completion was not significantly associated with other comorbidities. An adjusted multinomial logistic regression with interaction of cardiovascular and respiratory comorbidities indicated the risk of late treatment completion increased for patients with both respiratory and cardiovascular comorbidities (OR (95%CI) = 6.83 (1.26, 37.00), P = 0.03), Figure 2. The risk of not completing treatment increased for patients with cardiovascular conditions at baseline (OR (95%CI) = 6.70 (1.98, 22.63), P = 0.002), Figure 2. The risk of late completion was not significantly associated with other comorbidities in our cohort. An adjusted multinomial logistic regression with interaction of cardiovascular and respiratory comorbidities indicated the risk of late treatment completion increased for patients with both respiratory and cardiovascular comorbidities (OR (95%CI) = 6.83 (1.26, 37.00), P = 0.03), Figure 2.

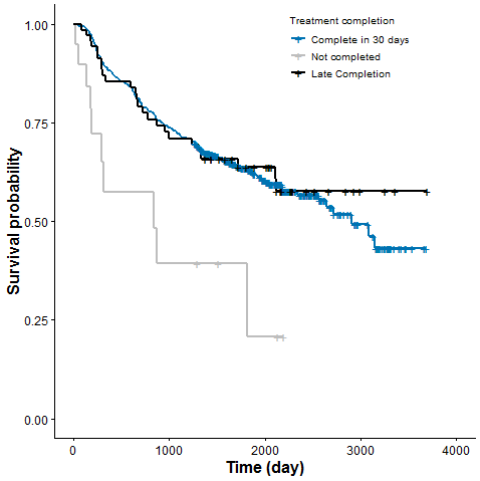

Figure 1 – Kaplan-Meier of adjusted Cox regression model according to RT treatment completion. Not completed the RT relative to completed RT is associated with worse survival. Also, age, performance status, smoking, and log(GTV) were associated with overall survival.

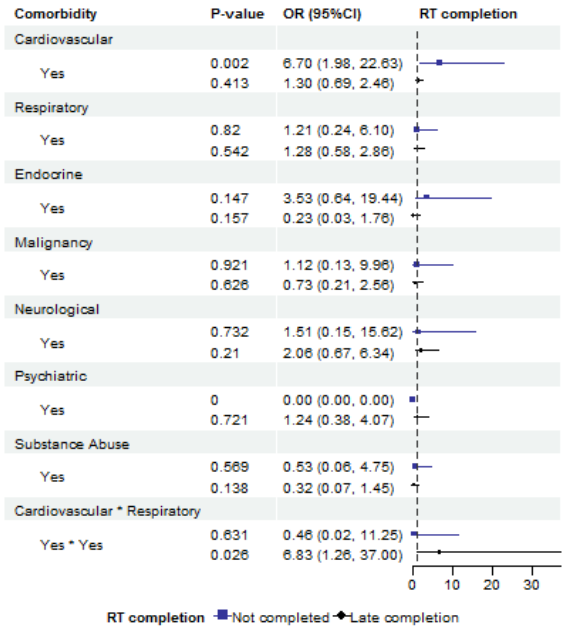

Figure 2 – Forest plot of adjusted multinomial logistic regression model including an interaction between cardiovascular and respiratory. Risk of not completing treatment relative to complete RT treatment in 30 days is increased in patients with cardiovascular comorbidities. Risk of late completing RT is increased with presence of both respiratory and cardiovascular comorbidities.

4 Discussion and conclusion

In this cohort of HNSCC patients treated with curative intent (chemo) radiotherapy, treatment completion was associated with improved OS, but late completion had no effect. Risk of not completing RT is associated with increasing comorbidity score, regardless of late completion. Our findings suggest that considering each comorbidity category generates a substantial improvement on the prediction of treatment completion. This underscores the importance of comprehensive comorbidity assessment for tailoring effective strategies for optimizing treatment outcome. In addition, individual comorbidities are associated with treatment completion. Risk of not completing was associated with presence of cardiovascular comorbidities and risk of late treatment completion was associated with the presence of both respiratory and cardiovascular comorbidities. This cohort come from observational data and includes small number patients who did not complete RT treatment, consequently the prevalence of comorbidities were low among this group.

Therefore, the obtained outcome came from no sufficient data. Further research is required to validate these associations and to propose methods to stimulate treatment completion.

Prediction of Acute Pulmonary Toxicity Events with 3D Convolutional Neural Networks from Radiotherapy Dose Maps

Abstract Predicting toxicity events in radiation therapy (RT) is highly beneficial for managing patients effectively. Identifying patients who are at a high risk of experiencing toxicity early on during their treatments can help in taking measures to reduce the risk of adverse events produced by this undesirable effect. Recent works in a related application, namely, acute pulmonary toxicity (APT) in lung cancer patients treated by RT, have demonstrated high accuracy in predicting such an event using dose maps features processed by a multilayer perception network. Thus, motivated by the success of convolutional neural networks (CNN) in learning semantically rich representation directly from images, this work investigates the suitability of CNN architectures in predicting APT directly from dose maps. Our results demonstrate the ability of some CNN models to predict APT from planning dose maps with an accuracy of up to 81% in terms of receiver operative characteristic's area under the curve. However, most of the architectures and configurations under evaluation led to non-satisfactory accuracy, as only shallower architectures using resized dose maps as inputs were able to train models with good accuracy in the testing set.

1 Introduction

Prediction of toxicity events related to radiotherapy (RT) could be very useful for better managing patients and personalizing treatment and follow-up. Indeed, identifying patients at risk of suffering from these toxicity events early in the course of patients monitoring (ideally, before initiating RT), could allow, in the best case scenario, modifying treatment (optimization of treatment planning, de-escalation of dose to sub-volumes of the organs-at-risk (OAR) most responsible for the toxicity, etc.) to reduce the risk, or at least, identifying patients that could benefit from intensified monitoring after RT to better prevent and treat toxicity symptoms. Recently, we have shown that analysis of dose maps can provide predictive markers of toxicity events in cervical [1] and lung cancer [2]. We used radiomics engineered features (i.e., intensity or textural metrics) extracted from the delineated OAR in the dose maps to train multiparametric models that demonstrated higher predictive value than the usual dose-volume histogram (DVH) approach. In another work, we developed an alternative approach where all dose maps were co-registered to a common spatial reference, and a specific region in the lung most correlated with the acute pulmonary toxicity (APT) event was identified through statistical analysis on a voxel-by-voxel level in the dose maps. Dose map features (e.g., mean dose) from this specific area, combined with clinical variables through a multilayer perceptron (MLP), allowed good accuracy (AUC 81%) in predicting patients with APT[3, 4]. The main advantage of this approach was the ability to both predict which patients are most likely to suffer from APT and to identify a spatial area in the lung that was most responsible. In the present work, we investigated the feasibility of achieving similar predictive power by relying on deep learning (DL) convolutional neural network (CNN) architectures trained using the dose maps as inputs, with or without the help of clinical variables. Our long term goals are i) to achieve similar (if not better) predictive power compared to the previous approach, ii) to provide some explainability of the prediction made by the network and thereby identify the area in the lung most responsible for the APT, on a patient-by-patient basis. Objective ii) will be investigated using interpretability tools such as saliency maps of the trained CNN model. Preliminary results will be reported in the present paper, focusing on reporting methods and results of objective i), while reporting on first results using saliency maps for objective ii).

2 Materials and Methods

2.1 Workflow

The APT classification task was conducted following the procedure presented in Figure 1, where the prediction model takes two inputs: the RT dose maps and clinical features (e.g., age, gender, tumor location...). The dose maps, in the figure represented by X_1 are forwarded through a CNN backbone, e.g., ResNet or DenseNet, from which a feature vector of size 512 is obtained and later concatenated with the clinical features X_2 to serve as input to a set of fully connected layers which delivers the final prediction outcome.

2.2 Dataset and pre-processing

The dose maps as images were previously generated and co-registered to a common spatial reference, namely a thoracic phantom, using a segmentation-based elastic registration via MIM Maestro (MIM v7.0.0, Cleveland, OH, USA) [3]. The segmentation used for registration was the volume combining the lungs and the heart. The dataset contains dose maps of dimension $512 \times 512 \times 237$ from 207 patients, out

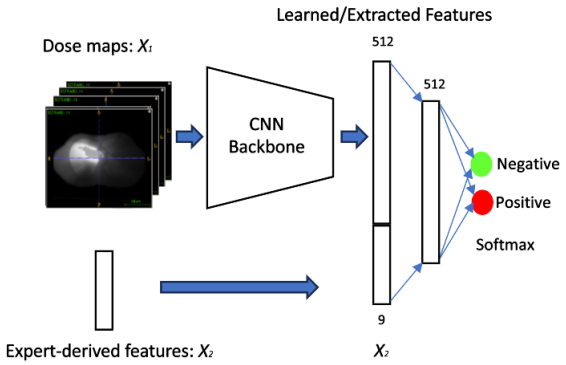

Figure 1: Proposed framework overview.

of which 45 experienced APT whereas 164 did not. Additionally, the dataset includes 37 clinical features for each patient, as described in [3]. Expert-derived knowledge considered as additional input consisted of features previously identified as predictive, i.e., Volume of the heart receiving at least 40Gy ($V40_{Heart}$), Volume of the homolateral lung receiving at least 10Gy ($V10_{LungH}$), Mean dose received by the two lungs ($DMean_{2Lungs}$), American Joint Committee of Cancer (*AJCC Stage*), Chronic Obstructive Pulmonary Disease (*COPD*), Mean Expiratory Volume/Second (*MEVS*), and smoking status [3]. The training set included the same 165 patients used in [3], while the remaining 45 patients were included in the test set. For validation purposes during training, we isolated 20% of the training samples.

2.3 CNN architectures

When using dose maps as input, 3D ResNet [5] and DenseNet-based [6] architectures were used, specifically, ResNet-10, 18, 34, 50, and DenseNet-121. We note that diverse other image classification architectures have been proposed, some with outstanding performance on different applications. To the best of the authors' knowledge, no specific architecture has been designed so far for APT classification. Therefore, we opted to evaluate seminal, general-purpose models, extensively used and well-documented, which we believe would facilitate the reproducibility of our experiments and results.

Succinctly, Residual Networks (ResNet), introduced by [5], aimed at improving convergence issues while training very deep network architectures. ResNet addressed the problem of vanishing gradients, which hinders the optimization process, and the degradation problem, i.e., adding more layers to a deep model leads to higher training error. Such problems, including residual learning blocks among the network layers, were dealt with. The degradation problem suggested that when the network's full capacity was underused for solving a particular task, the optimization process would have difficulty approximating nonlinear layers into identity mappings, which could automatically adjust network depth. Then, instead of hoping that every few stacked layers directly fit a desired underlying mapping, e.g., identity, ResNet explicitly lets those layers fit a residual mapping, which is easier to optimize. DenseNet, on the other hand, introduced by [6], similar to ResNet [5], addresses the vanishing gradient problem by adding densely connected blocks, which consists of linking each layer to any other previous layer. This allows the network to learn more efficiently by reusing features and reducing the number of trainable parameters. The principle behind this proposal states that concatenating the feature maps learned in previous layers allows each layer to access all features of all preceding levels.

2.4 Experiments implementation

In the experiments conducted in this work, we considered different input dose map sizes, see Table 1, the use (✓) or not (×) of data augmentation, and to take into account (✓) or not (×) the dataset imbalance. Each dose map and clinical features, except for AJCC Stage, was normalized with min-max normalization between 0 and 1. AJCC Stage feature was converted from categorical to binary variable. When data augmentation was considered, Gaussian noise, smooth, sharpen, and histogram shift were applied randomly. We used the MONAI library[1] to perform these transformations, as well as to set the network architectures. We used the Adam [7] optimizer and learning rate decay during training following [8]. We set the initial learning rate μ_0 and momentum β_1 equal to 0.0001 and 0.9, respectively. The batch size was set to 2, and the early stopping procedure was used to avoid over-fitting after 20 epochs without signals of accuracy improvements in the validation set.

The training/testing procedures were executed three times, each with a different (random) initialization of the trainable parameters. When class imbalance was addressed in experiments, we adopted a *weighted cross-entropy* cost function to compensate for class imbalance to train the networks, by assigning larger weights to the underrepresented ones, i.e., 0.2 for the negative and 0.8 for the positive class. Those weights were set experimentally.

2.5 Evaluation

Following [3]; the performance of models was evaluated using Receiver Operative Characteristic's (ROC) Area Under Curve (AUC). Considering each network architecture was trained and tested three times, the final performance is expressed in terms of the average AUC. It is worth noting that the standard deviation over the three runs was very low and thus not included in the table for space purposes.

3 Results

Table 1 presents the AUC (average of 3 runs) of each model in predicting APT events according to different criteria: using only dose maps, clinical variables, or both.

Table 1: Average AUC (%) for 3 executions of models.

First of all, results obtained by using only expert-derived knowledge as input (i.e., features previously identified in [3]) to a MLP, the highest performance of 60.2 % of AUC was obtained with balancing and data augmentation. On the other hand, the highest performances were obtained when using dose maps as input in dimensions of 64 × 64 and shallower CNN architectures, i.e., ResNet10, for which the best-achieved performance was 80.2% (80.4%, without data augmentation). Addressing the imbalance using weights in the cost function delivered the best AUC (80.4%) among these two results. Still considering dose maps-based results, ResNet50 obtained the lowest performance among all the experiment's configurations, i.e., around 22.5% for the lower result and 70.9% for the highest, which corresponded to the dimension 128 × 128 input dimension and without data augmentation. In the remaining experimental configurations, ResNet50 achieved results between 40% and 60% AUC.

Considering the results where dose maps and clinical variables were jointly used as inputs, the ResNet10 architecture outperformed the remaining evaluated architectures with 80.9% AUC. Such a result was reached without data augmentation and weighted cross-entropy to alleviate the imbalance. Although still low, It is worth highlighting the significant increase obtained by ResNet50's performance when clinical variables and dose maps were added.

The highest results, e.g., 80.2%, 80.4%, and 80.9%, were obtained with dimension 64 × 64, no data augmentation, and with the shallowest architecture, namely ResNet10. On the other hand, regardless of the use of data augmentation and *weighted cross-entropy*, consistently lowest performances were achieved with the larger dose maps size (256 × 256) and the deepest CNN architecture, ResNet50, with AUCs from 23.8% to 52.9% with only dose maps, and from 37.8% to 44% when both types of data were forwarded through the proposed prediction model. The results obtained by the DenseNet121 architecture were between those achieved by ResNet10 and ResNet50, i.e., in the range 64.7% to 76.9%.

4 Discussion

Our results suggest it is feasible to achieve satisfactory prediction of APT events in lung cancer patients following RT by training a CNN with co-registered dose maps as input. Interestingly, the overall accuracy reached by our best models (around 80% AUC) is similar to that reached through the previous approach [3], which relied on a combination of clinical and dosimetry features extracted from the lung area identified as most correlated with APT events. We should, however, emphasize that this level of accuracy could be reached without any clinical variables as inputs, as the results were not significantly improved using both dose maps and clinical variables, compared to the use of dose maps alone, whereas the use of clinical variables alone led to poor predictive power (60% AUC or less). Another important observation is that the choice of the CNN architecture, the use of balancing and data augmentation, as well as the choice of the input dose maps resize had a strong impact on the final performance. The best results were obtained with shallower architectures (ResNet 10), without data augmentation or balancing, and using smaller dose maps (64 x 64). We also tested using the original size of dose maps as input (512 x 512), but the results were even poorer, so we did not include them.

Considering the results obtained by larger CNN architectures, e.g., ResNet50, it is well known that the number of training labeled samples required for efficient learning increases with the depth of the network. Since ResNet50 contains significantly more trainable parameters than the other variants of ResNet, it is not surprising that it performs worse given the amount of available data. By contrast, the few configurations that led to the best performance in the testing (around 80% AUC) corresponded to the shallowest architectures. Additionally, with respect to this last point, the performance (around 70% AUC) of DenseNet deserves to be highlighted, as even though DenseNet encompasses more layers than ResNet50, its performance was consistently superior, which may be due to the dense blocks to alleviate the vanishing gradient problem.

Although we focused here on our first objective, we include in Figure 2 a preliminary result of using saliency maps generated with Grad-CAM [9] to illustrate how these could be further exploited in our future work to provide some interpretability of the CNN prediction output, as well as to confirm the location of the area most responsible for the APT event occurrence. The figure shows an overlaid representation of the phantom used for the co-registration of dose maps and the average of saliency maps computed by Grad-CAM. Note that the average saliency maps were computed only over the samples correctly classified by the CNN model, separately

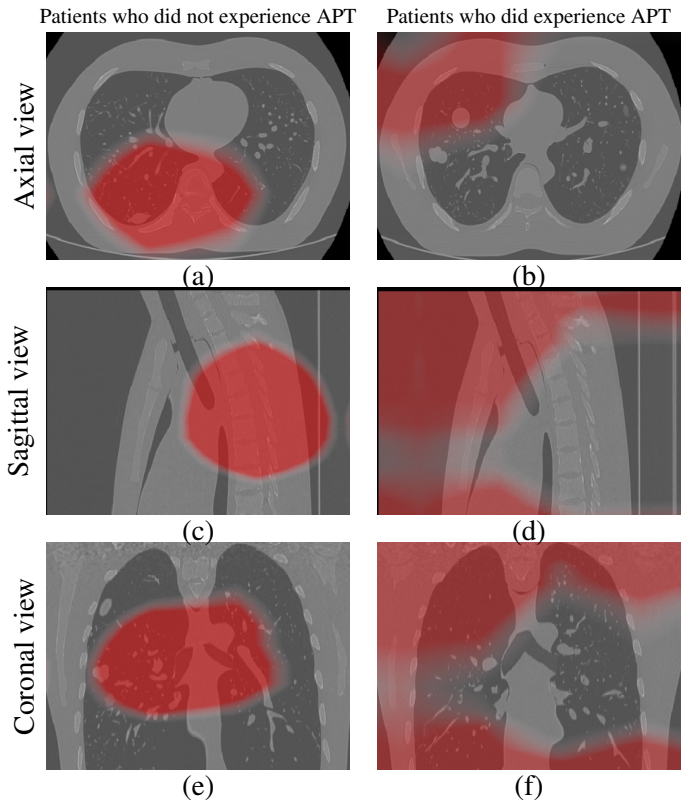

Figure 2: Saliency maps representations computed over ResNet10 architecture using Grad-CAM algorithm. The average of all saliency maps is overlaid on the phantom used for co-registration to visualize the localization of the parts of the dose maps relied upon by the CNN in axial (a/b), sagittal (c/d), and coronal (e/f) views for classifying patients without/with APT respectively.

for cases with and without APT. According to these saliency maps, prediction of the absence of APT events is achieved by the CNN by relying mostly on the dose information contained in lower lung areas, whereas prediction of the occurrence of APT events is achieved by relying on features located in higher lung areas but also strangely highlights top and bottom (coronal/sagittal view) of dose maps where the dose is near-zero, which is a bit puzzling. More work is necessary to understand better the explainability value of these saliency maps (including the comparison with other methods such as integrated gradient with or without smoothgrad) [10].

5 Conclusion

This study evaluated five 3D CNNs for predicting toxicity events based on 3D RT planning dose maps and associated clinical features. We also reported on the potential of Grad-CAM saliency maps to provide some interpretability of the toxicity predictions. Our results suggest that CNN can perform satisfactorily in this classification task. However, only a small part of the configurations of CNN architectures we tested led to good predictive performance. There is clearly room for improvement regarding the generalization capacity of these models. This could be achieved by better preprocessing the training data, using additional data augmentation techniques, or by simplifying the models regarding the number of parameters to avoid overfitting.

Abstract
Deep learning models have emerged as promising tools in predicting radiation doses, but their application to spine stereotactic body radiotherapy (SBRT) encounters challenges like critical structure proximity and dose heterogeneity, resulting in sub-optimal clinical accuracy. We introduce an innovative workflow for three-dimensional radiation dose prediction. Our goal is to enhance the accuracy of 3D dose prediction tasks using dose-level guidance. We propose a two-stage model approach: a dose level prediction model employing nnU-Net and a voxel-wise dose prediction model utilizing a cascaded 3D U-Net. The first model predicts clinically relevant dose levels. Whereas the second model incorporates the weighted predicted dose levels as an additional input to generate precise voxel-wise radiation dose predictions. We trained and evaluated these models using a dataset of 102 spine SBRT plans, comparing them to a baseline cascaded 3D U-Net. Our comprehensive evaluation involved metrics such as Dice score, dosimetric indices (D2, D98, and Dmean) for planning target volumes (PTVs) and 0.035 cc for spinal cord volumes, as well as clinical indices (conformity index, Paddick conformity index, and gradient index). The results showed a superior performance as compared to the baseline approach, demonstrating the potential of dose level guidance to boost the performance of radiation dose prediction tasks.

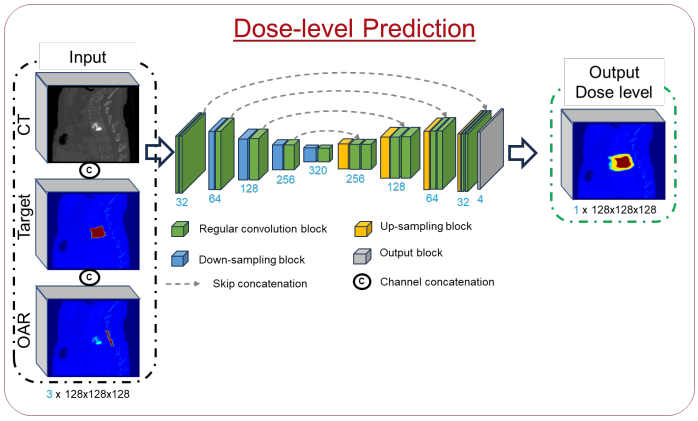
1 Introduction

In recent years, the emergence of stereotactic body radiotherapy (SBRT) has shown promise as an effective therapeutic modality for spine cancer. However, due to the proximity of critical radio-sensitive organs at risk (OARs), such as the spinal cord, the treatment planning process becomes increasingly complex. Also, traditional treatment planning is a time-consuming and labor-intensive process. To address these issues, in literature, various studies have explored the integration of machine learning (ML) and deep learning (DL) techniques to enhance dose distribution prediction [1–3]. The U-Net architecture [4, 5], initially designed for image segmentation, had gained significant popularity in predicting dose distribution without the need for conventional inverse optimization processes. Despite recent progress on U-Net-based 3D dose predictions [6], focusing mainly on prostate and head/neck cancers, spine cancer presents distinct challenges such as critical structure proximity and dose heterogeneity, among others, making it difficult to design an effective model [7].

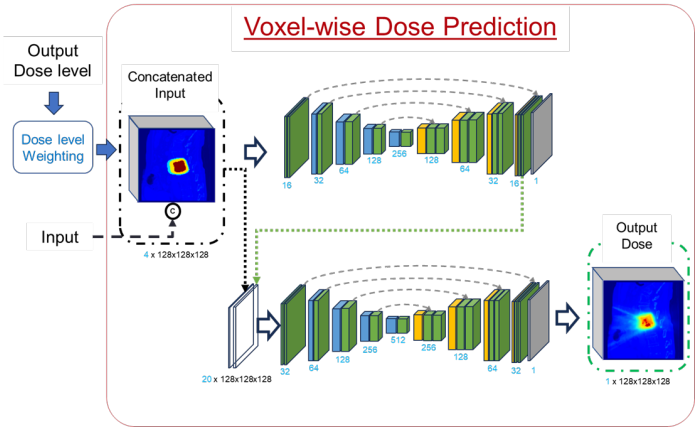
In this study, we introduce an innovative workflow consisting of DL-based radiation dose prediction with dose level guidance in spine SBRT. Our approach shown in Figure 1, consists of two key stages: first, predicting 3D dose levels, and second, leveraging a weighted version of the predicted dose levels to predict 3D dose distributions for spine cancer patients. Here, we introduce an innovation by incorporating the weighted version of the predicted dose levels as an additional input to train a conventional dose prediction network.

2 Materials and Methods

Data: An in-house institutional dataset used in this study consists of 102 spine SBRT plans, including cases of cervical-spine, thoracic-spine, lumbar-spine, and sacral-spine malignancies. The PTV volumes ranged between 8.312 cm³ and 131.280 cm³, with an average of 38.492 ± 30.303 cm³. The target prescription dose for the plans ranged from 16 Gy to 30 Gy, with an average of 20.609 ± 2.581 Gy. The dataset was randomly divided into training (85) and testing (17) sets. Network architecture: Cascading models have shown great ability in dense prediction tasks [6] and in this study, the off-the-shelf segmentation and traditional 3D dose prediction models cascaded for the first time for 3D dose prediction tasks. In this pursuit, the first model is used to predict the dose-level using a segmentation network, and the second model is used to further predict 3D dose distribution. The proposed workflow is a combination of the following two stage models: a) Dose level prediction model, b) Voxel-wise dose prediction model. The schematic of our proposed workflow for the three-dimensional radiation dose prediction is shown in Figure 1. The input of the dose level prediction model has three channels (CT image, PTV mask, and OAR mask) and the output has four channels corresponding to four dose levels such as dose level 3 (> 100 % of Rx), dose level 2 (50-100% of Rx), dose level 1 (40-50% of Rx), and dose level 0 (<40% of Rx). The predicted dose level is further used as an additional input to the voxel-wise dose prediction model. In this pursuit, we introduce a dose level weighting scheme to guide their utilization before employing



(a) a dose level prediction using nnU-Net [8] with three inputs: CT image, target (PTV) mask, and OAR mask, and a 4-channel dose level output



(b) a voxel-wise dose prediction using cascaded 3D U-Net [6] with four inputs. The fourth channel is a weighted predicted dose levels

Figure 1: Schematic diagram of the proposed workflow and network architecture.

it as an input to the voxel-wise dose prediction task. To this end, we propose a weight vector, denoted as [w0, w1, w2, w3], which can be empirically chosen to adjust the dose levels 0, 1, 2, and 3 respectively. As a result, the voxel-wise dose prediction model has four (3+1) input channels and an output dose map. To make the image resolution consistent among all data, images were resampled to a voxel size of 2mm×2mm×2mm and cropped to the image size of 128×128×128. The resampling is carried out in such a way that the PTV is located at the center after resampling.

3 Results

The evaluation of the first stage, dose level prediction model for spine SBRT plans is done through dice scores. Dice scores of 0.901 ± 0.034, 0.756 ± 0.082, 0.385 ± 0.109 are achieved across dose levels 3, 2, and 1, respectively. This effectively demonstrates the model's strength in predicting dose level 3, its notable performance with dose level 2, and the challenges encountered when predicting dose level 1. High dice scores for dose levels 2 and 3 in the first stage model indicate a better initial estimate which could help drive the second stage model for the three-dimensional dose prediction task. To analyze the dose prediction results for the second stage model we compare the dose map for the baseline C3D U-Net [6] dose prediction model and the proposed model. Figure 2 shows some examples of voxel-wise dose prediction from the proposed model and baseline model. It can be visually seen that our proposed method is best in detail in the three-dimensional dose prediction task.

Furthermore, we present the comparison for critical dose-volume indices clinical parameters, including Dmean, D98, and D2 for PTVs and 0.035 cc for the spinal cord volume. Figure 3 shows a visual illustration of these critical dose-volume indices clinical parameters (measured in Gy). The clear visual distinction reveals that our proposed approach tends to closely align with the clinical reality, reflecting a more accurate prediction of these parameters. Also, we present the dosimetric clinical parameters such as Conformity Index (CI), Paddick Conformity Index (PCI), and Gradient Index (GI) for evaluating the quality of the dose predictions. Figure 4 shows a visual illustration of CI, PCI, and GI, as assessed across the actual dose, nnU-Net [8] based dose level prediction, Baseline C3D U-Net [6] based dose prediction, and Proposed dose prediction. These results indicate a better resemblance to the actual dose distribution. Whereas the predicted doses obtained through the baseline C3D U-Net method exhibit poor alignment with the actual dose.

4 Discussion and Conclusion

We have developed a new deep learning-based workflow for 3D radiation dose prediction and tested on an in-house spine SBRT dataset. It is observed that the predicted 3D dose distribution of the proposed approach is more accurate than those of the other widely adopted dose prediction approaches. Here, we analyzed the new paradigm of deep learning-based 3D dose prediction with dose level guidance. In this direction, we presented a two-stage model approach combining a dose-level prediction task and a voxel-wise dose prediction task. The weighted version of the output of the first model is fed as input to the second model to enhance the prediction accuracy. Certain efforts were made to explore the various weighting schemes in improving the performance of the dose prediction approach on spine SBRT plans. Secondly, the evaluation of the spinal cord volume (0.035 cc) revealed limitations in alignment with actual doses.

In the future, we could further investigate the adaptability of our approach to different treatment sites, and leveraging larger datasets can enhance its generalizability in various clinical settings. The weight vector scheme introduced in this study, based on the mean of dose level ranges, opens new avenues for fine-tuning radiation therapy planning.

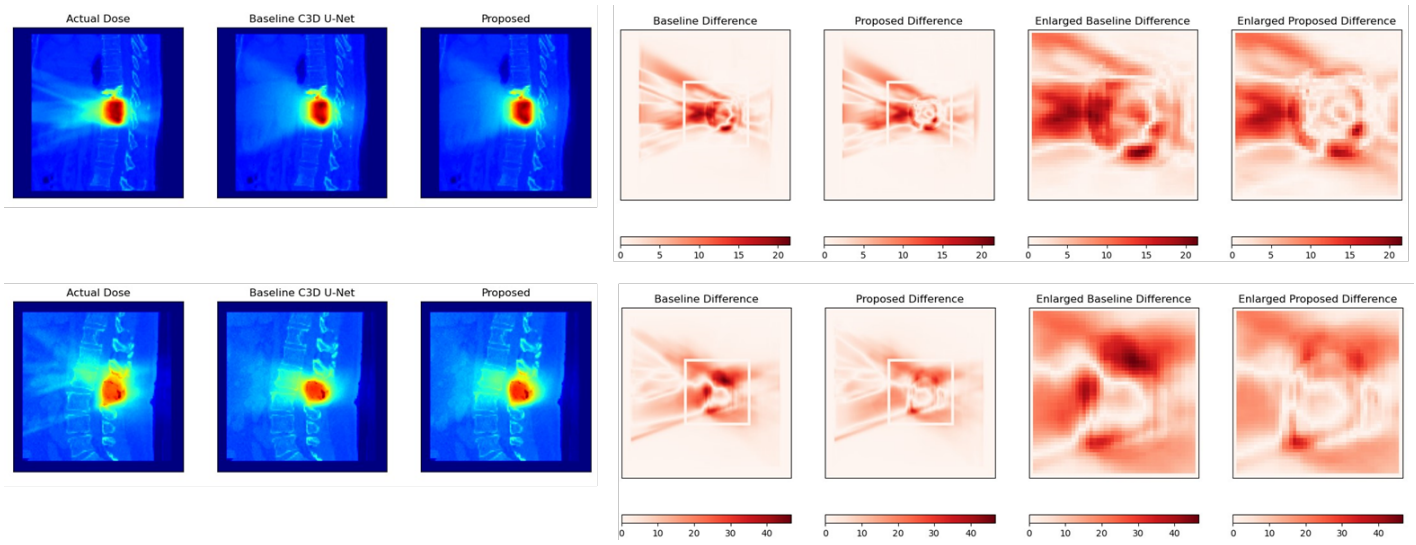


Figure 2: Comparison of actual dose vs. predicted dose for two test cases. Each row features columns, presented from left to right, depicting the following: the actual dose, the baseline C3D U-Net [6] dose, the proposed dose, and corresponding dose difference maps (in % of Rx). The dose difference maps include the baseline difference between the actual and baseline dose, the proposed difference between the actual and proposed dose, and corresponding enlarged difference maps.

Abstract Artificial Intelligence is gaining momentum in fields like radiation therapy. However, there is a lack of reliable and easy to implement quality assurance tools. To address this problem, we present a direct uncertainty estimation method for dose prediction models using input reconstruction error. Our method achieves a higher correlation between uncertainty and prediction loss than the state of the art and allows an easier identification of out-of-distribution data.

1 Introduction

The reliable and efficient estimation of uncertainty in artificial intelligence (AI) models poses an ongoing challenge in many fields such as radiation therapy. AI models are intended to automate manual steps involved in the treatment planning workflow [1]. We focus in this study on models that predict an optimal dose trade-off for each new patient for a specific treatment modality. They can be used to guide physicians in the optimization [2], for automatic treatment plan generation [3] or for decision support [4]. The clinical implementation of AI models is relatively slow compared with other fields. It is primarily due to the lack of reliable and easy to implement quality assurance tools [5]. Indeed, in critical environments like radiotherapy, AI must be used with caution since large uncertainty in the predictions can jeopardize patients safety. Uncertainty estimation techniques must also consider the constraints of the clinic such as limited time and resources. The two prominent methods are deep ensembling (DE) [6] and Monte Carlo dropout (MCDO) [7]. DE uses the variance of multiple networks predictions while MCDO combines several forward passes with randomly dropped out weights. Both require high inference time and MCDO has been argued to be unreliable on real world datasets [8], particularly in out-of-distribution (OOD) detection.

Direct uncertainty estimation methods try to remove the requirement of multiple passes by proposing one shot uncertainty estimation. For instance, direct epistemic uncertainty prediction (DEUP) [9] disentangles epistemic and aleatoric uncertainties by subtracting an estimation of the latter to the prediction of the error. The aleatoric uncertainty is approximated with the variance of labels for the same input by oracles. Despite its elegance, applications like radiotherapy dose prediction would require the generation of multiple treatment plans by different experts for the same set of patients. It is currently very difficult and unrealistic to obtain such data due to the time constraints of clinical environments.

In this work, we present a direct uncertainty estimation method using input reconstruction error. We propose to reconstruct the CT scan given in input from the latent representation of a dose prediction model. A CT reconstruction branch stems from the bottleneck of the U-Net based dose prediction model (see Figure 1). The mean squared error (MSE) of the CT reconstruction can be used as a surrogate of the uncertainty. Our method achieves a higher correlation between uncertainty and prediction loss than the state-of-the-art and requires less computation time. We also investigate its performance as an OOD detection by testing with patients treated for other head and neck sites. Our method allows an easier identification of OOD data, shown by a higher Z-score and no overlap between the distributions.

2 Materials and Methods

2.1 Architecture:

Our model is based on the HDUNet [10], a convolutional neural network, with a hybrid architecture between the popular U-Net [11] and DenseNet [12]. Our model plugs a second decoder branch to the bottleneck after the encoder, which aims to reconstruct the CT scan given in input, like an auto-encoder (see Figure 1). The training loss is the sum of two MSE, one for dose prediction and the other for CT reconstruction.

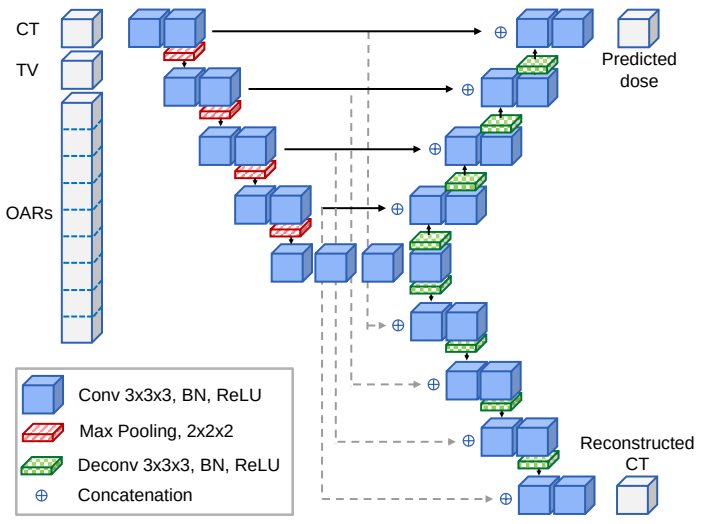

Figure 1: Architecture of the network.

2.2 Data:

Dataset 1 - ID

The training set of the DL dose prediction network is an anonymized database of 60 patients with oropharynx cancer. The treatment planning system used to generate the plans is RayStation 11B. For consistency regarding the planning strategy and the beam configuration, all selected patients have two dose prescription levels: 70Gy (CTV_HIGH) and 54.25Gy (CTV_LOW) on tumor and elective nodal volumes, respectively. PT plans are planned for pencil beam scanning delivery, using four beams. Each patient has a PT dose distribution, a CT image and a set of contours for the target volumes and the OARs.

Dataset 2 - OOD

The second database used to investigate its performance with OOD is a set of 10 patients obtained from the same institution. The cancer sites are also head and neck but not oropharynx: larynx, hypopharynx, nasopharynx, supraglottis and pyriform sinus. Each patient has a CT image and the same set of contours as the ID dataset.

2.3 Training:

Networks were trained to minimize the MSE loss functions from the two branches.In the ID analysis as described below, we used a 11-fold nested cross-validation approach. This method entails to set aside 3 patients as an outer test set and train multiple times the networks with moving training, validation, and test sets. The validation and test sets consist of 5 patients each, and we use the remaining 47 patients for the training. The process is repeated 11 times, allowing us to obtain predictions and uncertainty values on 55 patients (number of patients per test set times number of folds).

2.4 Uncertainty estimation:

The proposed surrogate of the uncertainty is the MSE between the clinical and reconstructed CT images. We consider the voxels in the body contour to keep relevant information in our metric and avoid a positive bias caused by zero values of the background around the patient. Moreover, couch setup can vary and should not be considered by our metric.

2.5 Evaluation:

We evaluated the performance of the input reconstruction method in three parts: its impact on the model performance, the accuracy of the uncertainty metric when fed ID data and its ability to perform OOD detection.

- **Impact of the additional branch on the model**: We compute the difference in dose-volume histogram (DVH) metrics between predictions of standard HDUNet and our model. A paired-samples Wilcoxon test was performed. The threshold for statistical significance is set at p-value < 0.05.

- **ID analysis**: The dose prediction model is trained and tested on the ID dataset following the training process described in the Training subsection. At inference time, we computed the Pearson correlation coefficient between the uncertainty estimation and the dose prediction error and compared it with MCDO and DE.

- **OOD analysis**: The dose prediction model is trained on the ID dataset and the inference is performed on the ID and OOD datasets. The two distributions are displayed as histograms for CT reconstruction, MCDO and DE. The Z-score indicates the distance between the distributions. We also computed the number of patients in the overlap between the ID and OOD histograms for the different methods.

  For MCDO, a Bernoulli law was used to drop the weights at inference time with probabilities of 0.1 to 0.5. The standard deviation is computed voxelwise on 20 inferences and the mean over the body is considered.

  For DE, we trained 20 models with the weights following the He initialization [13]. The standard deviation is computed voxelwise on the inference of the 20 models and we consider the mean over the body.

3 Results

The performance of the dose prediction model is shown in Figure 2. The median absolute error is close to zero in the D95 and D99 of the target volumes (Figure 2, bottom) and less than one percent of the highest prescribed dose for Dmean and D2 of OARs (Figure 2, top). The addition of the CT reconstruction branch does not impact in a statistically significant way the dose prediction of the network, as seen in Figure 2. The paired-samples Wilcoxon test over DVH metrics also showed that there is no statistical significance brought by adding the second decoder branch.

	Pearson Correlation	p-value
Deep Ensemble	0.447	6.2e-4
MC Dropout (0.1)	0.599	1.3e-6
MC Dropout (0.2)	0.606	9.1e-7
MC Dropout (0.3)	0.609	8.0e-7
MC Dropout (0.4)	0.613	6.4e-7
MC Dropout (0.5)	0.612	6.6e-7
CT reconstruction	0.620	4.5e-7

Table 1: Pearson correlation coefficients of mean squared error between the predicted and clinical dose in the body and mean squared error between predicted and clinical CT scan. The data was computed for in-distribution patients.

In Figure 3, we can see the distribution of the different uncertainty methods for the ID and the OOD databases. While the five MCDO methods fail to distinguish OOD from ID, DE almost separates between the two distributions with only one patient on the right-hand side of the histogram. Our input reconstruction technique on the other hand allows us to easily set a threshold between ID and OOD patient data. Table 2 shows distance metrics between ID and OOD for each uncertainty estimation method.

	Z-score	Intersection
Deep Ensemble	2.347	0
MC Dropout (0.1)	0.368	9
MC Dropout (0.2)	0.877	4
MC Dropout (0.3)	1.098	2
MC Dropout (0.4)	1.177	2
MC Dropout (0.5)	1.124	3
CT reconstruction	34.050	0

Table 2: Z-score and intersection (in number of patients) between in and out-of-distribution data for each method.

The uncertainty estimation of our method is obtained simultaneously to the main task which takes 10 seconds. MCDO and DE require 20 inference passes per patch.

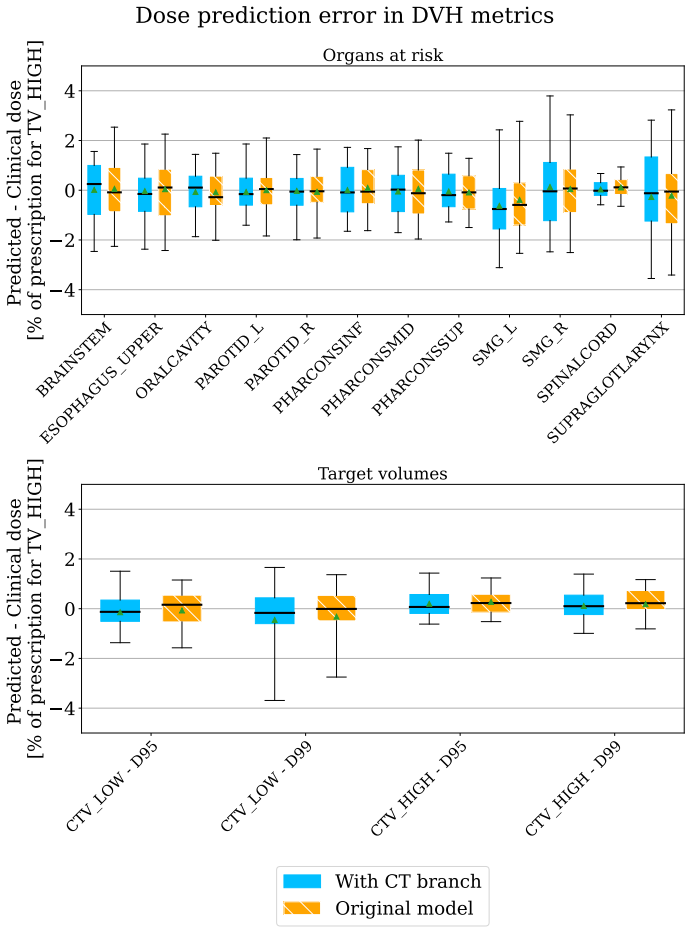

Figure 2: Performance in terms of clinical DVH metrics of the dose prediction model.

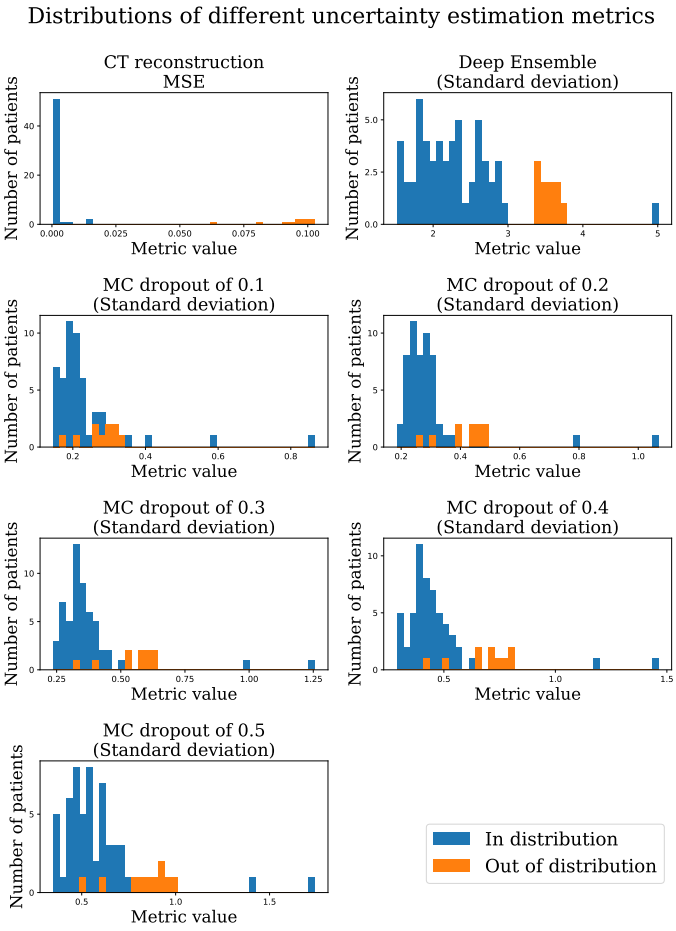

Figure 3: Distributions of the uncertainty estimation metrics

4 Discussion

In this study, we investigate a novel architecture to directly estimate the global uncertainty and detect OOD for a regression U-Net-like architecture by adding an input reconstruction branch. We applied it to an increasingly popular application in the medical field: the prediction of radiation therapy dose distribution. The surrogate of the uncertainty is the MSE of the CT reconstructed by the second decoding branch, grafted to the regular encoder-decoder architecture of a U-Net, as illustrated in Figure 1. The addition of the CT reconstruction branch and duplicate skip connections does not impact the prediction of the dose in a statistically significant way, as seen in Figure 2.

Table 1 shows that the CT reconstruction method presents the highest Pearson correlation coefficient compared with DE and MCDO with different dropout rates. Therefore, our method is a better indicator of patients susceptible to get a prediction with larger error.

In Figure 3, we notice that CT reconstruction is the only method allowing a clear separation with no overlap between the ID and OOD data. This observation is confirmed with the metrics in Table 2, where CT reconstruction has a Z-score of 34 whereas MCDO are less than 1.2 and about 2.2 for DE. Distribution shapes also differ. CT reconstruction distribu-

tion is positively skewed, DE is difficult to define and the five MCDO distributions are also positively skewed but with a wider spread. Two patients present much higher MCDO variances. They would be falsely considered as outliers if we used MCDO for OOD flagging. Despite having been used effectively for OOD detection in 2D image classification tasks in [14], MCDO does not appear to perform well for our regression task with 3D clinical data. DE also has one patient that would have been classified as an outlier. Interestingly, the patient with highest DE or MCDO variances is the same for all metrics. After a visual check by a physician, no striking difference with other oropharynx patients was detected. The patient with the lowest CT reconstruction MSE value from the OOD dataset is a patient with a centered tumor site of supraglottis whereas the furthest apart has a tumor in the lowest part of the larynx. This observation suggests a connection between the high uncertainty and the distance between ID and OOD tumor location.

The widespread adoption of MCDO and DE can be attributed, in part, to their ease of adaptation to various models. However, both techniques require on average 20-50 inference passes, which means that either you need more computational resources to parallelize inferences or more time. Our solution allows us to compute the uncertainty for free, since it is computed simultaneously to the main task. In a real-time scenario such as adaptive radiotherapy workflow, reducing the time spent by a patient on the couch is crucial.

Contrary to MCDO and DE, our method outputs a single value as uncertainty measure whereas the former techniques can produce 3D uncertainty maps. Reliable uncertainty maps are definitely an interesting tool to help physicians apprehend the regions of uncertainty and would be a great addition to the interface of the clinical workflow. There are still applications where a single value can be used and where our model could be beneficial. For example, to flag OOD patients, these patients could either be redirected to another network trained on closer patients or require the attention of a clinician to proceed with the treatment. Another application could be in the curation of networks with active learning. Active learning is the task of optimizing the selection of the training set among a pool of unlabeled data [15, 16]. Current active learning methods use MCDO or DE, rank unlabeled data according to their uncertainty and select highly uncertain samples for oracles to label [15]. We think that active learning would also benefit from our fast method.

One limitation of our study is that the addition of the CT reconstruction branch has only been investigated for a regression task. This implies that both outputs (predicted dose and CT reconstruction) are trained with the same MSE loss and therefore the correlation between the error and the uncertainty is more straightforward. It would be interesting to investigate the behavior of such an addition for a task where the main loss and the reconstruction loss are different. For example, also in the field of radiation therapy, a segmentation task uses Dice or cross-entropy as the main loss function.

5 Conclusion

In this study, we investigate a novel architecture to directly estimate the global uncertainty and detect out-of-distribution detection for a proton therapy dose prediction model by adding an input reconstruction branch. This method showed a higher Pearson correlation coefficient between the dose prediction error and uncertainty estimation metric than state-of-the-art techniques like Monte Carlo dropout (MCDO) and Deep ensemble (DE). Moreover, our method allows an easier identification of out-of-distribution data. Contrary to MCDO and DE, the uncertainty is computed simultaneously to the main task, which is ideal in time-sensitive applications. This technique could be investigated in the future for other U-Net like architecture like segmentation or detection.

Abstract: Purpose: This study investigates the predictive value of different race-based models constructed from radiomics and clinical factors, to predict tumor recurrence at three years for African American and Caucasian head and neck cancer patients. Two-hundred-two patients (78 African American, and 124 Caucasian), treated with definitive radiation/chemoradiation (70Gy, 35-Fraction) were studied. A five-fold nested-cross-validation (NCV) technique was used to evaluate forty-five unsupervised Kohonen-Self-Organizing Maps (KSOMs, topology: 5×5, five-folds for nine different models corresponding to different combined cohorts and information modalities) constructed from twenty-six one-hot encoded clinical factors and 447 radiomics features extracted from patients' gross-tumor-volume on planning-CT images. The NCV-based unsupervised predictive accuracy for African American and Caucasian-based models were: 0.712±0.048 and 0.633±0.066 for clinical factors, 0.736±0.069 and 0.678±0.074, for radiomics, and 0.756±0.088 and 0.693±0.093, for the ensemble model (combined information: radiomics + clinical-factors). The accuracy for the combined cohort ensemble models (combined clinical and Radiomics information) were: 0.798±0.093 and 0.734±0.084 for African American and Caucasian patients, respectively. This study demonstrates the value of different unsupervised modeling strategies for combining different information modalities, their sparsity levels and influence on the model sensitivity according to their class imbalance, and patient cohort sizes to reveal and improve the outcomes prediction power in diverse racial groups.

1 Introduction

Significant racial disparities currently exist in head and neck (H/N) cancer outcomes, with 5-year overall survival being ~30% lower in African American (AA) versus Caucasian (CC) patients [1-4]. After adjusting for age, sex, marital status, tumor site, and year of diagnosis, African American race has been found to be associated with worse OS and Disease-Specific Survival (DSS) Hazard Ratio=1.67, p<0.0001) [5]. Epidemiological studies have suggested several reasons for the disparity including lack of access of AA patients to high volume surgical centers, limited access to care, cost, and transportation limitations, etc. [1-4]. It is important to examine how imaging biomarkers and clinical factors can contribute to these outcome disparities. Image-based biomarkers in combination with relevant clinical factors can be used to develop predictive models, which can risk-stratify individual patients prior to cancer treatment to improve outcomes and ultimately reduce the disparities between these racial groups. This study investigates different unsupervised model development strategies and their predictive powers for inference of tumor recurrence after three years in H/N cancer patients in diverse racial groups.

2 Materials and Methods

2.1 Patient Population, Treatment, Outcome information, and Imaging: Two-hundred-two subjects were identified from a head and neck cancer database (REDCap 10.6; Nashville, TN) under an institutional review board (IRB: 8751-27) approved as a single institution retrospective study. Subjects diagnosed with head and neck cancer primary with an HPV status of unknown or negative were included for analysis. The recurrence Free Interval (RFI) information of the patients at three years was used as the outcome of interest for the model development. Seventy-eight African American patients (68 poor responders and 10 good responders) and 124 Caucasian patients (92 poor responders and 32 good responders) were studied. All patients were treated with definitive radiation/chemoradiation at our institution with fractionated radiation therapy (total dose was 70 Gy in 35 fractions) between February 2005 and December 2021. The patients were treated either with intensity modulated radiation therapy (IMRT) or volumetric modulated arctherapy (VMAT). Patient planning CT (pCT) images were acquired by a Brilliance Big Bore, 16-slice CT scanner (Philips Health Care, Best, the Netherlands). Reconstructed axial pCT images were 512×512 pixels with an in-plane resolution of 1.23×1.23 mm^2 and image thickness of 3mm.

2.2 Clinical Factors Information and Radiomics Analysis: We retrieved the following 6 clinical factors from our institutional head and neck database for the two cohorts (African American and Caucasian): 1- Age at Diagnosis, 2- Gender, 3- Total Charlson Comorbidity Index (CCI), 4- Alcohol Use, 5- Smoking History, and 6- Clinical T Stage. The clinical factors were selected based on their correspondence with the primary tumor since in the radiomic analysis, we only analyzed the primary tumor and did not investigate the lymph nodes. As shown in Table-1, for each patient, the 6 different clinical factors were encoded into 26 channels and mapped from categorical to quantitative/numeric information using One-Hot Encoding technique [6]. Quantitative image analysis of radiomics features was performed using RODiomiX [7, 8], a software system consists of a series of computation cores that has been developed by our group, and validated on the recommendations provided by the image biomarker standardization initiative (IBSI) [9, 10]. Data quantization, and image re-segmentation [9, 10] were performed prior to radiomic feature extraction as follows: Effects of variable

voxel sizes (SNR inconsistency) from pCT images were minimized by resampling the image voxels into a uniform and isotropic voxel size (1 mm^3/voxel) using proximal or Nearest-Neighbor interpolation technique [9, 10]. GTV intensities were then quantized and resampled into 64 intensity levels using a Fixed Bin Number technique [9, 10], as recommended by the IBSI. Volume re-segmentation was also performed to exclude any out of range voxels (due to resampling and FBN quantization) [9, 10].

Table-1: This table shows the clinical factors and their respective One-Hot encoding labels.

Ch.	Encoded Clinical Factor	Ch.	Encoded Clinical Factor
1	Race - (0: AA, 1: Caucasian)	14	CCI-0
2	Alcohol Use- None	15	CCI-1
3	Alcohol Use- Social Drinker	16	CCI-2
4	Alcohol Use- Occasional (1-10/wk)	17	CCI-3
5	Alcohol Use - Frequent (>10/wk)	18	CCI-4
6	Alcohol Use -Current drinker	19	CCI-5
7	Alcohol Use - Alcoholism- in the past, not currently drinking	20	CCI-6
8	Alcohol Use – Unknown	21	CCI-7
9	Smoking History - Never Smoker	22	CCI-8
10	Smoking History - Former use (Quit >3 months ago)	23	HPV Status – Negative
11	Smoking History -Current use	24	HPV Status - Not tested/Not done
12	Smoking History - Unknown/No Data	25	HPV Status – NA
13	Gender (0: Female, 1: Male)	26	HPV Status - Unknown/No data

Radiomic feature extraction was performed using the ROdiomiX software system [7, 8]. A series of 2D, 2.5D, and 3D IBSI-validated radiomic features (447 features, Chebyshev distance=1.0, symmetrical, 26-connected Neighborhoods, with 13 and 8 unique directions,) from 11 feature categories (LI, IBS, IH, IVH, MORPH, GLCM, GLRLM, GLSZM, GLDZM, NGLDM, and NGTDM) [9, 10] with 10 different IBSI recommended aggregation techniques (DHQ4, BTW3, SUJT, JJUI, ZW7Z, ITBB, IAZD, 8QNN, 62GR, and KOBO) were extracted from pCT images of the GTVs [9, 10].

2.3 Data Augmentation and Unsupervised Model Development: The radiomics and encoded clinical features were augmented (~ 10 times) using Synthetic Minority Over-sampling TEchnique (SOMTE [11]) to address the data imbalance between the number of patients within the two cohorts (AA and CC) and their respective poor and good responder sub cohorts. An unsupervised Kohonen self-organizing map (K-SOM)[12] or self-organizing feature map analysis was used to reveal the intrinsic association of radiomics and clinical factors and radiomics information with the RFI at three years. A five-fold nested-cross-validation (NCV, [13]) technique was used to evaluate forty-five unsupervised Kohonen-Self-Organizing Maps (KSOMs, topology: 5×5, five-folds for nine different models corresponds to different combined cohorts and information modalities) constructed from twenty-six one-hot encoded clinical factors and 447 radiomics features. The KSOM is an unsupervised machine learning technique used to produce a low-dimensional representation of higher dimensional data set with complex structures while preserving the topological structure of the data. During the K-SOM analysis, a competitive learning algorithm along with Best Matching Unit (BMU) strategy were employed to identify the winner nodes/neurons for a 5×5 topology. The cover steps for initial mapping of the input space for ordering the phase steps of the K-SOM was set to 100. The K-SOM's architecture was hexagonal with an initial neighborhood size of three, and the maximum epoch was set to 200 epochs for batch training mode. For each fold, a BMU-based hit map and its corresponding probability and fuzzed maps [14] were generated for the test and training cohorts using different information modalities and combined cohorts (Figure 1). Ultimately, the NCV-based classification accuracy for poor and good responders for different KSOM-based test models were estimated (at different probability thresholds) and averaged over five different folds.

3 Results

Subfigures 1A-J (left column) demonstrate the AA- and CC-based KSOM fused probability maps for outcome prediction of AA and CC patients using Clinical Factors (1A-B), Radiomics information (1E-F), and combination of Clinical Factors and Radiomics information (1I-J). Subfigures 1C-L (right column) demonstrate the (AA+CC)-based KSOM fused probability maps for outcome prediction of AA and CC patients using Clinical Factors (1C-D), Radiomics information (1G-H), and combination of Clinical Factors and Radiomics information (1K-L). The green, and red zones on the K-SOM topology maps (B–F and H–L) correspond to the good and poor responders predicted by the KSOM models. Subfigures A-F demonstrate 2D and 3D contribution level of diverse racial groups (green for AA and red for CC) into the information content of the KSOM's feature space for Clinical Factors (2A-B), Radiomics(2C-D), and Clinical Factors + Radiomics (2E-F). For a better visualization, the 2D and 3D surface maps are up sampled by 4 and 8, respectively. The NCV-based unsupervised predictive performances for African American and Caucasian-based models were: 0.712±0.048 and 0.633±0.066 for clinical factors, 0.736±0.069 and 0.678±0.074, for radiomics, and 0.756±0.088 and 0.693±0.093, for ensemble model (radiomics + clinical-factors). The accuracy for the combined cohort (AA+CC) ensemble models (combined clinical and Radiomics information) were: 0.798±0.093 and 0.734±0.084 for African American and Caucasian patients, respectively.

4 Discussion

The KSOM technique is an unsupervised learning method which enables detection and preservation of the topological relationship of the training features based on the information similarity. This implies that the underlying

properties of the feature space are uncovered to discover associations that are not easily identified from the raw information. We used a competitive learning algorithm along with Best Matching Unit strategy to identify the winner nodes for a 5×5 hexagonal topology.

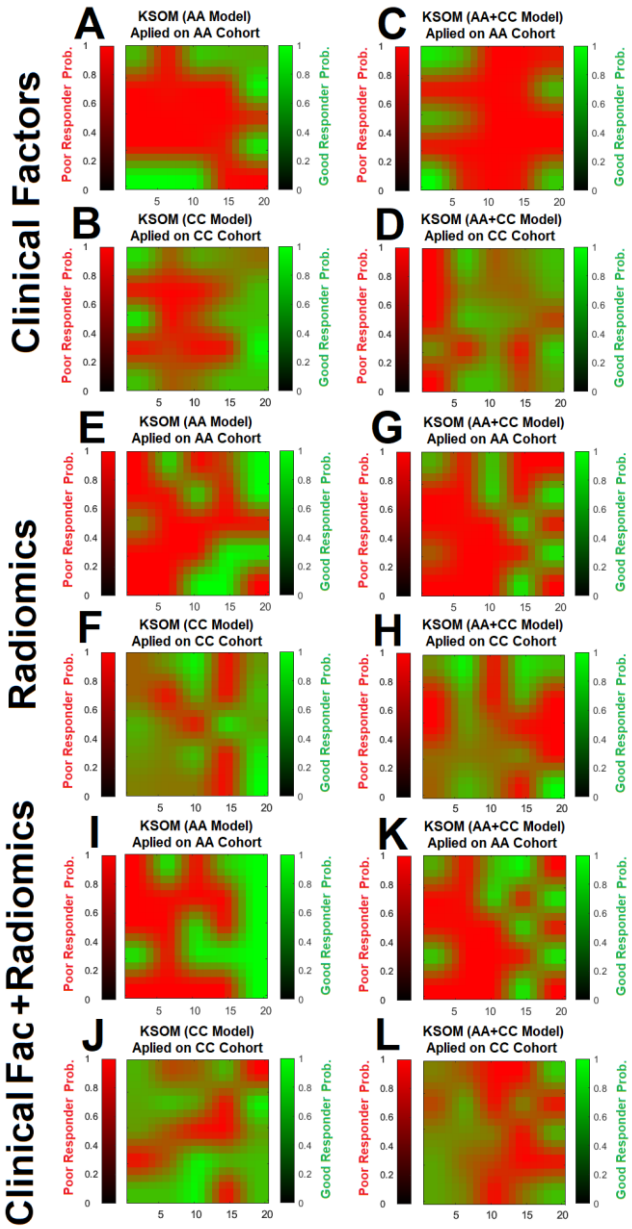

Figure-1: Subfigures 1A-J (left column) demonstrate the AA- and CC-based KSOM prediction probability maps for AA and CC patients for Clinical Factors (1A-B), Radiomics information (1E-F), and their combination (1I-J). Subfigures 1C-L (right column) demonstrate the (AA+CC)-based KSOM prediction probability maps for AA and CC patients for Clinical Factors (1C-D), Radiomics information (1G-H), and their combination (1K-L). The green, and red zones on the K-SOM maps correspond to the good and poor responders predicted by the KSOM models.

However, recruitment of different topology sizes can affect the quality of the KSOM algorithm in detecting the association and distinction of the information clusters on the KSOM's feature space. We also used a very conservative method of cross-validation technique, NCV, to prevent any potential information leakage between different training and test cohorts across different folds. The datasets used in this study were highly imbalanced (~ 7 times and ~2.9 times for AA and CC, respectively) with significant impact on the performance of the developed models. Although, the SMOTE technique was used to circumvent the class (poor vs. good responders) and cohort (AA vs. CC) imbalance issues, it can generate samples between actual samples that represent noise. thus, the augmented dataset can contain more noise than the original one, which can negatively impact on the performance of the model.

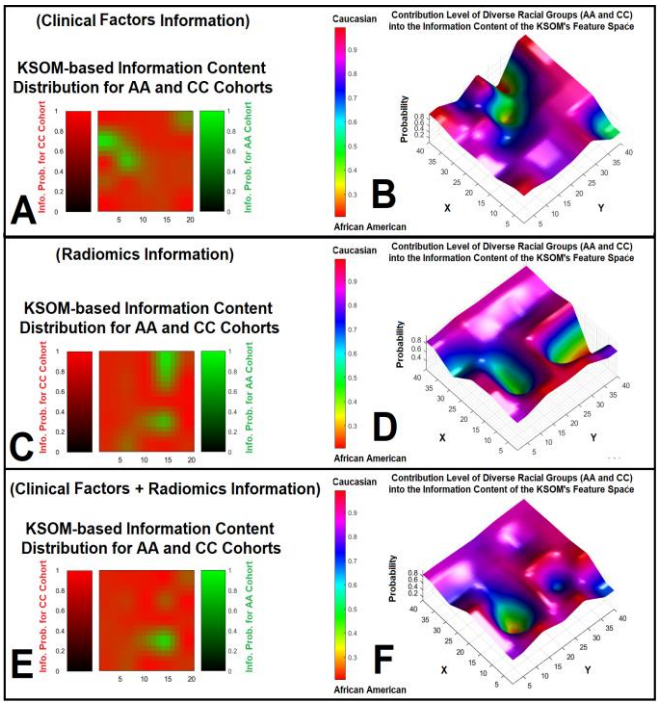

Figure-2: Subfigures A-F demonstrate 2D and 3D contribution level of diverse racial groups (green for AA and red for CC) into the information content of the KSOM's feature space for Clinical Factors (2A-B), Radiomics(2C-D), and Clinical Factors + Radiomics (2E-F). For a better visualization, the 2D and 3D surface maps are up sampled by 4 and 8, respectively.

As shown in subfigures 2A-F, compared to the CC cohorts, the information content for different information modalities (Clinical Factors, Radiomics, and Clinical + Radiomics) provided by the AA cohorts for all the KSOM models are insignificant. Thus, there is a domination effect from the CC patients' information content on the feature space with more information variabilities (see distribution of the information on 2A-F). The NCV analysis results imply that compared to the CC cohort, the predictive power of the Clinical information is higher (~8%) for the AA cohort and AA would benefit more from a separate model constructed from clinical factors. Also, when the clinical information of the two cohorts (AA+CC) is used to construct the KSOM, the predictive powers increase for both racial groups (~4% and 8% for AA and CC, respectively) while the uncertainty of the predictions for both races increase.

As shown in figures 1 and 2, the Radiomics information somehow outperforms the clinical information for both races, while it is more beneficial to the CC patients (2% vs. 4% for AA and CC, respectively). When a combined model

(AA+CC) is constructed from the Radiomics information, the prediction powers for both races increase (~2-3%). Thus, the AA patients benefit more from a combined model (AA+CC) constructed from Radiomics information. When the two information modalities are combined (Radiomics + Clinical Factors), the predictive power for both races are slightly improved (~2-3%). As expected, results imply that when the two information modalities (Radiomics + Clinical information) and cohorts (AA+CC) are used, the predictive power increases for both races (~3-4% for AA and CC, respectively).

In this study, distribution of different information modalities for the two racial groups were mapped on the feature space using an unsupervised method to reveal their cohort-based and information modality-based similarities and dissimilarities. Such analysis can reveal the importance and contribution level of different information modalities in construction of predictive models. Different modeling strategies for combining patient cohorts and their respective information modalities and their predictive powers were investigated. It was shown that the way these information modalities and patient cohorts are used in model development, can highly affect the performance and uncertainty of the prediction. The results of this study can be significantly influenced by the sample size, the cohort and class imbalance, and the data augmentation. In this study, no feature engineering analysis (feature selection, multicollinearity elimination, etc.) was performed prior to the KSOM analysis. Incorporation of these analyses as well as using different supervised models could also improve the predictive power of the models. In this study, the three-year RFI information was used as the outcome information. Investigation of the RFI information at different timepoints to discover the trend of its intrinsic frequencies can provide more insight into the available information content, our strengths, and limitations in the model development.

Although radiomics can serve as a useful tool for distinguishing differences in outcome between AA and CC patients, it is important to note that this study does not offer causal associations. Causality must include consideration of health care disparities such as access to healthcare, costs of care, and other factors that might limit ability for AA patients to receive equivalent quality health care for the same cancers as CC patients.

5 Conclusion

This pilot study demonstrates the value of careful modeling considerations for combining imbalanced information modalities and patient cohorts to improve the outcomes prediction in diverse racial groups.

Abstract
Esophageal toxicity is a common group of adverse events caused by radiotherapy treatment in the chest region. Previous work has shown that dose based prediction models are possible but there has been a lack of testing of the robustness of these models. We use patient dose information and outcomes (N=397) from the RTOG-0617 clinical trial to create esophageal toxicity prediction models using an ANN and LSBoost achieving an AUC of 0.707 and 0.691 for the prediction of grade ≥ 3 and grade ≥ 2 esophageal toxicity respectively. A MAE of 0.884 was achieved when predicting exact toxicity grades. The robustness of the models was evaluated by applying random noise to the test sets and observing the degradation of performance. Methods to improve the robustness including L2 regularisation, SMOTE, random noise-based data augmentation and ensemble model approaches were shown to be effective for different models.

1 Introduction

Esophageal toxicity often occurs after the treatment of lung cancer, or other cancers, by external beam radiotherapy (RT) with esophagitis being the most common esophageal toxicity. Many studies have been produced aiming to predict and limit the occurrence and severity of esophageal toxicity with older studies generally aiming to establishing radiation dose volume effects [1] and more recent studies generally aiming to build machine-learning based models to predict esophageal toxicity [2]. These recent studies generally report the AUC ROC for grade ≥ 2 or ≥ 3 toxicity which usually falls in the range of 0.6 to 0.75 when only using dose features [3].
This study applies two popular models, artificial neural networks (ANNs) and boosted decision trees, for the prediction of esophageal toxicity from dose and clinical information using data available from the RTOG-0617 clinical trial [4]. The robustness of these models was evaluated by applying random noise to the test data with incrementally increasing magnitude. Data augmentation by SMOTE and the application of random noise during training were used to increase model robustness as well as increasing the L2 regularisation of the ANN and combining the models as an ensemble to produce final recommendations for building robust toxicity prediction models.

2 Materials and Methods

Unless mentioned otherwise, all computational methods were applied using MATLAB R2022b v9.13.0 (The Mathworks Inc).

2.1 Dataset

This study uses data from the RTOG-0617 clinical trial [4], a multi-centre trial investigating the effects of standard (60 Gy) versus high (74 Gy) doses of radiation to treat lung cancer patients as well as the effects of using cetuximab during treatment. This is, to the authors knowledge, currently the largest public RT dataset with the necessary information for our analysis. Patients in the RTOG-0617 trial received either IMRT or 3DCRT from one of 185 different institutions in the USA and Canada. Of the 544 patients initially recruited to the RTOG-0617 trial, we excluded 147 patients from our study due to non-completion during the RTOG-0617 trial (N=49), an overall survival of less than 6 months post RT (N=57) or due to issues with the radiotherapy data (N=41) leaving N=397 patients for our study. The data from the RTOG-0617 study is available and was accessed through The Cancer Imaging Archive (TCIA) [5], [6].

Toxicity Grade	0	1	2	3	4	5
Number of Patients	84	99	148	62	2	2

Table 1: The number of patients that developed a maximum toxicity for each toxicity grade (as defined by CTCAE v3 [7]).

The following esophageal toxicities, as defined by CTCAE v3 [7] (the version used in the RTOG-0617 study), were considered; esophagitis, acquired tracheo-esophageal fistula, dysphagia, dyspepsia, esophageal ulcer, esophageal stenosis and esophageal perforation. The number of patients that developed an esophageal toxicity for each CTCAE grade is displayed in table 1.

2.2 Dose and Clinical Features

Dose-volume histogram features were calculated from the RT planning dose maps isolated to the esophagus volume that was available from the RT planning contours. The dose features calculated were the V_x (the percent of the total volume receiving over x Grays), the Vol_x (the total volume receiving over x Grays), the mean esophageal dose and the max esophageal dose. The V_x and Vol_x were calculated for the range 5-80 Gy in steps of 5 Gy. Available clinical features were also included, these features were; age, gender, Zubrod performance, carcinoma type, RT technique (IMRT or 3DCRT), smoking status and the primary tumour volume.

All features were converted to z-scores (mean = 0, std dev =1) before model training.

2.3 Model Training and Hyperparameter Tuning

The models investigated were an ANN and the LSBoost algorithm [8] for boosted decision trees, both using the features from section 2.2 as the model input. The ANN consists of an input layer, fully connected layer, activation layer, fully connected layer and an output layer connected in order. The models were trained as regression models where the output is a continuous variable that correlates to the expected toxicity grade. After training, both model outputs were corrected for variance bias by setting the mean and variance of the model predictions on the training set equal to the mean and variance of the training set ground truth by applying the following equation:

$$\hat{y}_C = (\hat{y} - mean(\hat{Y}_{train})) * \sqrt{\frac{var(Y_{train})}{var(\hat{Y}_{train})}} + mean(Y_{train})$$

Where Y_{train} and $\hat{Y}_{train}$ are the set of all ground truth and model predictions for the training set respectively, $\hat{y}$ is a new prediction and $\hat{y}_C$ is the corrected new prediction. The models were evaluated as an exact grade prediction model and as a binary classifier by defining a cutoff value, 1.5 for grade ≥ 2 and 2.5 for grade ≥ 3 classification. The models were evaluated using the AUC for both grade ≥ 2 and grade ≥ 3 binary classification and the mean average error (MAE) for the exact grade output. Additionally, the ANN and LSBoost models were combined as an ensemble model by taking a weighted average of the two model outputs where the weighting was a tunable parameter.

Test Data Split A 4-fold data split was taken where one fold was held back for testing and the other three folds were used for training and hyperparameter tuning. The training and hyperparameter tuning was repeated four times, leaving out a separate fold for testing each time so that testing could be repeated for the full dataset.

Training and Hyperparameter Tuning Data Split The data in the three folds left out for training and hyperparameter tuning were again split into four folds. One of these folds was used for hyperparameter tuning and the others were used for training. The loss function used during training for both models was the mean square error (MSE). Cross-validation was performed so the hyperparameter tuning was repeated on each fold and the average hyperparameters were used to train the final model on all of the folds (not including the test data). Hyperparameter tuning was applied by Bayesian optimisation to minimise the MSE on the validation set. The hyperparameters tuned and their average values are given in section 3.1.

2.4 Robustness Tests

To test the robustness of the models, random noise was incrementally added to the features of the test set and the degradation of model performance in terms of the AUC for grade ≥ 3 toxicity and the MAE was recorded. For all features in the test set, random noise, X, was added to feature F converting it to feature F_N by $F_N = F + X$. Here $X \sim U(-\alpha, \alpha)$ where $U(-\alpha, \alpha)$ is a uniform distribution with maximum and minimum values α and $-\alpha$. As the features had been converted to z-scores, a value of $\alpha = 1$ means that the noise has a range of 1 standard deviation in the positive and negative directions. The noise was added incrementally with α increasing in steps of 0.1 from 0.0 to 5.0. For all robustness tests, no hyperparameter tuning was performed and the average hyperparameter values given in section 3.1 were used.

2.4.1 Improving Robustness

Techniques were employed to improve the robustness of the ANN and LSBoost models. Again the AUC for grade ≥ 3 classification and the MAE for the exact grade prediction were calculated.

L2 Regularisation: L2 regularisation is known to increase model robustness by forcing a model to rely on features more evenly, reducing overfitting. The robustness test was repeated for the ANN with different values of λ, the L2 regularisation term.

SMOTE: Synthetic minority oversampling technique (SMOTE) [9] is commonly applied in radiotherapy prediction models [2] to improve model performance by generating synthetic training data. SMOTE was applied to the training data to oversample the underrepresented grades. Grade 2 was the most common grade for esophageal toxicity so SMOTE was applied to oversample grade 0, 1 and 3 cases to be as represented as grade 2 cases. SMOTE was not applied to the grade 4 and 5 cases as there were only two of each case in the full dataset so it is not possible to oversample these cases. The performance of the ANN and LSBoost model was recorded as noise was applied to the model after training with SMOTE.

Adding Noise During Training: The training dataset was expanded by adding random noise to the training data features to generate new training examples. This was applied using the equation $F_N = F + X$, described in section 2.4, with an α value of 0.2. The training dataset was expanded to 5 times its original size using this technique. This was done for both the ANN and LSBoost models both on its own and after the application of SMOTE.

Ensemble Model: Using a weighted ensemble, as detailed in section 2.3, was additionally investigated as a method for increasing robustness to noise.

3 Results

3.1 Performance Metrics and Hyperparameter Tuning

The results of the model training with hyperparameter tuning are displayed in Figure 2. The hyperparameter values most

Model	AUC (Grade $\geq$ 3)	AUC (Grade $\geq$ 2)	MAE
ANN	**0.709**	0.690	0.894
LSBoost	0.682	0.669	0.925
Ensemble	0.707	**0.691**	**0.884**

Table 2: Results for the hyperparameter tuning of the ANN and LSBoost models.

commonly selected by the Bayesian hyperparameter tuning for both the ANN and LSBoost models are given below. **ANN Hyperparameters:** L2 regularisation $\lambda = 0.1$, fully connected layer size = 20, activation function = sigmoid, loss gradient tolerance = $1e^{-4}$. **LSBoost Hyperparameters:** Maximum number of splits = 2, minimum leaf size = 2, minimum parent size = 5, number of learning cycles = 400, learning rate = 0.01. **Ensemble Weighting:** The weighted average ensemble weighted the ANN 4 times higher than the LSBoost model on average. Further details regarding the hyperparameters can be found in the MATLAB R2022b files for the functions *'fitensemble()'* and *'fitrnet()'* for the LSBoost and ANN models respectively.

3.2 Robustness Tests

The results of the robustness tests are displayed in figures 1 to 5. Figures 2 and 1 show that increasing L2 regularisation increases robustness in terms of both MAE and AUC for the ANN model. Figure 3 shows that using SMOTE or added noise reduces the performance of the ANN in terms of the MAE. Figure 4 shows an improvement to the robustness of the LSBoost model in terms of the MAE. The best-performing ANN and LSBoost models were selected as the final models. No observable change was observed in the robustness of the ANN or LSBoost model in terms of the AUC when applying SMOTE or noise during training so the figures are not included here. The final ANN model uses a high L2 regularisation term of $\lambda = 0.95$ and only the original data during training. The final LSBoost model uses both SMOTE and added noise during training. The AUC and MAE responses of these final models as well as their weighted ensemble are displayed in figures 5 and 6 respectively.

4 Discussion

We have shown that a model for the prediction of esophageal toxicity from dose maps can be produced to achieve an AUC of 0.707 and 0.691 for the classification of grade ≥ 3 and grade ≥ 2 respectively with a MAE of 0.884 when trying to predict exact toxicity grade. The ANN beats the LSBoost model on all metrics when no test set noise is added. The ANN also outperforms the LSBoost model for all robustness tests provided there is a high level of L2 regularisation present. However, using a weighted ensemble of the two models provides benefit from the LSBoost model by increasing the model robustness to noise in terms of the MAE while not impacting the AUC. To improve the robustness of the models it was observed that a high level of L2 regularisation was beneficial for the ANN and, for the LSBoost model, using SMOTE and adding noise during training was beneficial. L2 regularisation was not available for the LSBoost model but may also be beneficial if implemented.

Many of the improvements to the robustness of the models would not be apparent if the tests to add noise were not applied. For example, in Figure 1, where $\alpha = 0$ and no noise is added, all of the models perform equally. A sharp divergence is then observed for lower values of λ with added noise. This highlights the benefit of these robustness tests for reducing overfitting and building robust models.

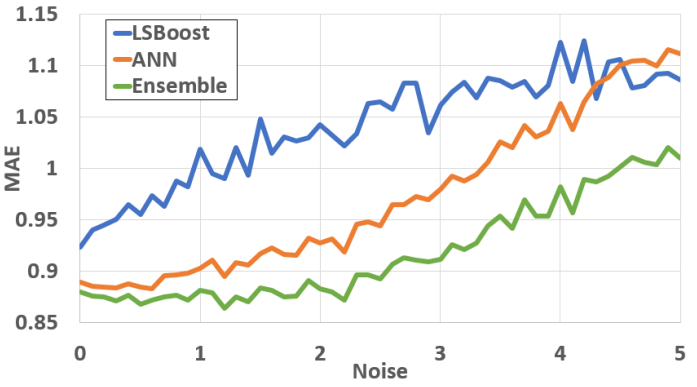

Figure 6: Final LSBoost, ANN and ensemble MAE plots.

This work may be expanded in the future to investigate the application of systematic errors to the test data to study robustness by altering the esophagus volume to simulate contouring errors or by randomly translating the esophagus volume to simulate positioning errors. Additional data augmentation techniques, such as the use of GANs to generate data, and their effect on robustness may also be an interesting avenue of further research.

5 Conclusion

ANN and LSBoost models were trained to predict esophageal toxicity from dose maps using the RTOG-0617 dataset. A weighted ensemble model formed of these two models achieved an AUC of 0.707 and 0.691 for classification of grade ≥ 3 and grade ≥ 2 toxicity respectively and a MAE of 0.884 when predicting exact toxicity grades. Model robustness was evaluated by adding random noise to the test data. This showed that for the ANN model, it is beneficial to include a high level of L2 regularisation and for the LSBoost model it is beneficial to use SMOTE and the application of random noise to augment the training dataset. Finally, it was shown that a weighted ensemble of the LSBoost and ANN approaches can further improve the model robustness.

Improving Dose Volume Histogram (DVH) based analysis of clinical outcomes using modern statistical techniques. A systematic answer to multiple comparisons concerns

Mirek Fatyga[1], Jiuyun Hu[2], and Jing Li[3]

[1]Department of Radiation Oncology, Mayo Clinic Arizona, Phoenix AZ, USA

Dose Volume Histogram (DVH) indices remain the backbone of treatment plan optimization in radiation therapy (RT). Optimization constraints are derived from clinical outcomes studies which search for DVH indices that are predictors of toxicity. Conventional studies treat DVH indices as independent candidate predictors, selecting indices that meet the fixed statistical significance threshold. This process leads to inconsistent results among studies and multiple comparisons concerns. We present a more systematic approach to toxicity modelling, using knowledge constrained Generalized Linear Model (KC-GLM). This approach identifies one or more dose thresholds beyond which DVH indices become truly predictive and generates Normal Tissue Complications Probability (NTCP) models which are more interpretable and likely more generizable. We propose a hybrid model for clinical use, by using a single index NTCP model in the predictive dose range to establish optimization constraints, with the full model used for final NTCP verification.

1 Introduction

Dose Volume Histogram (DVH) indices remain a backbone of treatment planning in radiation therapy. Clinical goals of target coverage and Organs at Risk (OAR) protection are expressed mathematically as constraints on DVH indices which define the optimization criteria. DVH constraints must be derived from clinical outcomes studies which seek to identify indices that are predictive for clinical outcomes and build Normal Tissue Complications Probability (NTCP) models based on them. A planning constraint on a DVH index is derived from the NTCP model by imposing a limit on the allowable risk of toxicity. Many outcomes studies treat DVH indices as independent candidate predictors and retain only indices that meet the statistical significance cutoff of p=0.05. Such a procedure raises multiple comparisons concerns (Bonferroni correction) and often leads to inconsistencies among studies which use randomly chosen DVH indices. Inconsistencies among studies can lead to doubts as to the applicability of results to the clinical practice, or even their veracity. In addition, Bonferroni correction significantly increases required sizes of patient cohorts, which is difficult to attain in realistic clinical studies.

Modern Treatment Planning Systems (TPS) retain full dosimetry information in their databases and give users programmatic access to this information through Application Programmers Interfaces (API). APIs allow users to scan the space of DVH indices and search for "optimum" DVH indices with lowest p-values. Such searches would not be feasible, however, if one treated DVH indices as independent predictors subject to Bonferroni correction. New approaches to DVH analysis are needed to enable more systematic analysis of DVH index space. DVH indices are very strongly correlated because of the physics of dose deposition. Thus, a more comprehensive approach needs to employ an array of DVH indices and account for the strong correlations among them. The purpose of this work is to construct a plausible approach and apply it to clinical outcomes data.

2 Materials and Methods

2.1 Patient Outcomes Studies

We used two patient outcomes studies: (1) grade >= 2 acute rectal toxicity in a cohort of 79 patients treated with conventionally fractionated radiation therapy (RT) for prostate cancer, and (2) cardiac toxicity in a cohort of 134 locally advanced, Non-small Cell Lung Cancer (LA-NSCLC) patients treated with conventionally fractionated radiation therapy, with overall survival (OS) as a clinical endpoint. Both cohorts were treated at Mayo Clinic Arizona.

2.2 Dosimetry Data Extraction

All patients had their treatment plans in Eclipse TPS (Varian, Inc). ESAPI interface was used to extract arrays of $V\%_D$ and $D_{V\%}$ indices.

2.3 Initial DVH Index Scanning Investigation

A "common sense" scanning of DVH index space was based on inserting a single DVH index into a logistic regression or a Cox model, fitting a family of models, each model with a different index (index scanning) and examining fit quality for each model. A model with the lowest p-value and/or best AUC could be picked as the "best DVH index". Insights from this investigation were used to construct a more integrative model.

2.4 Base Statistical Model for the Integrative Approach

A Generalized Linear Model (GLM) was used as the base model, with Fused Lasso operator to reduce the dimensionality and to account for strong correlations among indices. The dosimetry was represented by an array:

$$\theta = \beta_0 + \beta_1 X_1 + \cdots + \beta_p X_p$$

where

$$X_i = V\%_{D_i}$$

which is the percentage of OAR volume exposed to dose D_i or greater. Array Θ was used with the logistic regression model for the study of acute rectal toxicity, and with the proportional hazards Cox model for the study of cardiac toxicity through overall survival. A base other than $V\%_D$ could also have been used to construct the model. However, the $V\%_D$ base is easiest to interpret in the context of radiobiological constraints.

2.5 Knowledge Constraints (KC-Lasso model)

Two additional constraints on parameters β are motivated by radiobiological considerations.

The positivity constraint: $\beta_i \geq 0$

Since the risk of toxicity is monotonically dependent on the value of Θ, positivity constraint holds that none of the contributing DVH indices X_i can decrease the risk of toxicity.

The monotonicity constraint: $\beta_{i+1} \geq \beta_i$

Consider $X_i = V\%_{D_i}$ set to some value (eg. 5%). What will be the contribution of this term to the risk if D_i increases? The monotonicity condition states that the contribution of $X_i$to risk increases or stays the same when D_i increases. This condition can only be enforced by the hierarchy of coefficients β, as the only remaining degree of freedom in the sum θ.

We gave the final model the name of Knowledge Constrained Lasso (**KC-Lasso**) [1],[2].

3 Results

3a. Acute rectal toxicity in RT for prostate cancer.

A "common sense" approach to searching for the most predictive index is shown in Fig.1. A single $D_{V\%}$index was used in logistic regression and a family of models in $D_{90\%} - D_{10\%}$range was fit. The left side of Fig.1 shows p-values for each model. One observes a structure in the plot which indicates that $D_{V\%}$ are not independent predictor candidates. We hypothesize that the region of monotonically declining p-values represents a transition region which is dominated by strong correlations among indices. The true predictive region is approximately $D_{10\%} - D_{25\%}$ while the region $D_{25\%} - D_{55\%}$ is a transition region. This hypothesis is supported by the right-hand plot in Fig.1. We plot logistic regression coefficients on the X-axis, and Spearman correlation coefficients with respect to $D_{20\%}$ on the Y-axis. These two sets of numbers are almost perfectly correlated ($R^2 = 0.995$). A remarkable aspect of this plot is that the X-axis holds all the complexities of the clinical response, while Y-axis is just a "play" on treatment planning numbers. And yet, these two sets of numbers are nearly perfectly correlated.

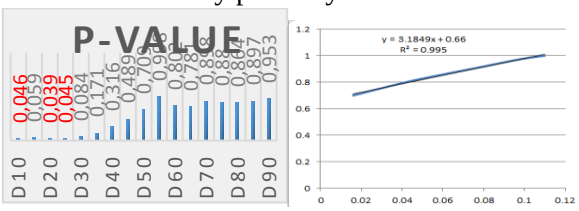

Fig.1 – left side: p-values for logistic regression models using one $D_{V\%}$index at a time.

Fig.1 – right side: a correlation between logistic regression coefficients in the transition region (X-axis) and Spearman correlation coefficient with respect to $D_{20\%}$ (Y-axis).

The KC-Lasso model was used in conjunction with the logistic regression model to detect the dose threshold separating the truly predictive region from the transition region in Fig.1. Two distinct dose thresholds which were predictive for grade 2 acute rectal toxicity were detected: 35Gy and 78Gy (Fig.2). Do note a p-value "break" in the hypothesized predictive region in Fig.1 which is interpreted by the KC-Lasso model as a second dose threshold. It is likely that the high threshold corresponds to rectal bleeding, while the lower threshold corresponds to the remainder of grade 2 toxicity.

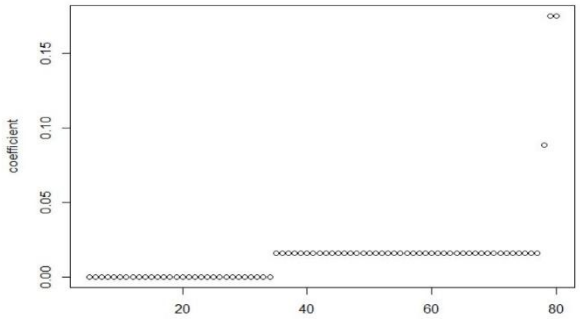

Fig.2 – coefficients β as a function of dose (Gy), acute rectal toxicity in prostate cancer treatments.

3b. Radiation induced cardiac toxicity in RT for LA-NSCLC.

The "common sense" approach is illustrated in Fig.3. A single heart $V\%_D$ index at a time was used in the Cox model, and Fig.3 shows p-values as a function of Dose D. One observes a pronounced minimum at D~55Gy with a monotonic decline in p-values, similar to the transition region in Fig.1. The minimum, rather than a predictive plateau, is caused by the loss of data for doses greater than the prescription dose (60Gy).

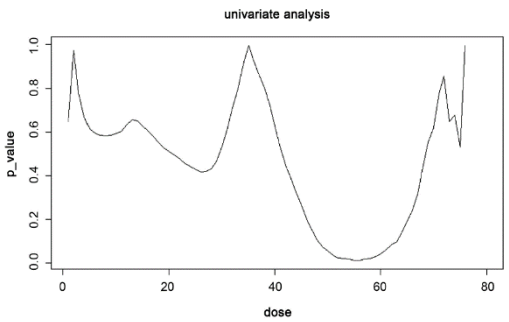

Fig.3 – p-values for a family of Cox models, using one $V\%_D$ index at a time, plotted as a function of Dose D.

The KC-Lasso model was used in conjunction with the proportional hazards Cox model and detected a single predictive threshold of 51Gy (p=0.035) for reduced overall survival due to cardiac irradiation in LA-NSCLC patients.

3c. Effects of knowledge constraints.

In Fig.4 we show results of fitting acute rectal toxicity data with several models with and without knowledge constraints.

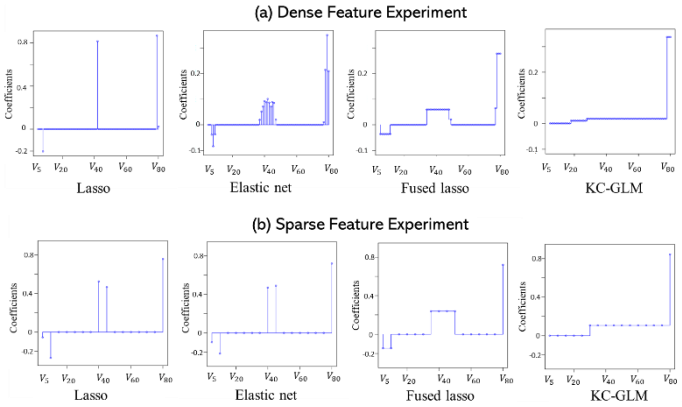

Fig.4 – coefficients β as a function of dose without (Lasso, Elastic Net, Fused Lasso) and with knowledge constraints (KC-GLM). Sparse and dense experiment refers to 5Gy and 1Gy steps. Grade 2 acute rectal toxicity in RT for prostate cancer.

In Fig.5 we show results of fitting Overall Survival against cardiac dosimetry with several models with and without knowledge constraints.

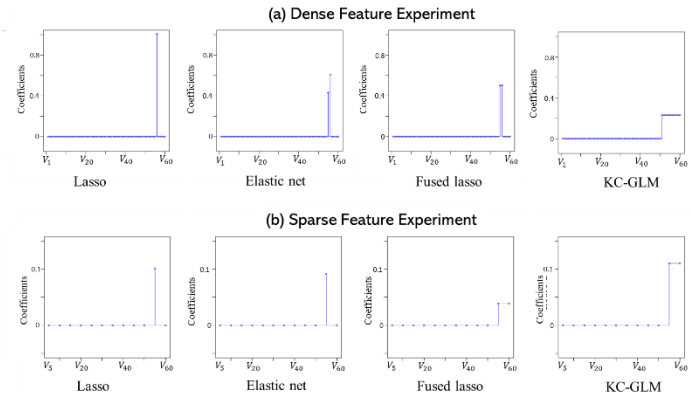

Fig.5 - -coefficients β as a function of cardiac dose without (Lasso, Elastic Net, Fused Lasso) and with knowledge constraints (KC-GLM). Sparse and dense experiment refers to 5Gy and 1Gy step. Overall Survival versus cardiac dosimetry in RT for LA-NSCLC.

Both Fig.4 and Fig.5 show that models without knowledge constraints (first three columns) produce results which are difficult to interpret, with negative and/or isolated coefficients. Such results are difficult to interpret because one would have to argue that one, specific $V\%_D$ index is predictive for the outcome while a neighboring index, at almost the same dose, is not. This result would be contradictory to the basic dose-volume relationship assumptions which form the foundation of treatment planning.

4 Discussion

The model which is presented in this work has been designed to account for an unavoidable intrinsic property of DVH indices, which is strong correlations among them because of the physics of radiation transport. One of the main objectives of this approach is to detect a dose threshold beyond which DVH indices become truly predictive for clinical outcomes. If one treats DVH indices as independent candidate predictors, one could assign significance to indices which are not truly predictive but generate low p-values because of their correlations with the predictive region. In addition, treating DVH indices as independent predictors implies the need for Bonferroni correction which is not applicable to an array of strongly correlated indices. Our work further suggests that models which are purely data driven must be augmented by knowledge constraints. As shown in Fig.4 and Fig.5, purely data driven models generate patterns of negative and isolated coefficients which are difficult to interpret and thus likely not generizable. By adding "knowledge constraints", which are motivated by radiobiology, one stabilizes models and makes them easier to interpret.

The results of KC-Lasso model cannot be used directly in currently available optimization algorithms; hence one needs to use a "hybrid approach" to make the model clinically useful. In a hybrid approach one selects a single DVH index in the predictive region identified by the model and uses this index to construct an NTCP model which is used to compute a DVH constraint, while the full model can be used post optimization to calculate the actual NTCP. While not perfect, this approach provides a path to clinical use. In the case of multiple thresholds (Fig.2), one can include two or more representative indices which correspond to two distinct, predictive regions. It is likely that two thresholds in Fig.2 correspond to two different "classes" of toxicity, namely rectal bleeding at high doses and the remainder of grade 2 toxicities at lower doses. In this case one can construct two approximate NTCP models

with an index in each range, or a single model with two indices.

5 Conclusion

Knowledge Constrained Generalized Linear Models can be used to improve on currently prevailing methodology of toxicity modelling in radiation therapy. Use of such models can address multiple comparison concerns and improve consistency of results from multiple studies. While the GLM cannot be used directly in present day optimization algorithms, a hybrid approach can lead to direct clinical applications. A GLM can identify truly predictive dose range, a single index can be chosen in this range, and be used as an approximate optimization constraint.

Abstract

In the realm of CT-based medical image segmentation, the selection of a loss function significantly influences deep neural network training. Loss functions, such as Cross Entropy (CE), Dice, Boundary, and Top-K, excel in specific areas but have inherent limitations for tissue segmentation. Our motivation arises from the understanding that relying solely on a single loss function can introduce bias to models. We have implemented a combination of CE, Dice, Boundary, and Top-K loss functions employing both loss-level linear combination and model-level ensemble on two large CT dataset cohorts to investigate model accuracy for auto-segmentation of normal tissues for different anatomic locations. Through extensive experiments on institutional and public datasets, consistent observations emerged: (1) linear combination of loss functions did not exhibit a clear advantage over single loss methods; (2) ensemble-based methods demonstrated a 2% - 7% average increase in DSC scores, and appreciable reductions in Hausdorff distances (HD's) and Average Surface Distances (ASD's) compared to both linear combination or single loss methods; and (3) ensemble approach with optimized weights generally characterized finer details in predicted masks, as evidenced by qualitative analyses. This study provides quantitative results on the accuracy of different loss functions employed in machine learning networks for automatic medical image segmentation. Enhanced accuracy was achieved using an ensemble approach with optimized model weights, compared to the use of a single loss function or a linear combination of loss functions.

1. Introduction

The training of DL models involves iterative parameter adjustments to minimize training errors, typically employing optimization methods such as stochastic gradient descent [1]. To quantify these errors, a loss function, also referred to as a cost function, is utilized to minimize the error between the algorithm prediction and the benchmark and thereby produce a convergent result. In the domain of medical image segmentation on CT images, CE and/or Dice are used commonly as loss functions [2-4]. CE loss [5] gauges the pixel-wise discordance between predicted class probabilities and ground truth labels. However, it tends to assign equal importance to background and foreground regions during training, resulting in potential class imbalance. Conversely, Dice loss [6] evaluates the overlap between predicted and ground truth labels, demonstrating effectiveness in handling class imbalance by emphasizing mask intersection, which is crucial for unbalanced classes. However, Dice as a sole loss function is subject to errors when dealing with small and irregularly shaped organ volumes. To enhance the precision of medical image segmentation, researchers have also introduced alternative loss functions such as Boundary loss [7] and Top-K loss [8]. Boundary Loss proves effective for smaller, imbalanced datasets but lacks global context and may not robustly address class imbalance. It is typically combined with other loss functions for more comprehensive segmentation tasks. Top-K loss aims to steer networks toward challenging samples during training, offering benefits for such classes or when imbalanced class distributions exist in the training dataset. Medical image segmentation relies on a range of loss functions, each with its unique strengths and weaknesses [9]. As such, segmentation based on a single loss model can introduce bias to the model training process. Improvement in loss-driven algorithms and computation power has made it possible to use these models simultaneously to improve robustness in medical image segmentation.

One method of concurrently utilizing multiple segmentation losses involves creating a unified model through a linear combination of various loss functions [9, 10]. This approach calculates a weighted sum of the individual loss function's contributions, with each loss being assigned a weight reflecting its relative significance within the overall loss. Such an approach permits the prioritization of specific aspects of the segmentation task, which can be tailored to domain knowledge, or the specific challenges posed by the dataset. Advanced options like ensemble learning [11] can be appealing for greater flexibility, especially when dealing with variations in architecture, hyperparameters, and training strategies. The ensemble approach frequently leads to enhanced segmentation performance by harnessing diversity among the models. Ensemble models have been extensively employed in medical image classification tasks, often in diverse dataset splitting scenarios and utilizing the CE loss function. However, there is a paucity of studies assessing the impact of ensemble DL models trained with different loss functions for medical image segmentation.

This study contributes to the existing knowledge as follows: (1) Evaluates the impact of unimodal and multimodal loss functions in multi-anatomy CT-based image segmentation; (2) Proposes a learnable ensemble approach that dynamically combines CE, Dice, Boundary, and Top-k loss-induced feature extraction modules to enhance segmentation performance and robustness; (3) Demonstrates the benefits of learnable ensemble models.

2. Materials and Methods

2.2.1. Network architecture

With the introduction of Fully Convolutional Networks (FCNs), the Attention U-Net (AttUNet) [12] stands out as an extension of the U-Net [5] architecture. AttUNet retains the U-Net's encoder-decoder architecture, capturing hierarchical features through generation of a segmentation map. AttUNet uses soft attention gates within skip connections to actively suppress irrelevant regions of the feature maps [12], thereby reducing redundant features and enabling characterization of fine details through the attention mechanism [12]. Recently, vision transformer approaches have emerged with the property of self-attention, which enables encoding of long-range dependencies and highly effective feature representations. Among these techniques, the shifted window UNet Transformer (SwinUNETR [4]) has shown superior accuracy for medical image segmentation. SwinUNETR exhibits several key design features: (a) adopts the Swin Transformer [13] architecture which captures long-range dependencies and contextual information through multi-layer self-attention mechanisms; (b) employs an encoder-decoder structure with the Swin Transformer to produce segmentation maps; (c) incorporates multi-scale processing via multiple encoder levels to handle objects of various sizes effectively; (d) integrates U-Net-style skip connections with residual operations to preserve spatial resolution and fine details; (e) employs patch-based image processing for efficient computations of large image datasets.

Here we employ AttUNet and SwinUNETR as two representative 3D segmentation architectures to investigate the impact of single and multiple loss functions on segmentation accuracy.

2.2.1. CE loss

Cross Entropy (CE) is derived from the Kullback-Leibler (KL) Divergence [14], which measures dissimilarity between two probability distributions, typically denoted as *P* and *Q*.

2.2.2. Dice loss

Dice loss directly optimizes the Dice Similarity Coefficient (DSC), a widely employed metric for segmentation evaluation. In general, two variants of the Dice loss are recognized (Isensee et al. 2021). One of them includes squared terms in the denominator (Milletari et al. 2016)

In the following experiments, the linear (non-squared version) as the default function.

2.2.3. Boundary loss

Boundary loss was introduced with the aim of minimizing dissimilarities between predicted and ground truth segmentations [7].

Here we use boundary loss in conjunction with the distribution-based CE loss:

$$\mathcal{L}_{CE+BD} = \alpha\mathcal{L}_{CE} + (1-\alpha)\mathcal{L}_{BD},$$

where α is a hyperparameter and can be optimized through empirical studies.

2.2.4. Top-K loss

Top-K loss is a variation of cross entropy designed to prioritize challenging samples during training. It retains the *K* percent worst pixels for loss, irrespective of their loss/probability values [8].

2.3.1 Linear combination

As depicted in Figure 1A, the combined loss or total loss is achieved by a linear combination of multiple losses.

$$\mathcal{L}_{Linear} = \lambda_1\mathcal{L}_{Dice} + \lambda_2\mathcal{L}_{CE} + \lambda_3\mathcal{L}_{CE+BD,}$$

where λ_1, λ_2, and λ_3 are the importance/contribution weights for each loss component. We found that when λ_1, λ_2, and λ_3 are set equally to the same weighting of 1.0, the obtained models after training showed better performance compared to other settings. Therefore, we represented the loss function as $\mathcal{L}_{Linear} = \mathcal{L}_{Dice} + \mathcal{L}_{CE} + \mathcal{L}_{CE+BD}$.

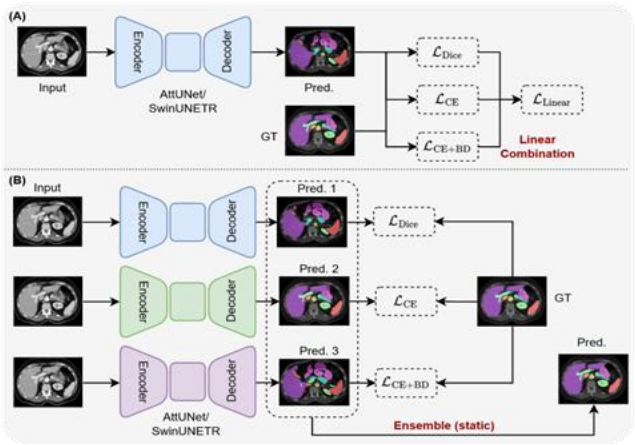

Figure 1: (a) The pipeline for a linear combination of different segmentation loss functions, and (b) the static multiple loss-driven model ensemble model strategy for CT image segmentation.

2.3.2. Static ensemble model

In this scenario (as shown in Figure 1B), we use an averaging ensemble technique by combining the predictions of multiple individual models trained with different loss functions. For instance, we have *K* different versions of trained models $f_{\theta_k} : k \in 1, ..., K$, where θ denotes the parameters of a model. Each of these versions of the model can rely on a specific loss function, e.g., $\mathcal{L}_{CE}$, $\mathcal{L}_{Dice}$, and $\mathcal{L}_{CE+BD}$.

The ensemble probabilistic prediction usually has a threshold of 0.5 to obtain a binary segmentation for each class for medical images. We refer to this approach as the static ensemble model.

2.3.3. Learnable ensemble model

With the learnable ensemble method, feature map extraction process is achieved by the concatenation of three branches of trained models (e.g., from $\mathcal{L}_{Dice}$, $\mathcal{L}_{CE}$, and $\mathcal{L}_{CE+BD}$). Then a few more iterations of training using the

Top-k loss function ($\mathcal{L}_{\text{Top-K}}$) are applied for the final segmentation prediction. We refer to this approach as the learnable ensemble model.

3.1. Datasets

All experiments were implemented on a server equipped with 8 Nvidia A100 GPUs, each with 40 GB of memory. All experiments are conducted in the PyTorch framework in Python 3.8.13, and each model is trained on a single GPU.

3.1.1. An institutional dataset: pelvic organs segmentation dataset

Institutional review board (IRB) approval was obtained for this study. We retrospectively selected planning CT and structure datasets from 300 patients diagnosed with prostate cancer. These 300 cases were randomly divided into three sets: a training set consisting of 225 cases, a validation set with 30 cases, and a testing set containing 45 cases. The testing datasets were held out from the training/validation steps and are considered "unseen". The models were trained for 200 epochs using the AdamW optimizer with an initial learning rate of 5e−4. An exponential learning rate scheduler with a warmup of 5 epochs was applied to the optimizer. Data augmentation was applied 'on the fly' during training. Random flip, rotation, and intensity scaling were used as augmentation transforms, with probabilities of 0.1, 0.1, and 0.2, respectively. We compared the automatic contours generated by our model against ground-truth .

3.1.2. Public dataset: CT organ segmentation dataset (CT-ORG)

A publicly available dataset has been used for evaluation in the CT-ORG task, as described in the reference [15]. The dataset comprises 140 CT scans, each including manual contours of the liver, lung, bladder, kidney, and bones. To maintain consistency with prior work [15], we adopted the same data split for training and testing. Nineteen CT datasets were reserved for testing (holdout), while the remaining 81 scans were used for training.

3.1.3. Ensemble modeling

In the static ensemble strategy, we directly perform averaging over several individually trained models, each utilizing different a loss function, without undergoing any further training. Conversely, in the learning ensemble strategy, we applied an additional training phase encompassing 20 epochs using the Top-k loss function for generating the final segmentation mask. We kept the other feature map generation modules static throughout this phase. We also applied the same data processing and augmentation techniques, albeit with a relatively smaller learning rate set to 1e−4.

We employed the Dice Similarity Coefficient (DSC), the 95th percentile Hausdorff Distance (HD), and Average Surface Distance (ASD) to assess the accuracy of segmentation.

3. Results

4. Discussion

The learnable ensemble model achieved the most accurate segmentation results across nearly all metrics for the institutional pelvic dataset and the public CT-ORG dataset across multiple organs.

These findings agree with previous studies showing improved accuracy of ensemble models for image analysis tasks, albeit on different network architectures [16, 17]. By combining multiple models trained on different loss functions, the proposed ensemble approach overcomes limitations of individual loss functions and integrates their complementary strengths. For instance, CE loss optimizes pixel-wise probabilities, enabling precise localization but ignoring class imbalances. Dice loss directly maximizes overlap with ground truth, overcoming imbalance but sacrificing localization accuracy. Boundary loss focuses on contour distances, handling smaller objects effectively. Top-K loss concentrates on challenging samples regardless of loss value. No single loss completely addresses all segmentation challenges simultaneously. The ensemble approach enables harnessing of complementary advantages of different losses.

The learnable ensemble model achieves superior performance by increasing model diversity through an additional trainable module, enabling dynamic weighting instead of fixed averaging to aggregate predictions, and allowing targeted optimization of challenging samples. This combination provides greater segmentation accuracy and robustness compared to the static ensemble or individual models with distinct loss functions, as evidenced by the statistically significant improvements in segmentation accuracy across multiple anatomic locations. However, the ensemble approach also has limitations. Training multiple models increases computational requirements for image analysis. Additionally, increasing the sample size will benefit from understanding the tradeoffs between variance and bias in the training datasets. Although we have utilized data augmentation, the influence of augmentation on the training data bias, variance and ultimately the generalization error is not fully understood. Determining the optimal combination of loss functions and models for a given segmentation task is a challenging task and one that is under further investigation. Studies providing greater insight into designing high-performance ensembles tailored to different imaging modalities and anatomical structures would be of benefit to the field.

5. Conclusion

Comprehensive experiments, conducted on institutional and public datasets, provide evidence of the superior performance achieved through a learnable ensemble model compared to results based solely on a single loss function or a linear combination of loss functions. These findings will inform future efforts to develop automated segmentation techniques for significantly enhancing efficiency and accuracy of segmentation of anatomy on CT images.

Scripted dosimetric validation of AI auto-contouring in prostate radiotherapy

Daniel R. Warren[1], Adam Chalkley[1], and Ian Stronach[1]

[1] Clinical Computing and Imaging Science Service (CCISS), Department of Medical Physics, University Hospitals Birmingham NHS Foundation Trust, Birmingham, UK

Abstract Artificial Intelligence (AI) contouring tools have the potential to optimise radiotherapy workflows and increase standardisation. Verification of these tools remains an important issue, complicated by rapid development cycles and explainability issues. The dosimetric impact of AI tools is of primary clinical importance, but models have largely been validated via geometric measures. In this study a simple scripted planning process has been applied to fifty prostate cases using the original clinical contours and four AI auto-contouring products, with unedited structures used to produce planning target volumes. Dosimetric clinical goals were assessed for the auto-contoured plans, and compared to standard geometric measures. Commonly used geometric measures, such as Dice, were found to be less useful surrogates for dosimetric measures than a simple metric that took into account the plan geometry (auto-contoured prostate length in z direction), which correlated with a systematic underdose when assessed on the clinical contours. This work suggests that a simple scripted planning approach to assessing auto-contouring output may help identify clinically relevant dosimetric changes.

1 Introduction

The accurate contouring of Organs at Risk (OARs) and target volumes is a key step in the production of radiotherapy treatment plans. Manual contouring is a time-consuming process and inter-observer variation remains a large source of uncertainty in radiotherapy treatments [1]. Many methodologies have been discussed for automating contour generation [2], normally focusing on the delineation of OARs, since tumour volumes show greater variation between patients and require more clinical judgement. Methods using artificial intelligence (AI), particularly deep learning, represent the current state of the art, and they are now being readily adopted into clinical practice [3]. In the UK, the National Institute for Health and Care Excellence (NICE) has recently identified nine commercial applications that have regulatory approval for use within the NHS [4]. In the case of prostate cancer, where a complete organ is typically treated, these auto-contouring systems can potentially outline both target and OAR volumes.

The NICE guidelines highlight a current evidence gap in the dosimetric impact of using AI auto-contouring tools. In the majority of studies, agreement to clinician contours has been assessed using geometric measures [5], but their relationship to dosimetric changes is unclear. To assess dosimetric consequences it is necessary to repeat the treatment planning process on a range of contours, which can require considerable manual effort. This presents a challenge to validating new or updated AI tools and for performing routine Quality Assurance (QA) [3]. NICE guidance, in common with many studies in the literature, recommends manual review of the contours for each patient for QA purposes. This review is an additional time burden, particularly for adaptive radiotherapy, where plans are generated on daily images [6], and may introduce additional error. There are therefore calls for a standardised, automated approach to validation, and interest in using AI tools to facilitate this [3]. Regional or national programmes may be required to avoid the time taken in commissioning new models negating time savings from using them.

The study presented here is development work, intended to inform the methodology for an internal procurement exercise to evaluate commercial AI auto-contouring tools. The primary objective was to automate the generation of plans from manual and automated contours in order to assess the impact of auto-contouring on key clinical dosimetric goals. The automation process was not intended to produce clinical plans, but to provide a consistent level of optimisation, enabling comparison between systems. Additionally, geometric measures were calculated and correlated to the dosimetric goals, to assess whether they could be used as surrogates for QA purposes.

2 Materials and Methods

The local Oncology Information System database was queried to identify a random sample of 50 patients who received radical prostate radiotherapy in the 6-month period starting June 2021 (prior to the introduction of AI contouring systems in our clinic). DICOM datasets comprising CT scans and oncologist-approved manual structure sets were extracted from the clinical image contouring package and de-identified for subsequent processing. The manual structure sets were used as the gold-standard reference in all subsequent analysis.

Four auto-contoured structure sets were generated for each patient by sending the CT scan to three commercial AI contouring systems (all certified medical devices) and one open-source system. Systems will not be identified, since this preliminary methodological work is not sufficient to draw conclusions on their relative performance when commissioned and optimised for clinical use.

Geometric agreement of the manual and auto-contoured structure sets was assessed using scikit-rt v0.3.27 [7], producing standard metrics including Dice coefficients, Haussdorf distance and mean distance to conformity [8].

Dosimetric agreement of radiotherapy treatment plans derived from the manual and auto-contoured structure sets was assessed via an automated planning process. This used

a suite of Python programs interfacing with the RayStation 11B (RaySearch Laboratories, Stockholm, Sweden) scripting API to perform five tasks for each structure set:

1. **Data import:** import structure set and associated CT scan as a new case
2. **Structure name normalisation:** rename structures to match a common naming convention
3. **Create derived ROIs (Regions of Interest):** use Boolean algebra and apply margins to generate Planning Target Volume (PTVs) and optimisation control structures
4. **Beam setup and optimisation:** set up a full single arc VMAT beam, add class solution dose objectives and run optimisation
5. **Plan evaluation:** extract dose-volume statistics for the optimised dose distribution using a) the planning structure set and b) the gold-standard manual set

Automated planning followed the local clinical protocol for intermediate risk prostate cancer (CHHiP volume definitions [9]; 60Gy/20fx prescription) with adaptations to accommodate limitations in the structures output by some packages (OARs used were rectum, bladder and femoral heads only; seminal vesicles were replaced by a proxy structure 2 cm posterosuperior to the prostate).

Table 1: Geometric comparison metrics (mean ± standard deviation) for ROIs generated by the four auto-contouring products compared to oncologist-approved manual contours across 50 patients. HD = Hausdorff distance; MDC = Mean distance to conformity; Bold = best score.

Table 1 presents a summary of geometrical measures comparing the primary prostate planning ROIs produced by each auto-contouring system to the reference clinician contours. The product with the closest match to the clinical contours varies by OAR and scoring metric. Score ranges overlap in the majority of cases, suggesting broadly equivalent geometric performance of all systems with a dataset of this size. In general, volume differences between AI and reference ROIs were systematically in the same direction for all products e.g. the prostate and bladder were on average smaller than the references; this is not readily apparent from the unsigned Dice and distance metrics. Femoral heads showed the worst agreement overall, which is due to differences in contouring protocols; products tended to contour the whole femur rather than the head.

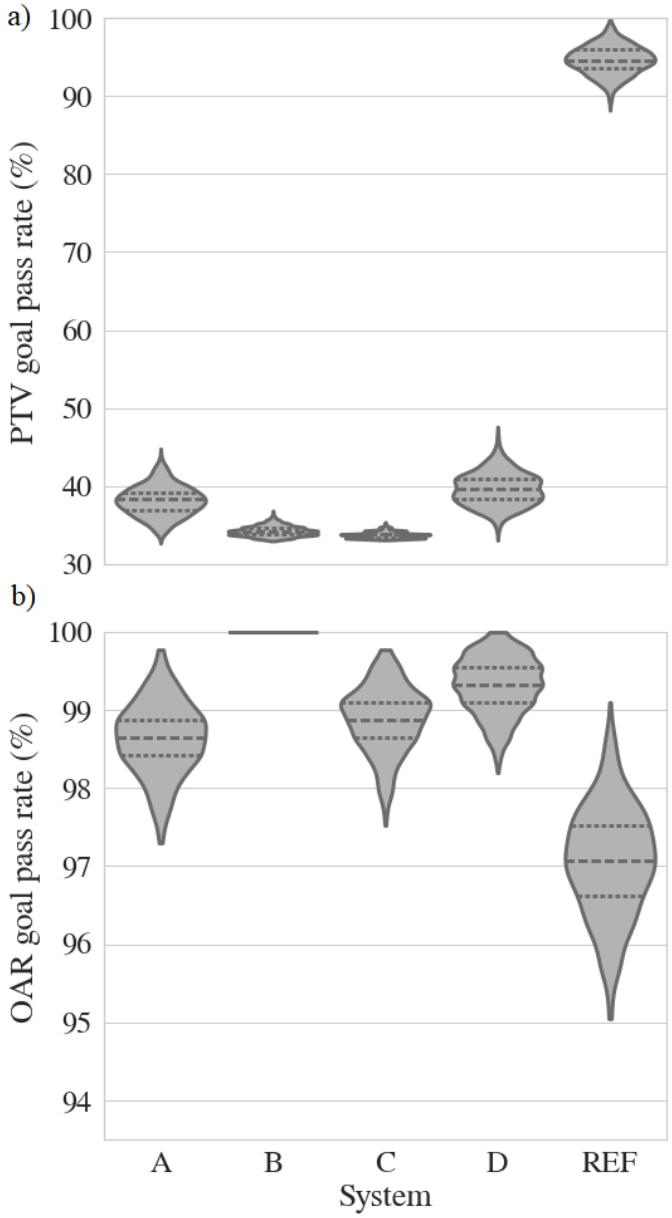

Figure 1: Pass rate for a) PTV and b) OAR clinical goals for automated treatment plans generated using structure sets from each auto-contouring system (A-D) and manual contours (REF) for 37 patients. Goals were assessed using the reference contours. Distributions calculated via bootstrap (n=500). Dashed lines indicate quartiles.

13 patients (26%) were excluded from dosimetric analysis due to missing or overlapping contours in one or more structure sets, which would require manual intervention within the planning pipeline to resolve.

Figure 1 shows the percentage pass rate for all clinical PTV and OAR objectives across all eligible patients when the standardised planning approach is applied to each product's contours, and to the reference clinical contours. Results presented use the gold-standard reference contours to assess goals across all products, since they represent the standard for clinical acceptability.

The PTV goal pass rates are poorer for each of the AI products, representing a reduction in reference target coverage when auto-contoured structures are used to generate the PTV. Conversely, it is notable that the OAR goals for AI contours had a higher pass rate in general compared to those produced on reference contours (for product B the rate was 100% meaning that bootstrapping did not produce a distribution).

The trends in PTV and OAR goal pass rate are partly driven by a general reduction in size of the prostate in auto-contoured cases (Table 1). Prostate ROI size is the main determinant of the size of the PTV in this treatment planning protocol, so coverage would be expected to be poorer in auto-contoured cases assessed using the larger PTVs of the reference dataset. Similarly, OARs will abut the smaller PTVs of the auto-contoured contours to a lesser degree, making it easier for the optimiser to minimise doses in them.

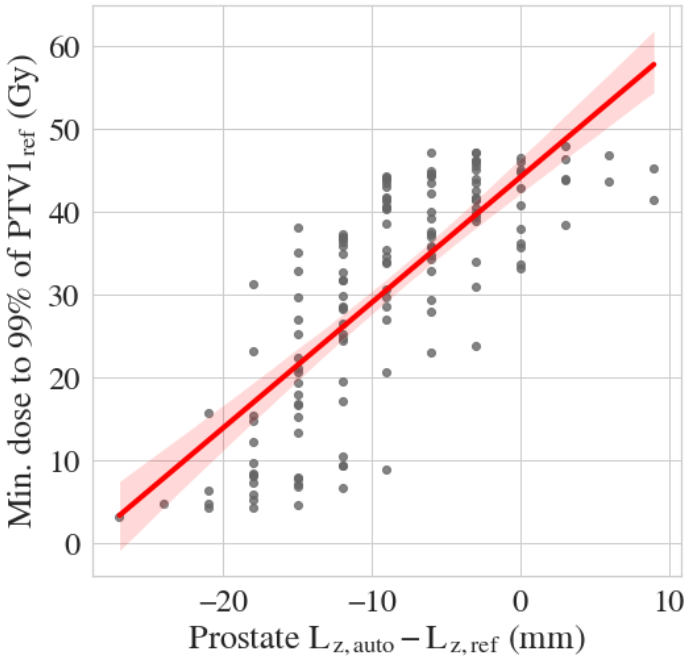

Figure 2: Plot of $D_{99\%}$ assessed on reference PTV1 versus difference in prostate length, along inferior-superior (z) axis, between auto- and reference contours. Shaded area show 95% confidence interval calculated via bootstrap (n=1000). Pearson correlation coefficient r=0.77.

The effect of prostate size was investigated in more detail with respect to the numerical value of the PTV goal $D_{99\%,PTV1,ref}$ (minimum dose to 99% of reference PTV1). Figure 2 shows a plot of this goal vs. difference in prostate length between auto-contoured and reference structures, along the inferior-superior (z) axis. Strong correlation is observed with Pearson correlation coefficient r = 0.77. Equivalent correlations in the x and y directions were considerably lower at r = 0.23 and r = 0.33, as were correlations with all geometric measures displayed in Table 1. These results imply that a shortening in the z-length of prostates was a major determinant of reduced target coverage in auto-contoured plans. This may be explained by the geometry of the single-arc treatment plan, which results in considerably steeper dose gradients along the gantry rotation axis (z) compared to the x-y plane where intensity modulation principally occurs.

5 Conclusion

This work has shown that a simple scripted approach can be applied to assess dosimetric consequences of implementing auto-contouring systems in radiotherapy. Geometric measures that consider treatment plan geometry may be more useful in assessing clinically-relevant dosimetric changes than traditional overlap or distance metrics. Further work to examine how optimisation approach (e.g. scripted class solutions, AI or full manual replanning) affects the discoverability of systematic changes is warranted.

Abstract This paper describes some of the development, decision-making processes, and outcomes of implementing a locally hosted service for automatic segmentation, using in-house trained models complying with national and international guidelines, of medical scans in cancer radiation therapy. By integrating this service, we significantly reduce the time from scanning to treatment planning, as the system automates tasks traditionally performed manually, thereby reducing the need for manual editing. We detail the service's architectural structure, discussing critical decisions in its design and addressing the constraints posed by the hospital's broader IT infrastructure. Our results highlight that automatic segmentation improves workload, and sheds light on practical considerations and challenges of embedding such technological solutions in a clinical setting.

1 Introduction

Artificial intelligence (AI) in radiotherapy, especially in auto-segmentation, has shown promising advancements in increasing consistency in segmentations compared to manual segmentations[3]. Yet, the practical application of AI in clinical settings lags behind.

To address this, we developed the AI Inference Service (AIS), a system designed to facilitate the use of AI for clinical auto-segmentation in radiotherapy in our department, using AI models tailored to our needs. AIS focuses on robustness, ease of use, and adaptability to various clinical scenarios.

The AIS operates transparently for the end-user, see Figure 1. In a typical workflow, scanners send images directly to the treatment planning system. With AIS, scanners transmit images simultaneously to the treatment planning system and AIS.

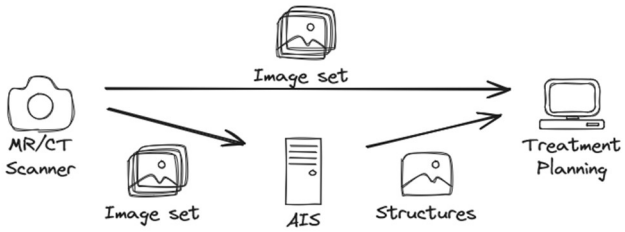

Figure 1: The workflow of the AIS as seen by the end-user.

Modular Service Structure

AIS is composed of four main modules, see Figure 2, each serving a distinct function within the service:

- Gateway: As an extension to a DICOM database, it filters incoming images, determining their suitability for segmentation and the appropriate AI model for processing.
- Watchdog: This module monitors a directory for new image sets, triggering AI inference processes. It ensures timely execution of AI scripts and limits the system to only have as many active inference processes as the available computational resources allow.
- Inference: Manages the conversion from DICOM to Nifti format, runs the nnU-Net[1] for segmentation, post processing, and converts the output back to a DICOM RTStruct file.
- Return service: Tracks both successful and unsuccessful inferences, managing the output RTStructs accordingly. It returns completed segmentations or error-coded RTStructs for failed processes. Currently, both the DICOM protocol and standard file copying are supported.

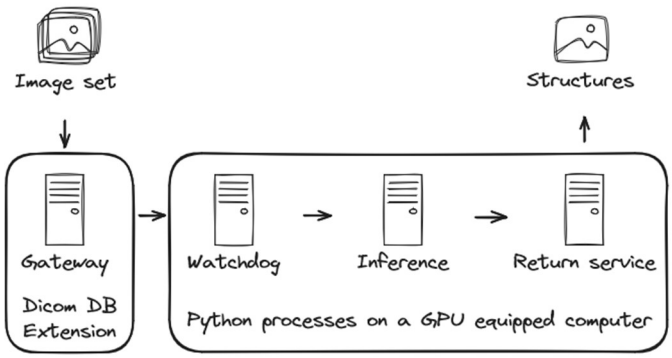

Figure 2: Modular structure of AIS.

Each delineation of an image set is allocated a unique directory on the inference machine, where all files relevant to that image set are stored. The system renames this directory based on the process stage, facilitating easy tracking and logging. In the event of successful segmentation and delivery, the directory is deleted. Otherwise, it is preserved with logs to aid in error identification and resolution.

2 Materials and Methods

System Architecture and Technical Specifications

The AIS is engineered to integrate into the existing IT infrastructure of our radiotherapy department. Image sets are sent directly to the normal recipient systems, while simultaneously being sent to AIS. The system's software components are primarily written in Python and Matlab, chosen for their robustness and compatibility with medical

imaging tools and the AI models produced using the nnU-net[1] architecture.

Ensuring reproducible results

After a model has been trained and validated, a hash for the files containing the trained model weights is calculated. This hash is used to ensure that an image set that is expected to be segmented using a specific model is indeed segmented using that model.

A separate service recomputes the hash for the installed models each night, so any change in the installed models will trigger an error.

Modular Design for Enhanced Functionality

To make the system robust, the four modules have clearly defined and non-overlapping responsibilities. As an image set progresses through the system, only one module handles the data at any given time.

Configurations

The Gateway has a configuration for where it should send files for inference.

Additionally, it has several trigger-configuration files. Each of these has:

- A set of DICOM tags and values that will trigger an inference process.
- Information on where to send the results.
- Information specifying custom changes for the structures needed by the clinicians.
- A "niceness" level. Image sets with lower "niceness" will be processed before image sets with higher values, if multiple image sets are waiting to be processed.
- The hash of the expected model to ensure correct model is used for inference.
- Whether or not to include a structure with metadata on the inference.

To enable the reading and, potentially, changing of these files by technical staff, they are plain-text files with an easy syntax.

We added the “niceness” level to allow for prioritizing inferences, e.g., for online treatments that need the delineations as fast as possible.

The Watchdog module configuration consists of:

- Where it should scan for incoming image sets, and at what interval.
- The command for inference.

The Inference process is configured with:

- System specific nnU-net information
- Structure information, nnU-net arguments for each enabled model

The Return Service mimics the Watchdog service and is configured with:

- Where it should scan for incoming image sets, and at what interval.
- When to clean up image sets that have encountered an error.

Process Management

The Watchdog, Inference and Return service are written in Python 3.11. To ensure robustness, they all implement a main process, which spawns a worker process that does the actual work. The main process monitors and restarts the worker if a crash or any other unrecoverable error happens.

Workflow

In AIS, each image set is processed in a unique, dedicated directory on the inference machine. This directory acts as a central node for all files related to the inference, including configurations, logs, and outputs. The system employs a dynamic directory renaming strategy to reflect the current stage of the inference process, enhancing transparency and trackability. Upon successful completion of the segmentation, the directory and its contents is automatically deleted to maintain system efficiency. In contrast, any failures in the process result in the retention of the directory, along with detailed logs, to facilitate error analysis and resolution.

The naming of the directories follows the format of "STATE_UID" where "STATE" is one of the following: *receiving*, *ready*, *active*, *inferred*, *error* or *handled_error*, and UID is a unique ID for that image set. Each module will only work on a directory in a subset of the possible states, and the renaming happens as the absolute last step of each module.

The representation of state via directory naming was chosen for its simplicity and ease of understanding. This approach ensures that even individuals with limited familiarity with AIS can easily understand and navigate the system's status.

Integration with Clinical Workflow

AIS's design emphasizes minimal disruption to the existing clinical workflow. Automated processes and streamlined data handling ensure that clinicians can access AI-aided segmentations without deviations from standard operational procedures. The system's adaptability allows for easy incorporation of future advancements in AI segmentation algorithms and models.

Communicating metadata to the end-user

AIS employs a simple approach to address the challenge of effectively communicating inference process details to the end-user, especially considering the limitations in DICOM for such metadata transmission. We utilize an empty structure in the generated DICOM-file, which is named to convey information about the AI segmentation process

despite being devoid of segmentation data. This naming convention serves two purposes:

- **Successful Inference**: In cases of successful AI segmentations, the empty struct's name includes the AI model used and the number of DICOM images used for inference. This provides end-users with accessible information about segmentations they are reviewing.
- **Unsuccessful Inference**: If an error occurs during segmentation, the empty structure is named with an error code and a concise description of the issue. This approach allows for rapid identification and understanding of errors, facilitating efficient troubleshooting and resolution without overwhelming the user with technical details.

Including the image count in the metadata is a critical feature, designed to address scenarios where an incomplete image set might be processed due to DICOM transfer failures. By detailing the number of slices in the metadata, AIS empowers users to identify and address such discrepancies quickly, ensuring the integrity of the treatment planning process.

Furthermore, AIS defaults to appending "_AI" to the names of all AI-generated structures. This simple yet effective naming convention allows clinicians to distinguish between manually created and AI-generated structures, thus maintaining clarity in treatment planning and review processes. This feature is configurable and naming can be changed per structure in individual workflows.

Image set filtering

The filtering in the Gateway module allows AIS to accept all image sets, but will only send image sets matching the filters to be inferred. This ensures that a model will only be used to delineate images of the same type as the images it has been trained and validated with. A model trained on CT-images may not be validated on MR-images and should not be used for those. Likewise, a model trained to delineate the male pelvis, should not be used on images of the female pelvis.

3 Results

AIS Deployment

The deployment of the AI Inference Service (AIS) within our radiotherapy department was a smooth process. The primary adjustments post-deployment involved fine-tuning the system's logging capabilities.

Inference Time Efficiency

Depending on the specific image set and model used, the inference process, which starts when an image set has been received and ends when the delineated structures have been delivered, typically takes between 2 and 3.5 minutes, even on consumer-grade GPUs like the NVIDIA 3090. This duration demonstrates the system's efficiency in handling inference within a reasonable timeframe, fitting well within the clinical workflow.

User Feedback and Workflow Impact

The reception of AIS among clinicians has been positive, even though the system is relatively new in production. While formal data collection and analysis is on-going but not yet finalized, initial user feedback suggests an estimated 30-50% increase in workflow efficiency when using AIS compared to not using AIS.

Challenges in Metadata Communication

A challenge encountered involves the transmission of metadata to end-users. Some treatment planning systems do not support the import of empty structures, hindering the intended communication method. We included a minimal geometric structure within the 'empty' structure to address this. This workaround ensures the conveyance of metadata.

4 Discussion

Extensibility of AIS with External Models

A key aspect of the AIS is its flexibility in integrating AI models. Currently, AIS provides delineation using four models:

- Male Pelvis Model[2].
- Head and Neck model[5].
- Heart model[4].
- Brachytherapy model for cervical cancer.

However, its architecture is designed for easy extension to include externally developed models as well. This adaptability significantly broadens the potential applications of AIS.

Windows-Based System: Constraints and Benefits

Operating AIS on Windows does impose certain constraints, particularly in terms of model compatibility, as nnU-net version 1 models do not run on Windows. Despite this, we believe the benefits, notably the access to comprehensive support from the hospital's larger IT system, outweigh the limitations. This support is crucial for maintaining system stability and reliability, which are paramount in a clinical setting.

DICOM database as a Potential Bottleneck

The integration of part of AIS as an extension in a DICOM database, while beneficial for data handling and processing, has been identified as a bottleneck in terms of total inference time. This may be a hindrance for using AIS in time-critical workflows. Exploring the possibility of excluding the DICOM database from the process could yield improvements in inference speed, enhancing patient experience and treatment efficiency.

Research AIS
A non-clinical variant of AIS, characterized by more flexible or entirely absent filters, is used by researchers and developers to test and validate new models before clinical implementation.

Future Directions
In addition to technical advancements, a significant focus is on optimizing AIS for faster inference times. This is especially critical in real-time treatment scenarios, where prompt decision-making is needed.

5 Conclusion
The implementation of the AIS in our department marks a significant step. AIS has demonstrated its potential to streamline workflows, enhance treatment planning efficiency, and provide high-quality auto-segmentations, proving to be a valuable asset in our radiotherapy treatments.

Key Achievements and Impact:
- AIS's smooth deployment and stable performance highlight its reliability in a clinical setting.
- The system's ability to process image sets efficiently, even with consumer-grade GPUs, illustrates its practicality and scalability.
- Positive feedback from clinicians, suggesting a 50% increase in workflow efficiency, underscores the system's effectiveness and user-friendliness.

Abstract
Pancreatic cancer is challenging to treat with radiotherapy due to anatomical changes during different fractions and its proximity to critical organs at risk (OARs). MR-Linacs facilitate treatment plan adaptation to the current patient anatomy based on daily session MR images. Target and OAR contours on the session images are a prerequisite for daily plan creation and currently involve labor-intensive manual contouring. Therefore, auto-contouring is crucial for an online adaptive MR-Linac workflow. One major challenge in training a robust auto-segmentation model is the availability of the substantial amount of data required. This study investigates an auto-segmentation approach using nnU-Net, in conjunction with generative model augmentations to improve performance. Balanced 3DVane images from 9 patients (7 train/2 validation) from multiple fractions were used to train our auto-segmentation model. An abdominal CT dataset was utilized for generative model inference. Compared to conventional augmentation, the generative network-based augmentation increased the average Dice score from 0.86 to 0.88 and reduced the average surface distance from 4.46mm to 2.78mm across 8 OARs. Our method can be integrated into an MR-Linac adaptive workflow to address time-intensive manual contouring.

1 Introduction

Pancreatic cancer is one of the most challenging cancers in oncology, marked by its aggressive nature and often limited treatment options. Radiotherapy plays a pivotal role as a treatment strategy for pancreatic cancer. However, the effective delivery of a sufficiently high radiation dose is challenging, due to the proximity of critical organs, such as the duodenum and stomach, which are highly sensitive to radiation-induced toxicity.
Recent advances like MR-Linac machines may increase the precision of radiation treatment delivery by enabling MRI visualization before/during treatment for target validation and healthy tissue sparing with their excellent soft-tissue contrast. MR-Linacs can acquire session images before each fraction to manually adapt contours to anatomical changes. Offline manual contouring of all OARs and the radiation target can take up to 3-4 hours; however, dedicating this time before each fraction, in an online workflow, is impractical. Therefore, image registration is employed to propagate structures from pre-treatment CT onto the session MR images, and then, re-contouring is selectively performed on specific areas, facilitating adaptation to changes. Hence, in the online workflow, the manual re-contouring process is streamlined to only 10-20 minutes and focuses solely on structures within the margin of the Planning Target Volume plus 2 cm (PTV+2cm), leading to inaccuracies beyond this margin.
Developing reliable auto-segmentation methods to speed up this contouring process is therefore highly desirable to improve efficiency in the MR-Linac workflow [1]. Various artificial intelligence (AI) methods with different architectures and techniques have been introduced to improve segmentation performance. Although auto-segmentation algorithms have seen significant advancements, unresolved challenges remain due to complexities from tumor and organ size, shape, and position variations, contributing to segmentation inaccuracies that impact radiotherapy precision [2]. Additionally, the diverse range of imaging modalities and contrasts necessitates the development of specific models tailored to each. In our investigation, we selected a set of MR images acquired using the 3DVane technique (Philips Co.) from MR-Linac machines. While these images offer robustness to motion [3], they may lack optimal soft-tissue contrast due to this trade-off. To the best of our knowledge, no previous studies have explored multi-organ auto-contouring for 3DVane images.
Limitations also exist regarding data availability for training an auto-segmentation model, particularly with scarce datasets of 3DVanes which pose challenges for training a deep-learning model. Additionally, in adaptation, only organs within the PTV+2cm margin are manually re-contoured, so outside this region instead of a robust ground-truth only propagated CT contours exist. Data augmentation has become crucial to address ground-truth data scarcity, allowing for the best use of the available data [4]. Nonetheless, conventional data augmentation methods show limited impact as they are usually applied globally or unrealistically.
Altogether, these pitfalls underscore the need for more robust and automated segmentation techniques and approaches with a prior realistic data augmentation pipeline. Therefore this study investigates to which extent an advanced, deep-learning-based augmentation method can enhance a previously published auto-segmentation approach.

2 Materials and Methods

We employed 3D nnU-Net [5], a U-Net-based framework with automated configuration and data augmentation for med-

ical image segmentation to investigate multi-organ segmentation in abdominal MR images. Following the preprocessing phase, this study bifurcated into two approaches. The first approach implements conventional augmentations, such as rotation, scaling, and using various filters. The second approach utilizes generative adversarial networks (GAN) and image registration.

2.1 Data Selection

The dataset for the auto-segmentation model contained various MR/CT images from the MOMENTUM study [6], but only patients who also had 3DVane images were used as they are the preferred acquisition technique at our institute. The selection of image contrast depends on clinicians' preferences. However, due to the availability of more images with balanced contrast, we chose balanced 3DVanes (b3DVanes). Hence, b3DVane session MR and pre-treatment CT images with structures from 9 patients (5-6 fractions each, 50 total) over multiple sessions were obtained.
After consultation with clinicians and physicists at our institutes and reference to prior research [7, 8], the dataset was consolidated into 8 structures, which include the duodenum, liver, left kidney, right kidney, spleen, stomach, spinal cord, and small bowel.
Another dataset, a publicly available pediatric CT dataset with expert contours for 29 structures and 325 images, was utilized to synthetically generate b3DVane images via generative networks. This dataset was selected because it contained all 8 structures [9].

2.2 Image Preprocessing

First, foreground organ regions were cropped to remove background objects. Some of the labels had overlaps. Overlapping labels were separated by assigning each voxel the label of its closest structure boundary, performed via a SciPy (v1.9.3) distance transform providing voxel-wise Euclidean distances. To reduce intensity inhomogeneities, artifacts, and noise in MR images, N4 bias field correction [10] and anisotropic diffusion filtering [11] were applied using SimpleITK (Ver. 2.1.1.2). The parameters for these tasks were taken from Arabi et al [12]. After basic preprocessing, the images/labels were augmented to account for data scarcity.

2.3 Augmentation Approaches

2.3.1 Approach I - Conventional Augmentation

The nnU-Net model uses spatial and intensity-based augmentations including rotation, scaling, noise, blurring, brightness/contrast changes, simulated low resolution, and gamma augmentation. These are applied randomly with varying magnitudes to introduce realistic variations and improve generalizability. In this study, these are referred to as conventional augmentation applied before training the nnU-Net.

2.3.2 Approach II - Synthetic MR Images

This approach was implemented to synthesize realistic MR images from CT images with ground-truth contours.
Registration - To enhance alignment and facilitate training convergence for generating realistic medical images, particularly since the initial image count was insufficient, initial registration of CT and MR images was performed. The registration was executed in two sequential steps. First, an affine registration for global alignment and then a B-spline deformable registration to account for local deformations were implemented using the robust Elastix toolbox integrated with the SimpleITK Python library [13].
The Model Configuration - After registration, images were locally deformed using the Platipy library (Ver. 0.6.0), increasing the initial 50 images to 244. Then, a cycleGAN featuring a patchGAN discriminator [14] was implemented. The input image was resized to 360x360x128 voxels, with a voxel spacing of 0.78x0.78x1.5 mm^3. Both CT and MR images underwent histogram normalization, and then intensity normalization (Z-score normalization) was performed using the 1st and 99th percentiles, scaling values within this range from -1 to 1.
Loss Functions - The generator and discriminator loss functions were calculated using mean squared error (MSE). The cycle consistency loss, which measures the error between the reconstructed and the original images, was computed using a weighted average of one minus the Structural Similarity Index Measure (SSIM) and the Mean Absolute Error (MAE). The identity loss, which measures how well the model preserves the input image when cycled through the generators, was also calculated using MAE.
Optimizer - Model optimization was performed using the Adam algorithm, with a learning rate of 10^{-4} and weight decay of 10^{-5} to regularize and prevent overfitting. To dynamically adjust the learning rate during training, a Cosine Annealing Learning Rate Scheduler was employed [15].
Training - The training process took approximately 5 days on a 24Gb NVIDIA RTX A5000 GPU.
Inference - After training the model, in the inference step, the pediatric abdominal CT images were employed to generate synthetic b3DVane images. As a result, 325 images were synthesized.

2.4 Training the nnU-Net

For approach I, the train and validation sets consisted of images from 7 and 2 patients respectively, with multiple sessions per patient. Training took approximately 16 hours. For approach II, the model was first trained on 325 images over 16 hours, and then the weights were updated by retraining on the 7 train/2 validation split for an additional 4 hours. All computations were performed on a 24Gb NVIDIA RTX GPU.

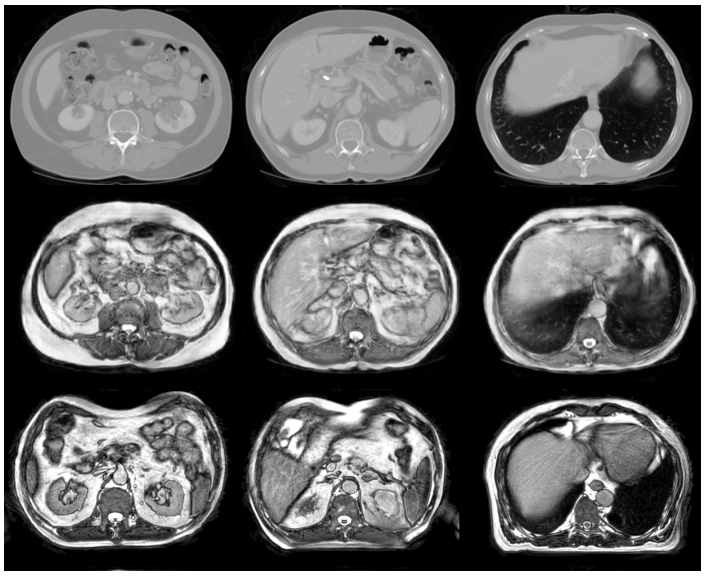

Figure 1: Pediatric CT images (top), generated b3DVane images (middle), and real b3DVane images (bottom).

3 Results

3.1 Image Synthesis

The cycleGAN employed in this study produced 325 b3DVane images resembling MR-Linac output. An example set of resulting images was verified by a clinician regarding its realism of appearance (Figure 1).

3.2 Auto-segmentation

Figure 2 compares auto-contour results between both approaches for the patient with a median Dice score. The model showed the highest Dice performance for the liver and the lowest for the small bowel with both approaches. However, in terms of Average Surface Distance (ASD), the spinal cord had the lowest error and the small bowel the highest. Figure 3 shows the case with the lowest Dice score versus the propagated ground-truth structures, highlighting some ground-truth issues by comparing prediction alignment with organ margins. Table 1 presents the auto-segmentation results for the 2 validation patients over multiple sessions, comparing the augmentation approaches. Our approach, from preprocessing to prediction, required approximately 30 seconds per patient on average.

4 Discussion

Precision radiotherapy delivery for pancreas cancer faces challenges due to anatomical changes that can occur throughout a treatment course. Adaptive radiotherapy workflows aim to account for these variations but are resource-intensive due to the time-consuming manual segmentation required on each treatment day. Overcoming these barriers is crucial to enable the full potential of adaptive radiotherapy.
This study investigated using 3D nnU-Net on 50 3DVane images from 9 patients over multiple sessions, improving performance via our customized auto-segmentation model to reduce manual delineation workload. The initial generative model training without prior registration and localized deformations with Platipy failed to converge due to insufficient training data. Altogether, 325 synthetic b3DVane images were generated from pediatric abdominal CTs with expert contours to address ground-truth inaccuracies and provide increased training data to improve model generalization. Our approach was significantly faster than 10-20 minute partial manual re-contouring for adaptation, without sacrificing accuracy while being comparable to inter-observer variation [16] despite 3DVane's lower soft-tissue contrast. As our model only auto-contours OARs, the target still needs clinician delineation. However, when integrated into an online adaptive workflow, we still expect substantial time-savings. One limitation was the availability of abdominal CTs with OAR contours, confining selection to pediatric CTs which were the only suitable contoured dataset. Our customized approach demonstrated that with only 9 patients, it is possible to produce good segmentation results compared to previous studies on abdominal multi-organ auto-segmentation even when using images with lower soft-tissue contrast and less available data [7]. However, to validate the generalizability of our model, testing on a larger set of patients is required.

Segmented Organs	ASD (mm)		Dice	
	Approach I	Approach II	Approach I	Approach II
Liver	1.45	**1.45**	0.93	**0.96**
Duodenum	3.03	**2.79**	**0.78**	**0.78**
L. Kidney	1.17	**1.05**	**0.93**	**0.93**
R. Kidney	1.18	**1.03**	0.92	**0.93**
Small Bowel	19.03	**8.85**	0.72	**0.75**
Spinal Cord	**0.66**	0.73	0.88	**0.90**
Spleen	1.39	**1.22**	0.91	**0.93**
Stomach	9.20	**4.86**	0.79	**0.82**
Mean	4.46	**2.78**	0.86	**0.88**

Table 1: Comparison between approach I and approach II. The highest Dice scores and lowest ASDs are highlighted.

5 Conclusion

Our approach coupled with nnU-Net demonstrated promising results even with low-contrast images from only a few patients and can be integrated with MR-Linac adaptive workflows to address time-intensive and inaccurate marginally-limited manual contouring.

Abstract *Introduction*: The development of new, often AI-based, automatic contouring solutions has escalated rapidly in recent years. Implementing these new technologies requires resources and specialised skills from the local staff, limiting access to them for smaller or resource sparse sites. This work explores a standardised infrastructure for sharing automated delineation technologies among centres. The infrastructure should be so easy to integrate that any site can access it, broadening the field of sites gaining the advantages of the technologies. *Materials and methods*: The proposed solution is based on the national RT dose plan storage infrastructure, DcmCollab, making an nnUnet-based head and neck OAR model available to a smaller RT centre. *Results*: A set of extensions to the DcmCollab system were implemented, and the test setup was evaluated over the course of seven months, processing 116 patients. The participating clinicians reported a potential time saving of 30%-40%. *Conclusion*: The proposed infrastructure was successfully implemented and is proven to be a viable means of sharing an automated delineation solution. Before a full clinical integration, the legal aspects must be considered, especially MDR compliance in the EU.

1 Introduction

In recent years, great advances have been made in the development of automated processes to improve the consistency and speed of routine clinical workflows in radiotherapy (RT). Many of these rely on artificial intelligence (AI) based contouring of medical image sets. Depending strongly on the treatment site, manual delineation for one RT treatment will typically require between 30 minutes and several hours per delination set [1,2]. This process can be sped up significantly by supplementing it with novel, automated solutions [1,2], and thus releasing precious workforce resources for other tasks.

However, institutions with many resources can often invest more in implementing new technologies for their workflows than those with sparse resources. This can have the unfortunate effect of excluding the clinics that need the automated solutions the most from gaining their benefits.

In this work, we explore a standardised national infrastructure allowing any centre with an automated delineation model to share this implementation with other clinics. The goal is that the standardisation of the infrastructure, along with the centralisation of the automated functions, will increase the ease of implementation of modern automation and, presumably, the homogeneity of the delineations and the conformance to national guidelines across centres as exemplified by Nielsen et al [3].

2 Materials and Methods

The national RT dose plan storage infrastructure, DcmCollab, serves as a basis for this work, providing both the DICOM network connections between all RT centres in Denmark and the mechanisms for handling the specific DICOM tags that trigger the processing of submitted data [4,5].

The automated delineation model used is an nnUNet-based Head&Neck (H&N) organ at risk (OAR) model [6] supplemented with locally developed pre- and postprocessors whose main functions are converting data from DICOM to NIfTI and back.

After implementing the necessary modules to support the proposed infrastructure, a testing agreement was made with an RT institution with limited resources for devoloping AI models locally. Given the limitation in available clinical resources at the testing site, the degree of detailed reporting and documentation possible was limited to subjective evaluations and rough estimates of potential timesaving in clinical workflows.

3 Results

An extension of the DcmCollab system was necessary for the proposed functionality. DcmCollab already supports and often uses the concept of features in DICOM data triggering functions within the system. These triggering features were limited to delineation structures in RTSTRUCT datasets with zero contours and a pre-defined description tag. Using these trigger structures, users can include the submitted data in a research protocol defined in DcmCollab, or trigger the automatic forwarding of a data set to a selected external destination. In order to support sharing automated delineation solutions, these mechanisms needed to be expanded with the following features: (1) Triggering should be possible on any combination of tags in the submitted DICOM data. Modality (0008,0060) and series description (0008,103E) were chosen for the test setup. For each shared delineation solution, a sufficiently specific set of identifying DICOM

tags must be defined to ensure that only the intended datasets are processed. (2) The creation of a derived trigger to handle the data returned from the third-party system should be added to the set of possible triggered actions. This will allow DcmCollab to recognize data returned from the AI delineation inference machine and forward it to the originating centre. (3) It should be possible to define a trigger to be used only once, both to avoid the risk of unexpected triggered actions and to minimise the number of active triggers the system needs to check for in all submitted data. This type of trigger is called a "one-shot trigger" henceforth.

Two new services were added to the DcmCollab system servers to handle the necessary new functions: One to assess submitted image data and estimate whether all data in a series was received. All non-image data, eg. RTSTRUCT, RTDOSE, and RTPLAN, is assumed to be complete as soon as it is received and analysed. The second service checks for and acts upon triggering features in the submitted data.

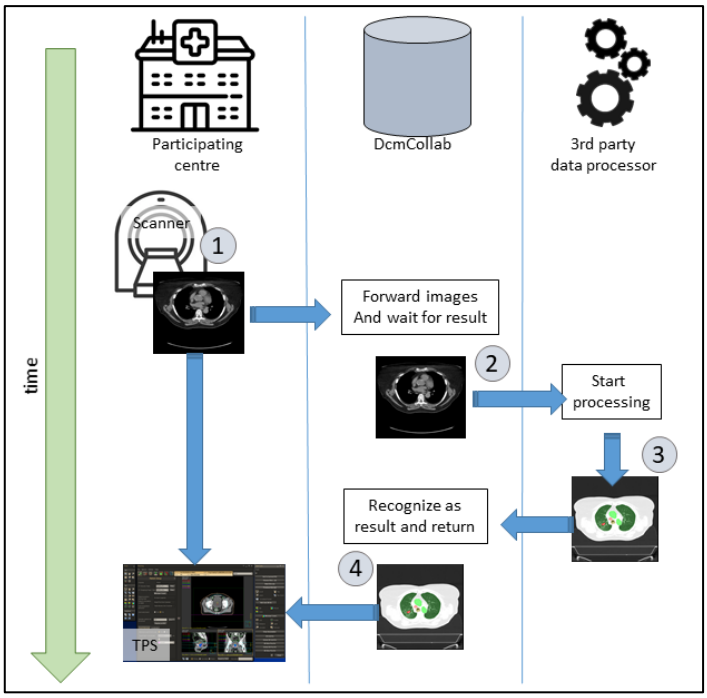

Figure 1 - The data flow of the proposed infrastructure: (1) An image set with a pre-defined text string in its DICOM Series Description is generated at the participating centre and exported both to DcmCollab and to the local treatment planning system. (2) The image set is received by DcmCollab and its triggering DICOM features are recognised. DcmCollab then prepares to receive the result from the 3rd party data processor by creating a derived trigger and forwards the image set to it. (3) The 3rd party data processor creates the AI-generated delineations in a DICOM RTSTRUCT SOP instance and transmits it back to DcmCollab. (4) DcmCollab recognises the returned data with its derived trigger and forwards it to the treatment planning system at the participating centre.

The final workflow is visualised in Figure 1. At the scanner in the participating centre, the DICOM image series has a pre-defined text string encoded in its Series Description DICOM tag and is sent using DICOM communication to both the DcmCollab system and the local treatment planning system (TPS). At DcmCollab, the image data is received. Once the received data is recognised as complete and containing the triggering features, the image series is forwarded to the third-party data processor - in the test case, an nnUnet inference machine. Furthermore, a derived one-shot trigger is created to handle the resulting delineations once they are returned from the inference machine. The one-shot trigger responds to a DICOM modality of RTSTRUCT and the Referenced Frame Of Reference Sequence (3006,0010) ‣ Referenced Study Sequence (3006,0012) ‣ Referenced Series Sequence (3006,0014) tag corresponding to the Series Instance UID (0020,000E) tag of the original image set. The latter tag indicates that the received structure set is generated from the submitted image set. The inference machine is configured to export its results to DcmCollab, where the one-shot trigger initiates the final export of the generated delineations to the submitting centre. After processing the one-shot trigger, DcmCollab disables it to avoid the set of active triggering features that must be checked for each received dataset to grow uninhibited.

In practice, the time elapsed from an image set is submitted from the scanner until the resulting delineations are received at the local TPS is in the range of 10-15 minutes, with the larger part being spent by DcmCollab assessing the completeness of the submitted image set. This duration is close to the minimum time passing from an image set is acquired until manual delineation is performed in the current clinical workflow.

The tested workflow was made available via the DcmCollab infrastructure in May of 2023 and has been used for 116 CT image sets from the participating institution. As mentioned, the participating institution did not have the resources for detailed individual registration of potential time saving for each patient. An overall subjective assessment was provided after four months of testing. The H&N team estimated 30%-40% potential time saving in OAR delineation with the implemented model. This measure relies mostly on the shared delineation model which is not he focus of this work. More importantly, the infrastructure used to utilize the model did not inhibit the benefit it introduced. Furthermore, the participating centre reports that they would not have been able to implement a local AI-based automatic delineation setup in the testing period.

4 Discussion

Given the subjectivity of the reported results, this work should mainly be perceived as a feasibility project. It is possible to implement an infrastructure in which a central entity provides participants with automated delineation functions and to embed such a solution in a clinical workflow. Furthermore, there are strong indications that doing so will result in significant timesaving and harmonisation of OAR segmentation. The H&N OAR segmentation model strictly follows the Danish Head and Neck Cancer Groups (DAHANCA) guidelines [7]. The clinical implementation and fine-tuning of the OAR segmentations can be validated using the DcmCollab system by comparing the raw AI segmentation with the clinical OAR segmentation. The process of fine-tuning can identify deficiencies in several aspects: It could be the local centre, which has a historical tradition for correcting specific structures, the AI segmentation model may be insufficiently accurate for specific areas, or it could be due to a need for an update of the national guidelines. In all three cases, the information would be found by comparing the final clinical delineation after manual correction and the raw AI segmentations. These observations are not specific to the H&N treatment sites, and it is not bold to assume that similar ones could be made for other RT treatment sites.

This work is strictly technical, and has not focused on the legal and licensing issues that should be addressed if an infrastructure of this nature is implemented in the clinical routine. The nnU-net framework is open-source, and the model used in the test setup described was developed locally, so in this specific case, licensing is trivial. If proprietary solutions such as MIM [8] or Siemens Healthineers Autocontouring [9] were to be shared, proper licensing would become a more complicated and costly issue to solve.

Legally, the solutions provided and the infrastructure supporting them should adhere to the European Medical Device Regulations (MDR) or similar. The provided solution should be tested and documented by the providing instance and the site using it. To minimise the resource cost in testing and documenting an implementation of an externally hosted solution in a clinic, it would be advisable to create a set of standard documents covering the majority of models and sites with a minimum of adjustments. These templates would then be provided to each participating centre along with access to the corresponding automated solutions.

To ensure traceability, each model made available should undergo strict version control, while each product of a model should be clearly marked with information about both that they are indeed the product of an automated solution and the name as well as the version of the model used.

5 Conclusion

This work has broken the first steps of a path to making cutting-edge solutions more broadly available in RT. Other paths towards the same goal exist; e.g. making the setup and installation process of new solutions as seamless as possible. Unfortunately, history shows that these aspects rarely are a priority when new technologies are developed. Furthermore, easily installed local solutions would not provide the added benefit of nationally homogenised uses of delineation models. Another approach could be a web-based solution, though such an implementation would inevitably be less integrated into an existing clinical workflow. The proposed infrastructure can be introduced with close to zero overhead in terms of human resources at the participating centre, and provides the added advantage of supporting the homogenisation of guideline interpretation and national consensus on which models to use in clinical practice.

To implement the proposed solution fully, some effort should be made to address the legal aspects of providing clinical services to external collaborators. The handling of such aspects has only recently reached maturity, specifically for AI solutions internally in an organisation, so one should expect to spend some resources on expanding this to cross-center collaboration. Finally, licensing must also be considered if proprietary solutions are to be shared in the framework.

In this work, a single AI delineation model was implemented to prove the efficacy of the concept. In larger scale use, considerations regarding computer resources should be made; should each model run on their own hardware, or should hardware be shared and access to it be managed by a queuing system? No investigation into these issues was made in the current context.

Abstract We previously proposed an AI-based solution for obtaining the location and shape of a glioblastoma tumor in a preclinical rat model using information obtained from the bioluminescence imaging (BLI). The utilization of spectral data in bioluminescence tomography (BLT) reconstruction through conventional model-based algorithms has demonstrated notable advantages. Therefore, in this study we investigate how the spectral data can be employed in the deep-learning approach. For this purpose, a novel multi-channel 3D U-Net deep learning model is proposed, concurrently incorporating bioluminescence skin fluence (BSF) and two additional input channels comprising spectral data obtained by applying specific optical filters to the detected BSF. Results indicate enhanced performance, as evidenced by a 74 ± 12% median Dice Similarity Coefficient (DSC) between the predicted tumor and the ground-truth CT-based tumor contour, compared to the previous full optical spectrum solution's 61%, affirming the efficacy of incorporating spectral data in the deep-learning approach.

1 Introduction

Bioluminescence imaging (BLI) is a powerful tool to monitor tumor growth in vivo in pre-clinical cancer research using luciferase-enabled light-emitting small animal tumor models [1], [2]. In its 2D form, BLI can merely provide relative tumor growth information from the integrated light intensity and an inaccurate 2D radiotherapy target region [3], [4], [5]. However, in order to monitor the tumor's volumetric information more effectively and enable quantitative radiation targeting, a 3D representation of the tumor is required, which can be achieved by reconstructing the 3D bioluminescence tomography (BLT) [6], [7].

In our previous publications, two distinct AI-based methods were introduced for BLI-based tumor targeting [8], [9]. Our first approach was based on predicting the central location of the tumor using a deep convolutional neural network (CNN) and deriving a spherical envelope around the predicted location to encompass the tumor [8]. The next step was accomplished by capturing shape information together with the location of the tumor by using a fully convolutional 3D ResNet model, which enabled 3D tumor mask predictions from the bioluminescence skin fluence (BSF), i.e. the sum of all the BLI images acquired at different camera viewing angles projected on the skin of the animal [9].

This study investigated the added benefit of using multispectral information, i.e. the resulting BLI images acquired with various optical filters, to improve the AI-based method for BLI-based tumor targeting. Utilizing such multispectral information has been shown to be informative in mathematically-driven BLT reconstruction solutions [10]. The utility of multispectral information in BLT reconstruction lies in its capacity to exploit wavelength-dependent variations in photon absorption and scattering, wherein photons of distinct wavelengths exhibit differential magnitudes of scattering and absorption, thereby providing valuable insights into the precise depth of tumor localization within the tissue. Therefore, this study aimed to implement a spectrally-driven deep learning solution for the BLT reconstruction problem that can enhance the quality of the previously proposed models. In order to obtain the multispectral data required for training and validation, in this study, a Monte Carlo simulation (MCS) environment is utilized, as described in our previous publications [8], [9]. MCS are often considered as the gold standard method for photon transport and therefore can be considered a good candidate to build a high quality training database for the AI solution.

2 Materials and Methods

The starting point for this study is a database of 57 contrast-enhanced cone-beam CT (CE-CBCT) scans of orthotopic glioblastoma model in rats, described fully in our previous publication [5]. In this database, hereafter called F98 database, various anatomical structures (tumor, brain, and eyes) in the CT images are manually contoured by expert biologists for brain and tumor contours. Thereafter, a MCS geometry is constructed for each case within the F98 database, excluding the tumors smaller than 10 mm^3, by assigning various optical properties to different tissues in the image according to the literature. Then, an optical light emission according to the emission spectrum of the firefly luciferase is assigned to the tumor and for each voxel inside the tumor 5×10^6 photons are generated.

In this study, photon transport is performed by using the Geant4 application for tomographic emission (GATE)[11]. More specifically, the photons generated from the tumor are tracked using the fluence actor inside previously described voxelized MCS geometry. This resulted in a 3D volumetric image with the same size as the MCS geometry with values equal to number photons passing each voxel. Therefore, to obtain the BSF using the MCS output a skin mask is applied

to remove all the values not visible to the optical camera. Additionally, separate MCS is performed for each spectral portion of the emission spectrum. In other words, due to the implementation issues with the MCS environment, the filtration is not simulated on the detection side, as it is performed in the real BLI measurements by blocking the photons reaching the detector outside the corresponding pass-band wavelength spectrum. In contrast, the optical filter is applied on the tumor emission spectrum, limiting the generated photons to the wavelength range of the detection filter. Although this might seem inaccurate, considering that only elastic scattering of optical photons is modeled in the MCS, which is the dominant type of photon scattering at this wavelength, this will result in the same output as photon filtration upon detection. Therefore, for each case in the MCS database, new MC simulations were performed for each optical filter by blocking different parts of the emission spectrum. Figure 1 represents the optical filters used in this study which match those in our small animal irradiator (X-RAD 225Cx, Precision X-ray Inc., North Branford, CT, USA). Furthermore, the number of photons emitted was kept to the original 5,000,000 photons per unit voxel in the tumor to provide good statistics in the output and to match the original MCS.

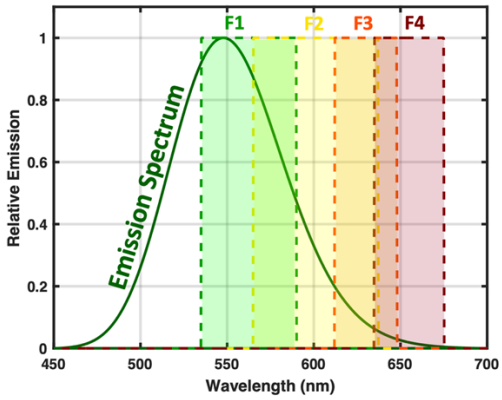

Figure 1: Bioluminescence emission spectrum of firefly luciferase and filters (F1-F4) used for modeling the spectrally driven measurements

Once the new multispectral MCS database was generated for all the samples, a new training database was obtained by stacking the 3D BSFs resulting from the two furthest spectral filters, depicted in **Error! Reference source not found.** as F1 and F4, together with the no-filter original MCS, hereafter called open filter, in the fourth dimension. In other words, the input of the Multispectral network is analogous to an RGB-colored image, which stacks red, green, and blue input channels in the fourth dimension for a 3D volumetric image. Conversely, here the three different spectral channels, each consisting of a 3D BSF image for different wavelength ranges, are stacked in the fourth dimension.

The multispectral MCS database is then utilized as the input of a DL network with a similar architecture to the previously proposed network[9]. The DL network comprises of a 3D U-Net architecture, namely the RatLesNet [12], with a slight modification in the number of input channels to accommodate the multichannel nature of the input data. Furthermore, the hyperparameters of the DL network, including the optimizer and its learning rate, loss function, and number of filters, were automatically optimized, using Optuna [13], to ensure the best optimized hyperparameters for the newly generated input.

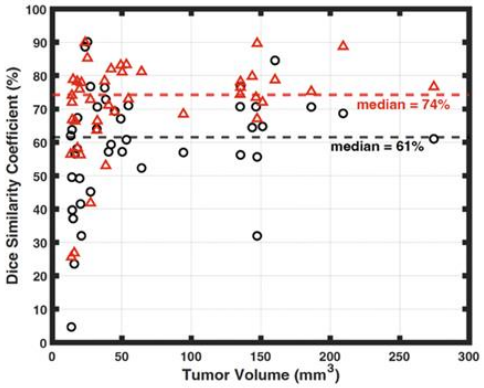

Figure 2: performance evaluation of the proposed multispectral solution (red) compared to the open filter counterpart (black).

3 Results

Training a deep learning solution with the multispectral BSF images increased the performance for most cases in the database over open filter BSF images, presented in our previous publication [9]. The overall performance comparison between the multispectral network and its open filter counterpart is depicted in Figure 2 and further visualized for a few cases in Figure 3. As presented in **Error! Reference source not found.**, the median DSC between the predicted and ground truth tumor contours increased from 61%, for the open filter BSF to 74% for the multispectral BSF. In other words, in 75% of the cases within the database, inclusion of the complementary multispectral information resulted in a better performance compared to the open filter counterpart.

4 Discussion

It has been shown that the complementary information obtained using different optical filters can be used to distinguish the shape variations for the majority of the cases, as presented in Figure 2. This resulted in a 13 percentage point median DSC increase over the entire database. However, it is important to note that memory limitations during AI model training can be a bottleneck for using more and more multispectral information. Hence, in future investigations, optimizing the quantity of complementary data and refining its incorporation into the deep learning model can prove advantageous for

maximizing the utilization of limited hardware capacity in a more efficient manner.

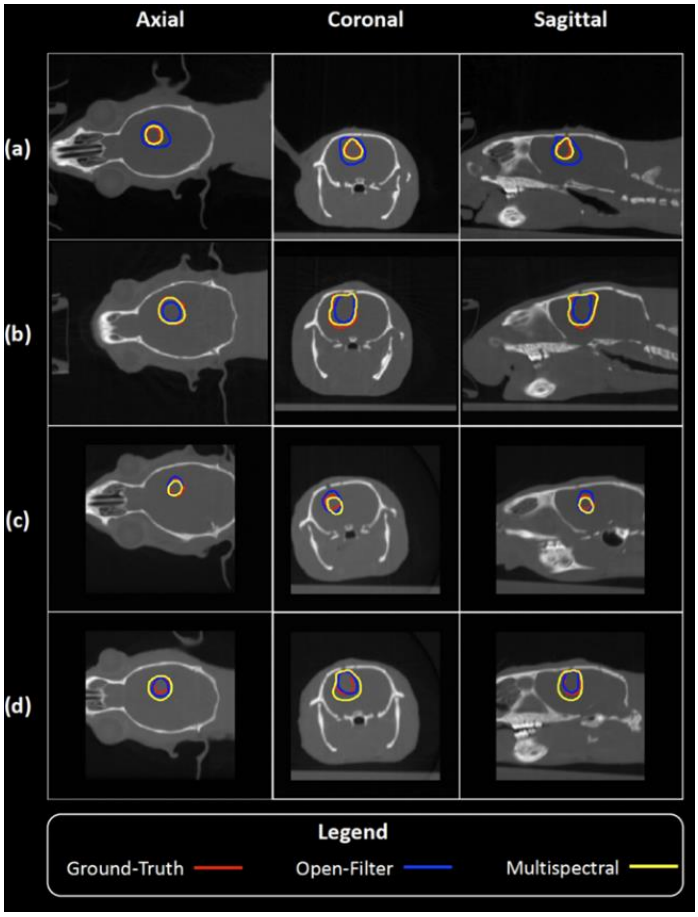

Figure 3: Tumor contour visualization for the multispectral network (yellow) compared to the open filter network (blue) and the ground truth CT-based contour (red): (a,b) present the best cases in the database with improved performance from the added information and (c,d) depict the cases with reduced performance.

The proposed BLI-based solution in our previous publication fails to capture the correct volume for some cases, such as flat tumors located close to the skull. This study provides proof that the multispectral measurements can help alleviate this issue since each spectral bandwidth includes a different portion of the absorption coefficient and can help distinguish smaller flat tumors close to the skull from larger deep-seated tumors. To clarify this further, assume the two different cases where a flat surface tumor and a deeper larger tumor result in approximately the same number of photons reaching the skin. Consequently, these two tumors are considered to have similar volumes just based on the amount of open filter bioluminescence light exiting from the skin. However, the multispectral information holds important details that differentiate the two cases since photons emitted from the larger tumor have to transport in a larger portion of the biological tissue. Therefore such a tumor gains more photon intensity since a different photon spectrum, particularly the near-infrared spectrum, passes through the tissue more easily and reaches the surface due to differential absorption in different wavelengths. This study shows that the provided multi-channel AI model can use this additional information to improve the performance of the BLI-based tumor segmentation.

In future work, a combination of the AI models with physics models of the light propagation, in the form of novel physics-informed AI models, can help to improve the results even further. These models can incorporate the flexibility of AI solutions with the explainability of physics models. Furthermore, such models can alleviate the uncertainties in AI models caused by small-sized databases and perform better with data limitations in mind.

5 Conclusion

This study presents a comprehensive examination of a multi-channel deep learning framework designed to exploit the complementary multispectral characteristics inherent in luciferase emission, with the aim of refining the precision of Bioluminescence Tomography (BLT) reconstruction in the context of an orthotopic glioblastoma rat model. This comparative assessment underscores the superior efficacy of the proposed multi-channel deep learning approach. The results highlight the significance of integrating multispectral data within the luciferase emission spectrum, showcasing its potential to elevate the accuracy and reliability of BLT reconstructions within the specific domain of orthotopic glioblastoma rat models..

Abstract

We present a Monte Carlo virtual source model for generating photons emitted during the decay chain of alpha-emitter radionuclides. The model, integrated into GATE 10, utilizes Geant4 databases to extract photon emission lines from decaying daughters. Employing Bateman equations for decay chain abundances and activities within a specified time range, it generates photons' energy and temporal distribution. By avoiding the need to simulate the entire decay chain, it reduces the computation time compared to reference ion source. The source model can be applied to any alpha-emitter radionuclide in the Geant4 database. It facilitates the investigation of (SPECT) imaging photon emission from alpha-emitters.

1 Introduction

Targeted Alpha Therapy (TAT) is a type of Radiopharmaceutical therapy (RPT) that exploits the short range and high linear energy transfer (LET) of alpha particles (^{4}He) to enhance targeted tissue dosages [1]. Examples of radionuclides for TAT include ^{223}Ra (Xofigo™) for castration-resistant prostate cancer (CRPC) with metastatic bone disease [2] and, more recently, ^{225}Ac (Ac-225-PSMA-617) combined with PSMA for metastatic prostate cancer [3]. Investigation of other alpha emitters such as ^{149}Tb, ^{211}At, ^{212}Pb, ^{213}Bi, ^{223}Ra, and ^{227}Th is underway. The LET of alpha particles, approximately 50-200 keV/µm, is about three orders of magnitude larger [4] than the LET of β^- particles emitted by conventional radionuclides such as ^{177}Lu or ^{90}Y. The alpha particle's range, around 50 to 100 µm, is close to the diameter of a few cells [5], leading to high tumor damage, but also with potential toxicity risks.

The assessment of the dose spatial biodistribution and temporal biokinetics is critical to mitigate these risks. In-vivo imaging is feasible for certain alpha emitters using emitted photons in the decay chain, detectable by SPECT systems [6]. For instance, imaging feasibility has been reported for ^{212}Pb [7] (phantoms) and ^{225}Ac [8] (patients).

However, each radionuclide's decay chain produces distinct photons with different energy lines. SPECT acquisition must be tailored by selecting appropriate energy windowing, scatter correction, and reconstruction methods based on the emitted photons' energy ranges and quantities. For high-energy photons (>400-450 keV), challenging for Anger camera-based SPECT systems, alternative imaging systems like Compton Camera may be considered [9]. Monte Carlo simulation is an important method for investigating SPECT image acquisition parameters and advancing new imaging systems [10, 11]. In this study, we propose an efficient source model generating gamma and X-ray emissions from alpha emitters, encompassing associated energy spectra, intensity, and timing.

2 Materials and Methods

The proposed photon source model is based on two primary components. Firstly, it involves identifying and compiling all photon lines, incorporating their energies and intensities, from decay daughters and processes into a list of energy-intensity pairs. The origin of these photons is attributed to (1) isomeric transitions and (2) atomic relaxation. Bremsstrahlung radiation, depending on the media, is neglected here. Secondly, the model automatically computes and utilizes Time Activity Curves (TAC) to express the relative abundances of decaying daughters as a function of time. During simulation runtime, the Geant4 engine sequentially generates primary photon events, considering their relative intensities, energy levels, and associated timestamps.

Gamma emission data from isomeric transitions (IT) is extracted from the Geant4 database, and relative intensities are computed recursively for all decay channels and energy levels. Initial examination of a radionuclide's decay channels involves referencing the decay table of the `G4RadioactiveDecay` process object. The relevant data, including excitation energies and deexcitation channel details, are stored in files (e.g., `z89a225` for ^{225}Ac). Each deexcitation channel provides gamma transition energy, relative intensity, and the total internal conversion coefficient. Recursive computation of the final gamma emission rate considers branching ratios, gamma emission probabilities, total transition probabilities, and recursively accumulated channel probabilities. This process is performed for common radionuclides (^{149}Tb, ^{211}At, ^{212}Pb, ^{213}Bi, ^{223}Ra, ^{227}Th, etc.) and their decay daughters.

Photons from atomic relaxation (AR) are extracted from the IAEA website using the provided web API[1] (ENSDF Evaluated Nuclear Structure Data Files). Similar to the isomeric transition process, the obtained data are stored in a file, as lists of photon emission energies and associated probabilities. Geant4 incorporates the Bearden database, aligned with the IAEA website and activated using `/process/em/fluoBearden true`. Considering the

[1]API documentation: https://nds.iaea.org/relnsd/vcharthtml/api_v0_guide.html

nanosecond timescale of atomic relaxation decay, characteristic X-ray emission is treated as prompt, excluding delayed fluorescence [12].

The photon lines with their respective energy and probabilities extracted from IT and AR are not sufficient, we also need the relative abundance of each daughter radionuclide. This is done by solving Bateman equations that compute the time-dependent decay of radioactive nuclides and their daughter products, accounting for changes in population over time due to parent nuclide decay and subsequent daughter decay. These equations yield to TAC for all daughters based on specified time points.

In summary, the proposed source model automatically retrieves comprehensive information (daughters, half-life, TAC, etc.) for a given radionuclide. It incorporates relative activity from computed TAC, coupled with emitted photons from isomeric transitions and atomic relaxation, to selectively generate primary photons with accurate energy, intensity, and timing within the specified timeframe.

3 Experiments and results

We compared the photons emitted from a reference Geant4 simulation and the proposed model. The simulation used a ^{225}Ac point-like source of 1000 Bq, in a water box, during an acquisition time frame of 1000 seconds starting 14 hours after injection of the radionuclide. Photons from the reference simulation were extracted from a phase space that contains all particles that have been created and tracked together with the kinetic energy, their Geant4 creator process, and their associated timestamps. At the end of the simulation, the phase space was processed to extract the photons whose creator process is IR or AR and whose timestamps are between 14 hours and 14 hours plus 1000 seconds. The resulting reference photon energy spectrum was compared to the one obtained from a second simulation in the same condition but using the proposed source model. Figure 1 shows very good concordance between most of the photon lines except for the very low energy (<20 keV).

We also simulate a projection from Siemens Intevo Bold SPECT/CT device equipped with High Energy collimator (8000 holes of 4 mm, 2 mm septal thickness) coupled to 9.5 mm thickness NaI crystal. We simulated the NEMA IEC body phantom with six spheres filled with 100 kBq/mL ^{225}Ac (around 0.5 MBq total) and no background activity. The acquisition was one single-angle orientation with a time frame of 210 seconds starting at t=24h like in [8]. We compared three types of sources: (1) the reference ^{225}Ac ion source, (2) a simplified dual gamma source of 218.12 keV (11.4%) and 440.45 keV (25.9%), like the one in [13], and (3) the proposed source model. Figure 2 shows the obtained projections and associated profiles. The proposed source model is in good agreement with the reference profile, while the simplified model depicts larger discrepancies.

Using the reference ion source involved the tracking of a lot of different particles and required to start from t=0, and filter the desired photons. If we consider an acquisition of 200 seconds with a ^{225}Ac source of 3 kBq, about 15.8×10^6 particles will be tracked for only 2.7×10^5 photons that should be simulated (32 seconds vs 1.4 seconds). In the previous experiment, computation time was 28 hours for the reference source, 1.6 hours for the simplified two peaks source and 3.7 hours for the proposed one.

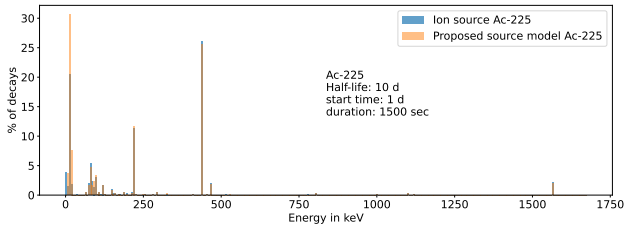

Figure 1: Comparison of emitted photons from the reference ion source and the proposed source model for ^{225}Ac.

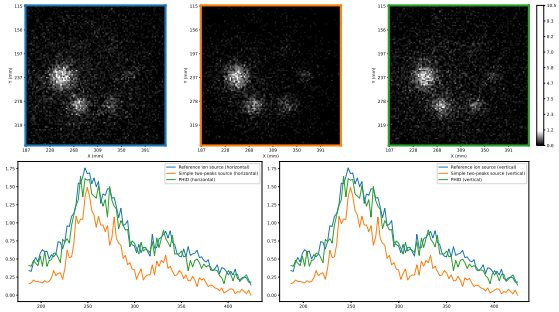

Figure 2: Top: ^{225}Ac SPECT projections of the IEC phantom for an energy window around 218 keV (energy window equal to 196-240 keV), with the reference ion source (left), the simplified two-peaks model (middle), and the proposed source model (right).

4 Conclusion

We presented and evaluated a specialized Monte Carlo source model for alpha emitters, specifically designed for the generation of photons within a specified timeframe. This approach provides computational efficiency benefits compared to conventional ion sources that require the generation and tracking of all decay products. Obtained photons are in good agreement with the reference ones except for the low energy range below 20 keV. The proposed source model is versatile and has been applied to various other alpha emitters. It can be useful for optimizing acquisition protocols, refining scatter correction parameters, and exploring advanced reconstruction methods. The source model is open source and available in GATE 10.

Acknowledgments

This work was performed within the framework of the MOCAMED project (ANR-20-CE45-0025), the SIRIC LYriCAN+ Grant INCa-DGOS-INSERM-ITMO cancer18003. We gratefully acknowledge the support of NVIDIA Corporation with the donation of the Titan Xp GPU used for this research. This work was granted access to the HPC resources of IDRIS under the allocation 2019-101203 made by GENCI (Jean Zay computing center).

Abstract Radiation treatment relies on Treatment Planning Systems (TPS) for precise dose calculations. However, challenging cases, like strong heterogeneities or complex target movements, needs reference calculations such as Monte Carlo model. This study introduces a Monte Carlo model of a helical radiotherapy device (Accuray Radixact). GATE platform v9.1 simulates the linac head using data from the manufacturer. The model is validated by comparing measured and simulated dose distributions. A distinctive feature is its consideration of all accelerator element movements including individual Leaf Open Time. The model will find application in diverse contexts.

1 Introduction

In France, External Beam Radiotherapy (EBRT) is used to treat more than 60% of cancer patients (1). In routine, the absorbed dose is calculated by commercial algorithms that are fast and accurate and that give satisfactory results in most clinical cases (2). However, in complex situations, these algorithms, based on simplifications, show their limits. In these cases (inorganic material, dose to skin, out of beam doses) Monte-Carlo methods are considered as the reference computation (3). They can also provide basic data of dose detectors (e.g. output correction factors or OCF) for the determination of absolute dose (4). These methods cannot be implemented in clinical routine for several reasons: complexity of the tools (such as Geant4 (5)), long time computation and a lack of certification.

After have proposed a full open-source model of the TrueBeam linear accelerator (Varian, Palo Alto, CA) (6) based on GATE (7) and showed its potential applications (8) our team is implementing a model of an helical linac i.e. a Tomotherapy unit (Radixact, Accuray, Madison, WI). The complexity of this modeling in GATE/GEANT4, is the way that the dose is dynamically delivered by the Radixact Unit. The patient couch is moving continuously, while the gantry is rotating and, above all, during each control points on the helical-shape trajectory of the gantry, each of the 64 leaves of the Multi-leaf Collimator (MLC) has a very short (<300-400 ms) and unique Leaf Open Time (LOT). The leaves are fully open or fully close on these machines (with a very short opening/closing time).

This present work describes the implementation of the model, including the source tuning, the geometry, and the management of the time slices to model the MLC motion. Then some validation results based on a comparison to measurements are presented, including basic measurements in water for an open-field fixed beam gantry but also results for a fully dynamic irradiation based on a plan provided by the real machine (i.e. DICOM RT Plan). A confidentiality agreement between the manufacturer and our team is signed. Thus, we cannot provide exact figures of the geometry in this article.

2 Materials and Methods

A. General modelling

A comprehensive modeling of the accelerator head was conducted, considering the electron beam, target, primary collimator, jaws, multi-leaf collimator (MLC), and the associated movements of each component. All the elements contained in the head of accelerator are shown in the Figure 2. All complex shapes of the linac head (MLC, jaws, etc.) are reproduced using Blender. The produced .stl file is accepted by GATE.

B. Monte Carlo Model

The model was developed using the GATE Monte Carlo open-source software (version 9.1) associated with Geant4 (version 10.7.2). The physics list is the standard option 3. Cut-off ranges equivalent to an energy of 1 keV for photons and 10 keV for e−/e+ were applied. The dose calculation was performed using the regional high-performance computing, Olympe. Simulations was computed on 6 nodes, each with more than 5×10^9particles, allowing to keep statistical error under 1%

Source

To implement the device, the electron beam was directed towards a tungsten target that has been designed, based on relevant scientific literature (9,10) and adjusted to reproduce Percentage Depth Dose (PDD) profile in water (see hereafter).

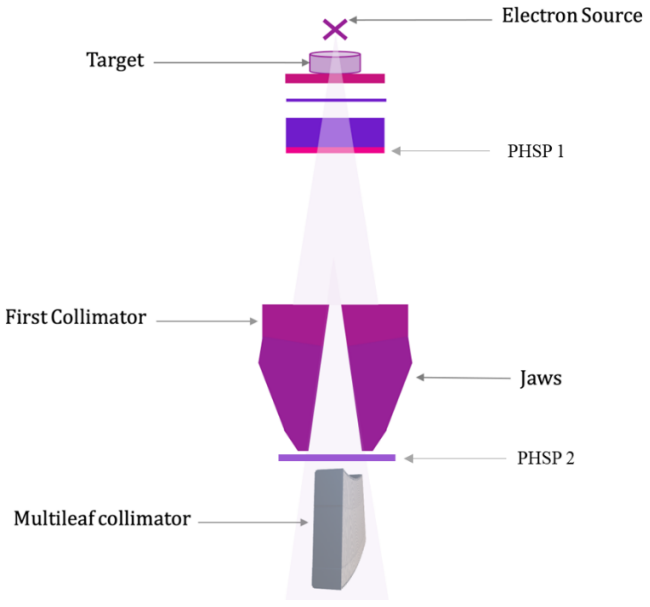

Figure 1 – Schematic representation of the elements of the head

Collimation system

The energy of the electron beam was represented by a Gaussian distribution centered at 6 ± 0.5 MeV energy. To reduce simulation time, intermediate phase spaces files (in format .IAEAphsp) were used. Two phase space files were stored: the first immediately following the target (to avoid simulating the interactions in the target at each simulation) and the second after the jaws (one for each of the three possible jaws opening).

The collimation system included a primary collimator, a set of jaws and a multileaf collimator. Three longitudinal distances can be adjusted using the jaws: 1, 2.5 and 5 cm.

The multi-leaf collimator is composed of 64 binaries leaves, which allows to modulate the field in transverse direction. When all the leaves are open, the field opening is 40 cm at the isocenter.

Dynamics fields

In GATE, the movement is generated with an update of geometries, using *time slices*. To model the modulation, plans are generated with the Treatment Planning System (TPS) and were exported as DICOM RTPLAN object. A locally developed Python code is used to retrieve all the data concerning the movement (gantry, jaws, couch and MLC) and stored in *placement files* in the GATE format. For gantry rotation, couch translation and for each moving leaf, one *placement file* was created. Figure 2 shows the principle of the different modeled time slices. For each CPI, a first *time slice* (corresponding to the first geometry) is generated, with the duration of the shortest LOT. Thus, a second time slice is added with this first leaf closed, and a duration corresponding to the difference between the two shortest LOT, and so on. Finally, the number of created time slices corresponds to the number of open leaves of the CPI. For Radixact unit, the MLC has 64 leaves and there are 51 CPI/rotation. The number of generated time slices may be considerable.

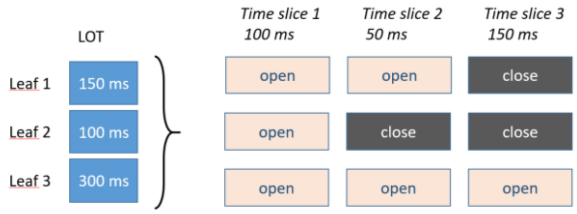

Figure 2 – Principle of the creation of time slices for a single CPI (with only 3 leaves in this example).

C. Validation of the system

Several validation steps were achieved. To assess the radiation source and, by extension, the geometry of the collimator jaws, depth dose distributions and dose profiles in a water tank were realized. For the three field sizes, simulations and measurements were conducted on depth dose distributions and dose profiles. The measurements were performed using the A1SL ionization chamber within a water phantom. PDD, longitudinal (LPD) and transverse (TPD) dose profiles were measured. The GATE simulations were computed under the same conditions with a size of voxels of 1.25^3 mm^3. The dose ratio D20/D10 was calculated on PDD for both measurements and computation. Attention was given to full width at half-maximum (FWHM) and penumbra on LPD, while the TPD was assessed using the width at 25%.

The geometry of the MLC was verified with an simple MLC static pattern (alternating sequences of 4 open and 4 closed leaves). Computation results were compared to a measurement with a radiochromic film. In the context of dynamic field simulations, model validation was established using a TPS plan. A gamma index was employed to compare the dose distributions between the simulation and the TPS.

3 Results

A. Static Mode

Measurements and GATE results of PDD, LPD and TPD in water are represented in Figure 3.

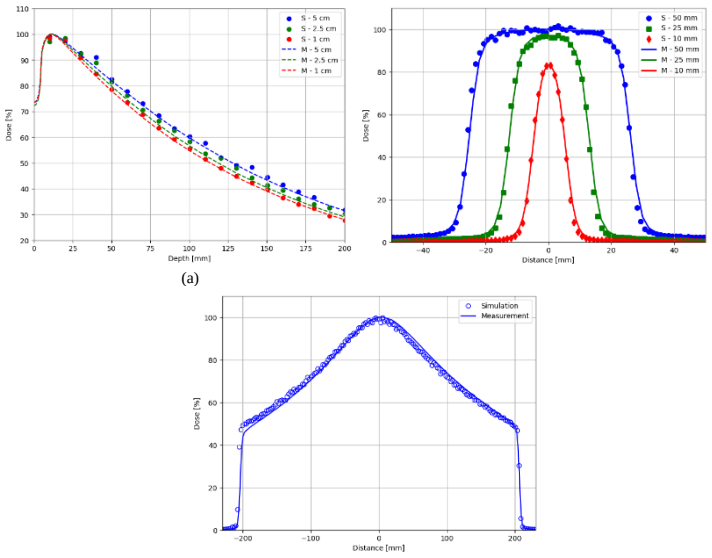

Figure 3 – PDDs (a) LPDs at 1.5 cm depths (b) and TPDs (c) at 1.5 cm depth obtained by simulations and measurements. Curves are normalized at maximum dose (PDD) and on central axis of the largest opening field (LPD, TPD)

Using 2%/2mm gamma index analysis, the passing rate for PDD ranged between 96.35%-99.6% between simulation and measurement curves. D20/D10 for measurements and GATE were 0.527 and 0.531 respectively (<0.7% difference). For LPD, the passing rate with the same criteria (2%/2mm) ranged between 98.14-99.9%. The difference between the values of the half-height width and the penumbra values from the simulation and the measurement was less than 1 mm. For TPD, gamma rates were over 95% and the differences between the values of the width at 25% of the dose are below 2 mm for the three fields.

For the static MLC pattern the comparison between simulation and measurement is shown in Figure 4.

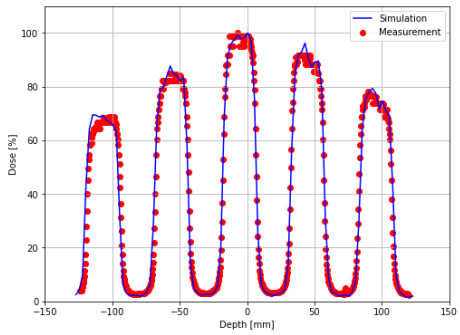

Figure 4 - Comparison of an alternating 4 open/closed leaves between GATE and Gafchromic film measurements

The gamma index pass rate between the simulation and measurement value (3%/2mm) was 95.15% for this static MLC pattern confirming the consistency of leaves modeling.

B. Dynamic acquisition

A plan was developed to compare the dose distributions from the simulation and those determined by the Treatment Planning System (TPS).

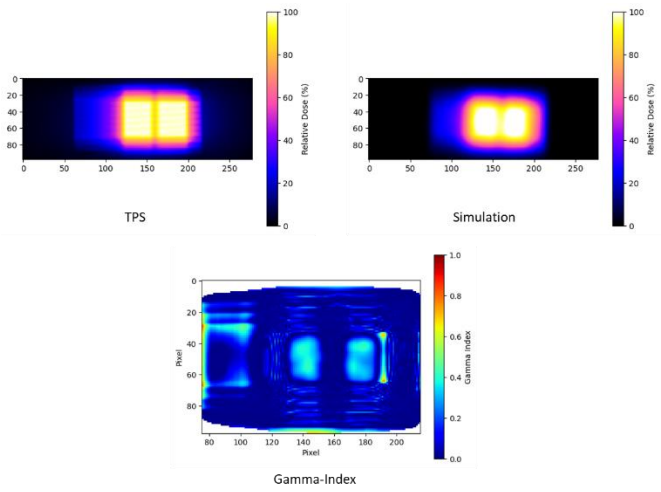

Figure 5 - Dose distribution of a dynamic plan, comparison between TPS and simulation with gamma-index

The plans obtained with both the simulation (smooth image) and the TPS are shown in the following Figure 5. The gamma index at 3%/3mm has been calculated between the two dose images.

4 Discussion

The aim of this work was to validate our GATE/Geant4 model of the Accuray Radixact unit. Other Monte-Carlo models of older Tomotherapy units (e.g. Tomo HD) were published, in particular based on Penelope code (11) or MCNP (9). However, this is the first model of the RADIXACT, to our knowledge, that is Geant4-based and that models each individual LOT. To achieve this goal, the GATE simulation is divided in a large number of time slices (up to 10k).

The first step of the validation was to find the optimal target geometry to obtain the Radixact energy spectrum. The final spectrum was slightly different than previously published model of Tomo HD spectrum (10) (not presented here). But the simulated PDDs in water were consistent with the measurements (in particular the D20/D10 index). Moreover, the consistency of LPD/TPD and of the static MLC pattern allow validating the general geometry of the model. Finally, the dynamic simulations were achieved to verify that all the system movements (couch, gantry, jaws, MLC), extracted from RT Plan file, were correctly reproduced using our *time slices* generator. Further, more complex plans with clinical cases will need to be used later on.

The next step of this project is to use the model for different needs in the field of dose computation: presence of inorganic materials in the patient body, determination of the dose in the regions where TPS results are poor (skin, out-of-field zone), or e.g. to determine OCF of different dose detectors. As these simulations are still very computing time consuming, we are currently working on the validation of time-reduced simulations with some tools to reduce the noise or retrieve the signal from our data.

5 Conclusion

The aim of this study was to obtain a full GATE model of a helical radiotherapy device. All the elements of the accelerator were modeled and validated. In the future, the model will be used for several applications such as reference computation beyond the limits of commercial TPS.

Abstract:

FLASH radiation therapy is an innovative modality that relies on the delivery of ultra-high dose rates (UHDR), threshold of 40 Gy/s in a pulsed beam structure. This modality reduces normal tissue complications without compromising tumor control, termed as "FLASH effect". However, the mechanism governing this effect remains elusive, prompting ongoing debates on the plausible mechanisms. This effect might depend upon the early physical-chemical events and biochemical events. The main aim of this study is to track the yields of water radiolysis, particularly the toxic reactive oxygen species Hydrogenperoxide (H2O2). TOPAS-nBio Monte Carlo track structure simulations were conducted across diverse conditions, such as dose rates, number of pulses, and particle beam energy. The yields of (H2O2) exhibited a notable linear increase with the delivered dose, and the dose rates were significantly impacting the (H2O2) across all three particle beams. Whereas these yields (H2O2) can be ranked: FLASHphoton > UHDRproton > UHDRelectron > CONVelectron.

1 Introduction

FLASH Radiation Therapy (FLASH-RT) emerges as an innovative approach in radiation oncology. Its innovation hinges on an ultra-high dose rate (UHDR) delivery, this accomplished by administering radiation under UHDR (≥ 100Gy/s), with a single or a series of pulses, within intra-pulse dose rate in the range (10^4 − 10^9 Gy/s) [1]. FLASH-RT demonstrates exceptional effectiveness in sparing normal tissues. This effect demonstrates an in vivo response wherein mitigating normal tissue toxicities is observed, while maintaining equivalent efficacy in controlling tumor growth comparable to conventional radiotherapy (CONV-RT). Initially, it was observed in various experimental animal models and in different organs, [2,8]. In the realm of FLASH-RT, the concentration of chemical species yields is expected to be altered. Ultimately, this would change the diffusion and kinetics of different radiation chemical reactions. Consequently, these changes would influence the cellular response to irradiation. In this context, hydrogen peroxide plays a pivotal role in water radiolysis. Contributes significantly to DNA damage, primarily inducing single-strand breaks, by its interaction with cellular complexes results in the formation of hydroxyl radicals (OH−) and solvated electrons, augmenting oxidative stress within the biological system, in addition, it diffuses across cellular compartments and participates in Fenton 1 electron chemistry, oxidizing Fe2+ to Fe3+ and generating the hydroxyl radical.[3]. The purpose of this research is to investigate the yields of water radiolysis, with particular attention given to Hydrogen Peroxide (H2O2). Tracking the yields of H2O2 for prolonged time scales till the homogeneous chemistry stage. Under varied particle beams (i.e. Electron, Protons, and Phtons), different pulse beam structures, dose rates. The study involved different proton beam energies, including oxygen concentration, and specified a neutral pH medium. In addition to that, the study encompassed the consideration of temperature effects [4], investigating its impact under CONV versus UHDR. This exploration aimed to gain further insights into its pivotal role in driving reactions and molecular diffusion under both modalities. Moreover, it sought to establish a fair comparison between the MC simulation and the experimental outcomes.

2 Materials and Methods

In the context of FLASH-RT, to simulate water radiolysis, it requires the following chemical species beyond 1us [5]. To this end, the scoring example performed by the TOPAS-nBio collaboration data base, was executed in a manner where two methodologies were employed: independent histories and accumulated histories. The latter method was utilized to consider the interaction of multiple histories within a single pulse within a width 1-2μs. A "history" was defined as the interaction of the primary particle and all its secondaries with the medium, which spanned the subsequent production of all chemical species present after the nonhomogeneous chemistry stage. The methodology to simulate this temporal pulse shape has previously been elucidated by Ramos-Mendez et al. [6]. The mean time was determined based on pulse number and dose rate. The independent reaction time (IRT) algorithm was employed to simulate each pulse independently, under the assumption of no interpulse contributions. Within TOPAS-nBio toolkit, a physics module (TsEmDNAPhysics) is employed, specifically tailored to simulate the complete range of interaction events involving charged particles within water detailed in [7]. To activate the chemical models, we utilized the TsEmDNAChemistry model within TOPAS-nBio. The reactions involving all chemical species studied in this research are detailed in Table1 within [8]. Notably, dissolved oxygen with a concentration of 52μM (4%), is incorporated in this simulation, however, it was represented as a continuous background. Figure 1 shows the full geometry set ups used in this study.

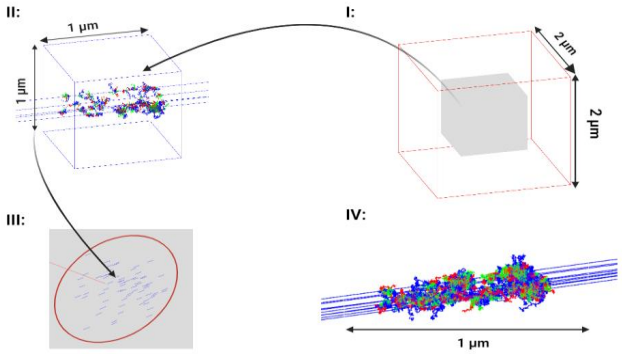

Figure 1: The illustration of the geometry employed in this study :(I) The entire geometry, encompassing the outer box (2 μm^3), constituting the world volume filled with G4−Water. The inner box (1 μm^3), represents the scoring volume, filled with G4−Water. (II) Depicts the scoring volume, showcasing the trajectory of primary particles in the Z direction and the diffusion of chemical species.

3 Results

The evolution of H2O2 concentration as a function of time was simulated with TOPAS-nBio, for various pulsed electron beam structures within 1 MeV energy. The left panel (Figure 2) exhibits the temporal evolution of [H2O2] for FLASH-RT dose rates (500Gy/s). Across the entire range of total doses simulated, the temporal behavior of [H2O2] consistently displays a stable pattern, for all total doses.

For instance, when a total dose of 10 Gy was delivered in three squared pulse beams, each with a mean width of 1μs, it resulted in a concentration of [H2O2] equal to 0.9μM, within an irradiation time up to 1ms. To administer a total dose of 20Gy, an increased number of pulses up to six was used. This adjustment doubled the [H2O2] yield to 1.74μM. Meanwhile, a similar behavior was observed with other total doses (30 − 60Gy). Furthermore, in the medium panel (Figure2), the depiction illustrates the progression of [H2O2] under CONV-RT conditions, which characterized by dose rates of 2.8 Gy/s. Consistently observed across the entire spectrum of simulated total doses, the temporal trends of [H2O2] exhibit persistent stability, even amidst a substantial number of simulated pulses and escalations in irradiation duration up to seconds. Delivering a total dose of 10 Gy by CONV-RT (2.8Gy/s) scenario requires involvement up to three hundred square pulse beams, each spanning a mean width of 1μs, culminating in an [H2O2] concentration of 0.77μM within an irradiation period of up to 13.5 s. Scaling

the total dose to 20Gy and 30Gy or even more, which, doubling the resulting [H2O2] yield to 1.45µM or tripling to 2.25µM , respectively. This trend persisted across varied total doses (30 − 60Gy), manifesting a linear correlation between the total dose and [H2O2] concentration at the end of irradiation period as depicted in left panel (Figure2). In addition to that, dose rates significantly increased the yield of H2O2.

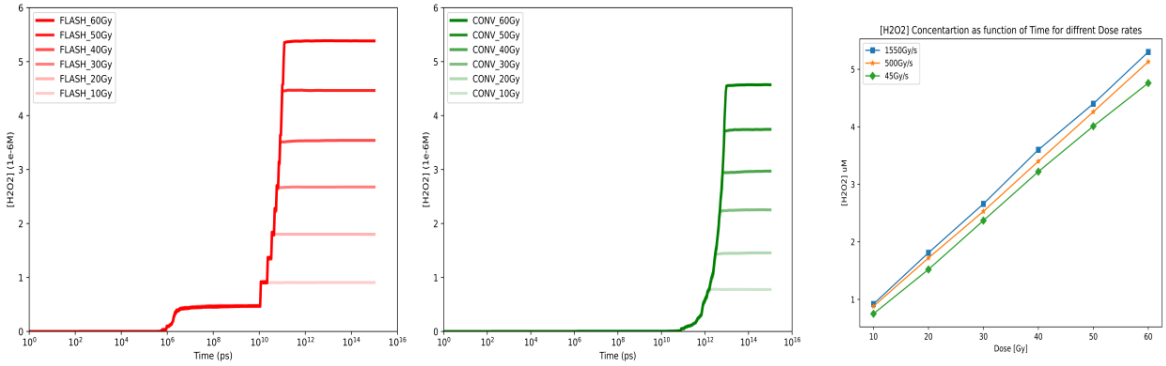

Figure 2: HydrogenPeroxide Concentrations ([H2O2] µM) as function of (log10(T ime)), under UHDR and CONV-RT pulsed electron beams, oxygen concentration 52µM considered. The Total dose delievred was increased by an increment of 10 units up to 60 Gray, as described in the legend by different opacity.

The demonstrated promising outcomes associated with Proton beams, as highlighted in contrast to electrons and photons [9]. Alongside, the mitigation of proton-induced effects on ROS yields, prompt an inquiry, within the framework of MC-Simulation, a systematic exploration encompassing a comparative analysis of particle beams on [H2O2] concentration is depicted in Figure3.

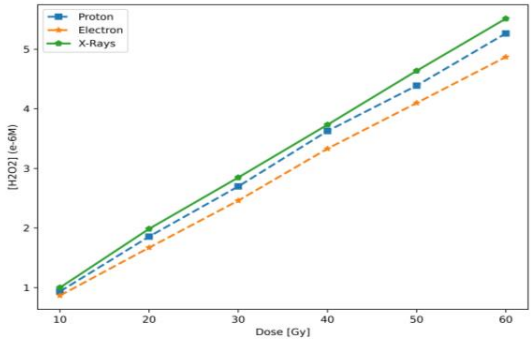

Figure 3: H2O2 concentration as function of total dose, for electron, proton and x-rays. Within a ultrahigh dose rates value 500 Gy/s with same previous pulse beam structure.

Whereas the same beam structure was used to achieve dose rates of 500 Gy/s, protons were chosen with an energy of 300 MeV to have 0.3 keV/µm of (LET), and electrons adjusted to an energy of 0.5 MeV, and X-rays with 250 keV. It's clear from (Figure 3) that X-rays produced more H2O2 compared to other particle beams, and for proton compared to electron across all total doses, where the [H2O2] response to total dose was maintained (increases linearly).

4 Discussion

In the context of FLASH-RT, simulating water radiolysis necessitates consideration of chemical species beyond 1 microsecond. Leveraging our Monte Carlo (MC) simulation methodology, we successfully addressed ultra-high dose rate values akin to those employed in biological experiments. Additionally, the pulse width in our simulations was aligned with those applied in clinical applications. Our findings align consistently with prior MC investigations documented in the literature [8]. However, the generation of

reactive oxygen species (ROS) is notably sensitive to factors such as the concentration of dissolved oxygen in water, (LET), chemical reactions, reaction rates and temperature. In addition to other parameters related to UHDR modality, like number of pulses, dose pre pulse, and mean dose rates.

The findings reported in [8] were obtained by implemented an algorithm called Gellespie which takes the simulation to very long period, whereas some additional reaction contributing to H2O2 generation occurred, which is not in our case. Thus, make some changes in term of (H2O2) amplitude for same total dose, and dose rates. However, 90 % of (H2O2) yields are from self rection of OH (OH+OH->H2O2).

On other hand, biological experiments are expecting (H2O2) to be decreased when dose rates are increased [9], which is not pronounced with MC simulation findings. However, to compare the biological outcomes and MC simulations findings in a rigorous manner, it is worth noting the multitude of parameters that significantly influence water radiolysis, particularly (H2O2) yields. Including LET, which emerges as a crucial determinant, as demonstrated in Figures 2 and 3. Furthermore, the time window during which (H2O2) was calculated and the choice of organic samples also play pivotal roles, given their heightened sensitivity to (H2O2). Further investigation is needed to explore the mechanisms behind the FLASH effect. Water radiolysis alone is not sufficient; it is imperative to consider other biological moieties and plans for future studies involving radical scavengers are underway.

5 Conclusion

In summary, our observations underscore the significant impact of dose rates on H2O2 yields, in addition to the influence of LET. Increasing dose rates and utilizing different particle types resulted in elevated H2O2 yields. Conversely, a high number of pulses led to a substantial reduction in H2O2 production. Our findings shed light on the necessity of understanding the early chemistry stages and their driving factors, which might contribute to the FLASH effect.

Abstract

Monte Carlo (MC) simulation is one of the accurate dose calculation methods in radiation therapy applications. However, long calculation time for simulation is major drawback makes it difficult to utilize MC simulation in practical applications. In this study, we developed log file-based MC calculation application using GPU for proton pencil beam line scanning therapy. The beam parameters of the simulation were determined using beam measurement data for clinically used energy range. To validate the log file-based GPU MC method, eight patient-specific quality assurance plans was used. The two-dimensional absorbed dose at a depth 2cm of water phantom from log file and GPU-based MC was compared with that of the log file and CPU-based MC calculation with gamma evaluation using 2% / 2mm and 5% high dose threshold criterion. The average, maximum, minimum, and standard deviation of 2% / 2mm gamma evaluation were 99.6, 100, 97.9 and 0.55%, respectively.

1 Introduction

Monte-Carlo (MC) simulation is one of the accurate dose calculation methods in radiation therapy applications. However, most of currently developed MC codes are severely time-consuming to calculate high-resolution volumetric doses due to less efficient calculation of CPU. Therefore, it is difficult to utilize the MC simulation deliberately for quality assurance (QA) procedure in most of hospital environments.

Recently, some studies developed GPU-based MC methods for various radiation therapies. For proton therapy, Lee H. et al developed GPU-based proton dose calculation toolkit named Monte Carlo code for quick proton doe calculation (MOQUI) that uses DICOM RT format files [1]. They benchmarked against Tool for particle simulation (TOPAS) MC simulation [2], which was based on Geant4 simulation toolkit [3]. The speed of the MOQUI was increased with simplified physics model and techniques of general-purpose computing on graphics processing units. However, the method cannot simulate proton pencil beam line scanning treatment plan because a DICOM RT-ion plan of the line scanning plan consists of line segment points, dissimilar to the spot scanning plan. Furthermore, the DICOM-based dose calculation does not reflect realistic beam property from daily treatment machine output variation. Thus, the actual beam delivery of treatment plan cannot be accurately accounted for practical environments. In this regard, we developed a log file-based dose calculation method using MOQUI MC simulation in this study. The log file of line scanning has spot-type data with very short time resolution (60 μs) to monitor continuous beam irradiation, which can be adapted to MOQUI. In addition, log file data reflects daily condition of treatment machine and deliverability of treatment plan. To validate log-file and GPU-accelerated MC simulation method, dose calculation results of our previous study [4], the log file-based patient-specific QA method based on TOPAS MC simulation toolkit was used.

2 Materials and Methods

To convert log files to readable information format for the MC code, in-house MC code generation graphic user interface program was developed (Figure 1). The program reads calculated isocenter position of beam and dose count value (MU count) which is proportional to MU from flatness monitor and dose monitor of proton pencil beam line scanning nozzle, respectively. The beam information was reconstructed to plan type files that can be utilized for MC simulation using TOPAS and MOQUI.

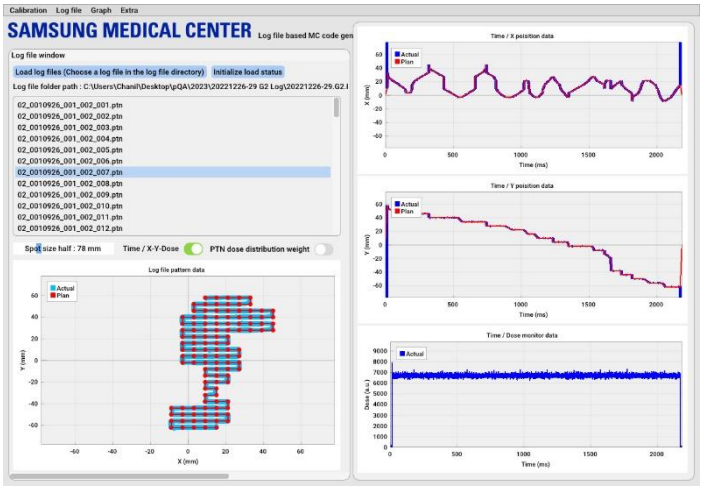

Figure 1. In-house Monte Carlo simulation code generation program

The measured beam data of spot size, angular spread and energy spread was used to determine beam parameters of both MC code for beam energy range of 70 to 230 MeV. The conversion of log file MU count to number of particles in MC simulation was determined by Equation 1, which was validated in the previous research using TOPAS MC toolkit [4]. $MU\ count_{log}$ is MU count of log file, $ED_{Dose/MU\ count}$ and $ED_{Protons/Dose}$ are energy dependent relationships for dose (Gy) per unit MU and number of protons per unit dose (Gy), respectively. Those relationships are determined using MC

simulation and measurement with an ionization chamber array (Octavius 1500, PTW, Freiburg, Germany). R_{DM} is dose monitor (DM) range value saved separately in treatment system console database. Owing to numeral limitation of MU count in a log file, the DM records overflowed MU count from high intensity beam as smaller MU count, with dividing DM range value. The one-level higher DM range value is three times higher than lower-level DM range value.

$$N_{Protons} = MU\ count_{\log} \times ED_{Dose/MU\ count} \times ED_{Protons/Dose} \times R_{DM} \quad (1)$$

The total number of generated particles using Equation 1 for each QA plan was ranged from 1×10^8 to 8×10^8. The GPU computing node for the simulation consisted of Intel Xeon (R) Gold 6326 CPU (2.9GHz) and Nvidia RTX A5000 24GB GPU.

To validate log file-based MOQUI against log file-based TOPAS MC, eight patient-specific QA plan consists of the lung, esophagus, liver, abdomen, brain, and craniospinal irradiation (CSI) for water phantom geometry, were used to calculate three-dimensional (3D) absorbed dose and compared two-dimensional (2D) dose at a depth of 2 cm with that of TOPAS MC.

The calculated MOQUI 2D dose distribution was compared with that of TOPAS using gamma evaluation of 2%/2mm, suppressing dose below 5% of maximum dose of calculated volume.

3 Results

The run-time of the simulation was ranged from 20 to 100 minutes for each patient case to calculate 3D dose of the water phantom using log file-based MOQUI, while the log file-based TOPAS required 8 to 40 hours to simulate for 2D dose at depth 2 cm. The total scorer volume of water phantom using MOQUI was $400 \times 400 \times 400$ cm^3 with $1 \times 1 \times 1$ mm^3 resolution, and that of TOPAS was $400 \times 400 \times 2$ mm^3 with $1 \times 1 \times 2$ mm^3 resolution. The number of energy layers and beam energy for each QA plan field were ranged from 9 to 56 and 70.0 to 171.6 MeV, respectively.

For eight patient QA plans with total 25 treatment fields, the average, maximum, minimum, and standard deviation of 2% / 2mm gamma evaluation were 99.6, 100, 97.9 and 0.55%, respectively.

4 Discussion

In this study, we developed patient specific QA method utilizing log files and GPU-accelerated MC simulation. The accuracy of the proposed method in water phantom condition was validated against the results of previously developed log file and CPU calculation-based MC simulation method. The gamma evaluation for 2D dose distribution was performed with 2% / 2mm and 5% high dose threshold, the acceptable assessment criterion for clinical environments.

Owing to faster dose calculation speed and reflection of practical beam conditions due to log files, the efficient three-dimensional dose calculation and gamma evaluation for patient specific QA are feasible with the proposed method. Furthermore, four-dimensional dose calculation attract attention recently attributing to feasibility of investigation on patient's responsiveness from diverse treatment planning strategies. Using the actual beam irradiation time records in a log file, the synchronization between beam irradiation and position of internal target and critical organ is more practical than the DICOM RT-ion plan computed on planning CT and breathing information. In future studies, the proposed system will be validated against diverse treatment plans and complex geometry. The comparison study of 3D gamma against 2D gamma criteria is underway.

5 Conclusion

We successfully developed log file and GPU-accelerated MC-based dose calculation method and demonstrated the potential of utilization for the clinical applications. In future studies, we aim to optimize MOQUI code for faster calculation speed to use efficiently and assess proposed method with a patient geometry to evaluate the accuracy of the method in inhomogeneous environments.

1 Introduction

Particle therapy has established clinically in the last decades as it can apply the dose to the target with high precision and conformity and has proven to be particularly effective for certain types of cancer. Moreover, in recent years the ultra-high dose rate "FLASH" irradiation has gained a lot of research interest, as it is thought to reduce the side effects in healthy tissue and increase the therapeutic window [1–3].

However, moving tumors pose a challenge to the conventional multi-energy raster scanning method due to the relatively long irradiation time and the resulting "interplay" effects between the scanned beam and the target motion, which can lead to strong dose inhomogeneities [4,5]. Furthermore, it is difficult to achieve ultra-high dose rate FLASH irradiation due to the switching time between the individual energy layers.

3D range-modulators (3DRM), optimized for a single energy and individual tumor shape are a promising and viable solution for FLASH dose delivery in particle therapy. In combination with a high-intensity accelerator, irradiation time can be reduced tremendously [6,7]. However, a 3DRM is an additional beam modifying device in the beam line, and as such it is important to understand and analyze the impact of potential misalignments on the dose distribution.

2 Materials and Methods

A 6 cm side-length cube, rotated twice at 45°, was used in Eclipse as a target shape to develop and optimize a 3DRM for 250 MeV proton-beam. The rotated cube form ensures relatively sharp proximal and distal edges of the 3DRM and consequently of the dose distribution and together with the maximum pin length of approx. 8 cm can be considered close to a "worst-case" scenario. The dose distribution (reference dose) in water behind the 3DRM and a 17 cm thick PMMA absorber was simulated with the FLUKA Monte Carlo package [8–10]. Subsequently, 5 different modified simulations were performed and compared with the reference dose:

- Raster plan shifted **1** mm in **X**
- 3DRM shifted **1.5** mm in **X**
- 3DRM shifted **1.5** mm in both **X** and **Y**
- 3DRM rotated **0.5**° around **Y**
- 3DRM rotated **1.5**° around **Y** (Figure 1)

The rotation point used was X=20 cm, Z=18 cm in front of the 3DRM and relative to its own isocenter as it approximately represents the mechanical mounting point, which will carry the weight of the 3DRM and the PMMA in the snout and might be susceptible to a weight-dependent tilt.

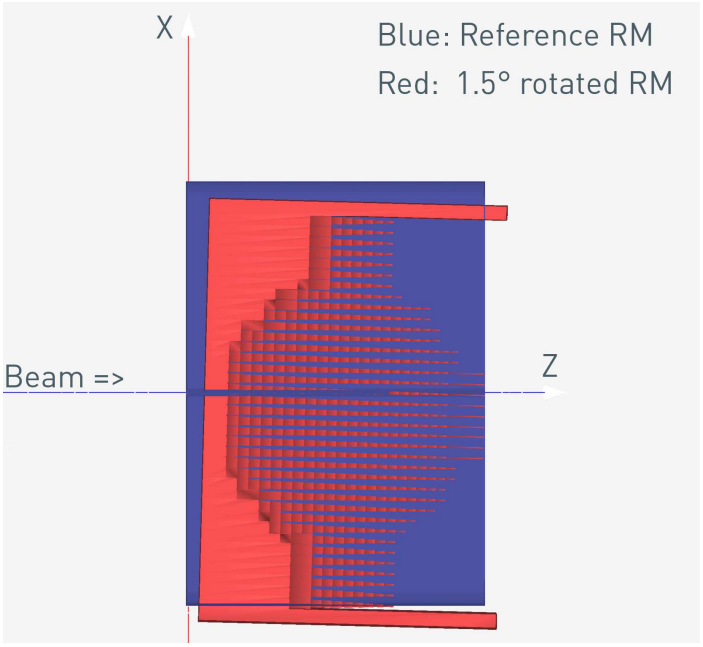

Figure 1: The reference (schematic view) and the rotated (cross section view) 3DRM

3 Results

Figure 2 shows the 2D Gamma Index (GI) for the different scenarios for one proximal (11 cm depth) and one distal (16 cm depth) slice. Additionally, a dose comparison for the 0.5° and 1.5° angular deflection case are plotted (Figure 3 - Figure 4).

Shift/Rotation	Gamma Index (2%/2mm, local)	
	Proximal (11cm)	Distal (16cm)
Raster plan: **1**mm shift in **X**	100%	100%
3DRM: **1.5**mm shift in **X**	100%	100%
3DRM: **1.5**mm shift in both **X/Y**	99%	73%
3DRM: **0.5°** angular deflection	99%	86%
3DRM: **1.5°** angular deflection	77%	23%

Figure 2: 2D Gamma Index for one proximal and one distal depth slice for the different scenarios

4 Discussion

The SOBP transitions to a broad, Gaussian-like distribution with increasing RM rotation, whereas the sharp distal dose is laterally shifted.

5 Conclusion

A shift/rotation of the 3DRM shifts the distal dose. The dose deviations depend thereby on the specific 3DRM and its shape. Precise positioning is important. However, increasing the pin base is expected to mitigate the SOBP dose deterioration to a large extent. It can be concluded that even complex 3D modulators with long pins are robust against a slight misalignment of 0.5° rotation or 1.5 mm shift.

Abstract Optimization of hadrontherapy treatments implies careful consideration of the secondary particles produced by the ion beam fragmentation in the patient. Unfortunately, this is still far from being possible in the software currently used for treatment planning, and research projects are needed to improve the multi-scale calculations of secondary particle production and associated radiobiological effects.
In order to accurately replicate biological responses to ionizing radiation, understanding both the physical and chemical effects of ions is crucial. The CLINM (Cross-Sections of Light Ions and Neutron Measurements) project, aims to comprehensively characterize secondary particles from ion fragmentation on tissues and their associated chemical effects, comparing both simulation and experimental results.
To investigate both chemical and physical effects, radiolysis measurements are conducted alongside the analysis of the secondary particles physical properties (energy, charge) using a ΔE-E telescope. Experiments were carried out at CNAO hadrontherapy center. Water samples were placed after a tissue-equivalent target, irradiated with ^{12}C ions at various energies, in order to study water radiolysis generated by the beam and its secondary particles.
This work will focus on the physical part of the experiment: a ΔE-E telescope, consisting of a thin plastic scintillator (2 mm) and a cerium bromide crystal scintillator ($CeBr_3$), was employed at two different angles (0 and 5°) behind the target, in order to characterize the secondary particles field. Experimental data were compared to simulated results obtained with Geant4.

1 Introduction

During a cancer treatment with particle therapy (heavy ion or proton beam), nuclear reactions of the primary beam with the targeted volume need to be quantified in order to calculate exactly the dose received by the patient. Charged particle therapy (CPT) permits, compared to therapy using X-rays, to deliver a more conformal dose to the tumor while sparing healthy tissues. However, the primary beam and target fragmentation lead to the production of lighter fragments, which may contribute to undesired dose in healthy tissues. Dose calculations in particle therapy rely on high-performance algorithms which include both physical and biological processes. These calculations are based on data provided by Monte Carlo simulation codes. However, there is currently a lack of experimental data regarding nuclear reactions in particle therapy, which can introduce inaccuracies in dose calculations.
In order to accurately reproduce biological phenomena occurring in case of irradiation of living cells with ionizing radiation, it is necessary to properly reproduce the physical interactions of this radiation with matter, as well as its chemical effects, such as the radiolysis of the different molecules composing the cells (water, proteins, DNA…). While several studies have addressed the question of physical properties of secondary particles produced during CPT [1–3], the crucial chemical step, that makes the link between physical and biological effects of radiations, is often neglected. The CLINM (for Cross-Sections of Light Ions and Neutron Measurements) project aims at proposing a global characterization of the secondary particles produced by fragmentation processes of ions on tissues, and of their chemical effects.
These chemical effects are studied through the measurement of the radiolysis products generated by the secondary particles, while the physical properties (energy, charge) of these particles is performed thanks to a ΔE-E telescope. A first experimental campaign of the CLINM project was performed at the CNAO hadrontherapy center (Pavia, Italy), and the achieved results of this campaign will be presented in this work. This abstract especially focus on the preliminary comparison between the obtained physical data with simulations performed with the Geant4 Monte Carlo code.

2 Materials and Methods

During this experiment, the secondary particles produced by different carbon ions energies on different thicknesses of RW3 slabs phantom were measured. Different thicknesses of RW3 were used: 5 cm and 23 cm, with ^{12}C energies of 200 MeV/u and 400 MeV/u respectively. The goal was to achieve a ^{12}C energy of 120 MeV/u exiting the target in all configurations.

The setup to measure the physical characteristics of the secondary particles (charge, energy, yields) is presented on Figure 1(a-b). It was made of a ΔE-E telescope, with one plastic scintillator of 2-mm thickness (ΔE) and one cerium bromide crystal of 5 cm thickness (E). The $CeBr_3$ detector is a cylindrical 2×2 inches crystal scintillator, from Advatech UK Ltd [**Advatech**], coupled to a R6231-100 Hamamatsu photomultiplier (PMT). An entrance window in front of the crystal inside the $CeBr_3$ is made of 400 μm of aluminum and 1 mm of polytetrafluoroethylene (PTFE), used as a reflector. In order to be able to detect ions such as ^{12}C without saturating the system, the high-voltage on the PMT

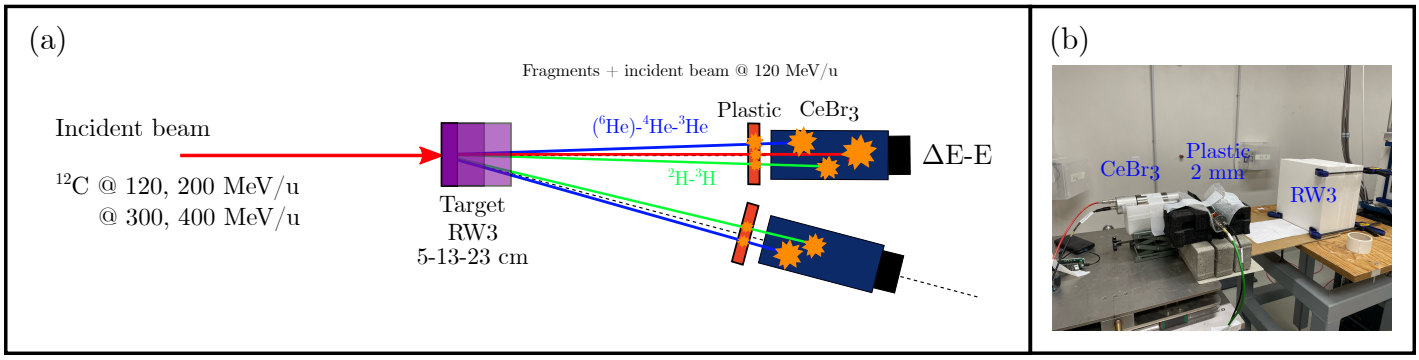

Figure 1: Scheme of the experimental setup used at CNAO.

was considerably reduced (down to +350V for ^{12}C ions) compared to the usual operating voltage (around +1200V), following recommendations from [4, 5].

The plastic scintillator, from Eljen Technology (EJ-228), is a square of 6×6×0.2 cm^3, put in coincidence with the $CeBr_3$, and coupled to XP3990 photomultiplier tube supplied with -1200V high-voltage.
Both detectors signals were aquired by a WaveCatcher digitizer module, developed by the LAL laboratory (Paris, France) [6]. The sampling frequency was set to be 3.2 GHz. This digitizer allows to reconstruct the full signal of the scintillators composing the telescope.
Obtained data were all compared with Monte Carlo simulations, carried out with Geant4 10.07, with the INCL physics list [7]. The INCL physics list implements the intranuclear Liège cascade model [8], in which nucleons are modeled as a free Fermi gas in a static potential well. A quasi-target composed of participating nucleons from the projectile entering the target as well as a quasi-projectile was built. The pre-defined QGSP_INCLXX_HP physics list was used for this final list.

3 Results

3.1 Secondary particles energy spectra

An example of ΔE-E bidimensional plot, obtained at 0° with 398.84 MeV/u ^{12}C interacting with a 23-cm thick RW3 target, is presented on Figure 2. The energy deposited in the plastic scintillator is presented as a function of the total energy released in the cerium bromide. Several populations can be distinguished, each of them corresponding to a different charge Z of secondary particle. It can be clearly seen that the helium isotopes (Z=2) are the main contribution to the secondary particles field. The incident carbon beam (Z=6) is also clearly visible on the figure.
Bidimensional ΔE-E maps were used to perform graphical cuts, in order to select the different charges that could be identified. Figures 3 and 4 present the comparison between measured and simulated energy distributions of the different charges of particles, at two different angles (0 and 5°) and

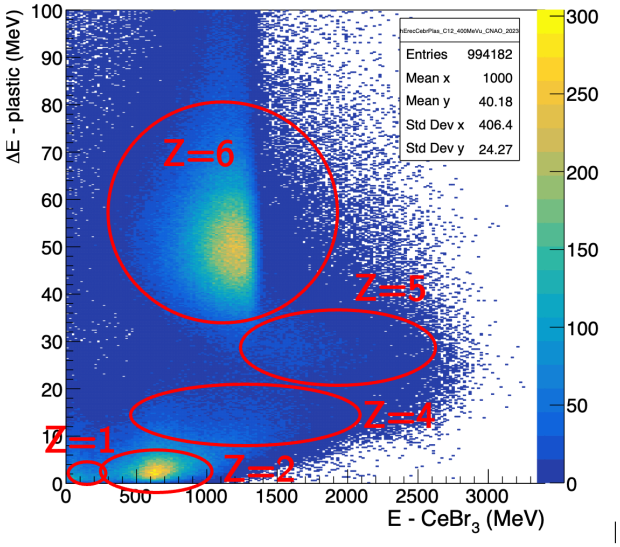

Figure 2: Energy deposited in the plastic scintillator (ΔE) as a function of total energy released in the cerium bromide (E), after the interaction of a 400 MeV/u ^{12}C beam with 23 cm of RW3 target.

two different target thicknesses (5 and 23 cm). Distributions were normalized by their integral in order to compare their shapes.
It can be observed that the shape and the average energy of measured secondary particles are in a relatively good agreement with the simulations for each Z, at 0° (Figure 3), except for Z=2 (Figure 3b), where an important underestimation of the simulated energy can be observed. At 5°, except for Z=1, the simulated energy distributions are all underestimated compared to the experimental data. In a similar fashion than what is observed at 0°, the underestimation of the energy by Geant4 is more important for Z= 2, with a factor 2 between the average measured energy and the simulated one.

4 Discussion

When the measured energy distribution of Z=2, corresponding to helium ions, is compared with the initial energy distribution of each simulated alpha-particle (Figure 5), it can be observed that both distributions are in a good agreement. It

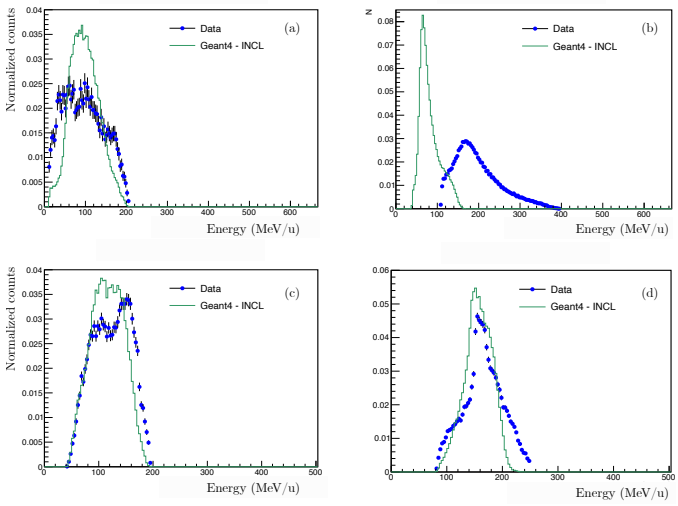

Figure 3: Comparison between simulated (green line) and measured (blue dots) energy distributions of Z=1 (a), Z=2 (b), Z=4 (c) and Z=5 (d) produced by a 400 MeV/u carbon ion beam interacting by 23-cm RW3 phantom.

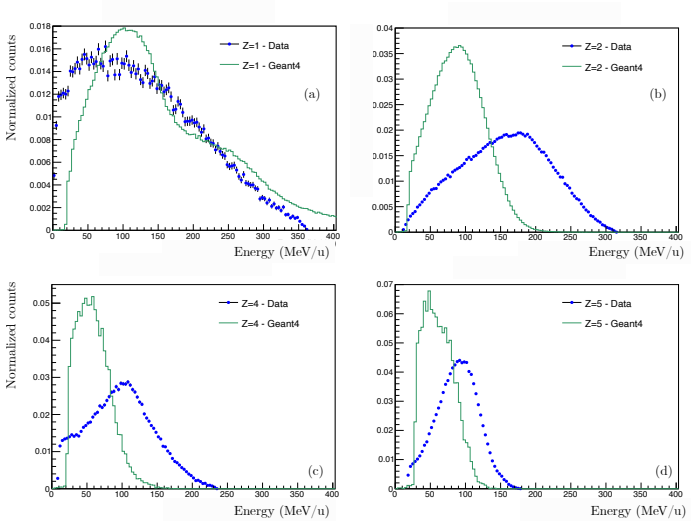

Figure 4: Comparison between simulated (green line) and measured (blue and red dots) energy distributions of Z=1 (a), Z=2 (b), Z=4 (c) and Z=5 (d) produced at 5° by a 200 MeV/u carbon ion beam interacting with 5-cm RW3 phantom.

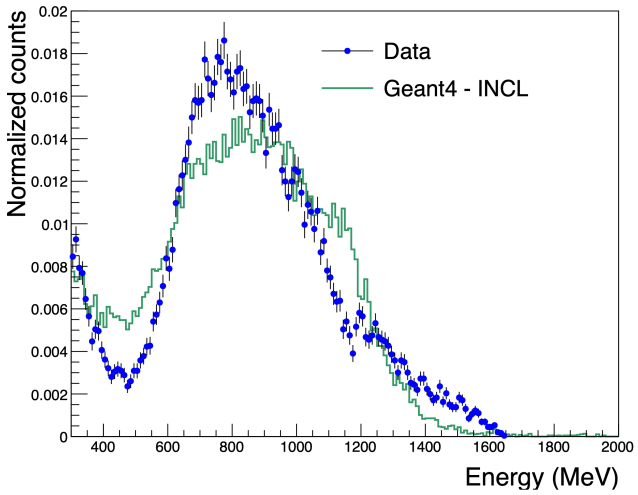

Figure 5: Comparison between the initial energy of each single helium ion simulated by Geant4 (green line) and the measured helium ion energy distribution (blue dots). Both distributions were normalized by their integral to allow better comparison.

should be emphasized that helium ions with initial energies predicted by Geant4, which are peaked around 800 MeV, do not stop into the cerium bromide scintillator of the ΔE-E telescope. Nevertheless, the measured energy in the telescope is peaked around 800 MeV (around 200 MeV/u), which indicates that the helium ions are stopped into the crystal in experimental conditions. This discrepancy between Geant4 and the measurement originates from the fact that the ΔE-E telescope measured two alpha-particles arriving on the detectors at the same time (therefore produced by the same initial carbon), while INCL is predicting that the energy corresponding to two helium-ions is actually carried by a single ion.

5 Conclusion

Preliminary results obtained at CNAO with ^{12}C ions interacting with RW3 targets have highlighted discrepancies between the INCL hadronic model predictions of Geant4 and the measured data, especially on the production of Z= 2 fragments. These results demonstrate the interest and the importance of performing measurements to benchmark Monte Carlo codes in the context of hadrontherapy. Further studies will be carry out with different types of ions and targets.

Abstract
Modern radiotherapy has significantly improved cancer patient survival rates, yet challenges remain in optimizing both tumor response and quality of life. Out-of-field doses play a role potentially impacting patient overall survival, but are not well-estimated by the conventional treatment planning systems. We propose here the development of a full Monte Carlo simulation model of the Elekta VERSA HD accelerator to assess the out-of-field deposited doses. We introduce an original Compton splitting method aiming to compensate for simulation low convergence in the out-of-field region. Results emphasize that achieving a 5% statistical precision on the far out-of-field deposited dose requires 200 days of simulations on a single thread. The proposed variance reduction technique led to a 1.4 efficiency gain. This model will be used to generate out-of-field dose maps on a large database of patients that will be used to train a deep learning model for quick dose calculation [1].

1 Introduction

Photon therapy modalities, such as Intensity-Modulated Radiation Therapy (IMRT) or Volumetric Modulated Arc Therapy (VMAT), use multiple beams with distinct configurations, enabling a highly conformal dose deposition within the targeted tumor volume. This involves an expansion of the irradiated volume compared to traditional 3D-Conformal Radiation Therapy (3D-CRT) [2]. However, the Out-Of-Field (OOF) deposited dose, often considered to be less than 5% of the prescribed dose, is notably lower than that within the irradiation field, but still is around 100 mGy at 15 cm far from the 5% isodose curve [3].
These very low doses can contribute to the development of radiation-induced malignancies or lymphopenia (lymphocyte deficiency), both of which reduce overall patient survival post-radiotherapy [4]. To quantify these effects and strive for the inclusion of lymphoid organs as potential organs at risk in Treatment Planning Systems (TPS), a key consideration is the precise estimation of the OOF deposited dose within the patient. However, conventional TPS are designed for in-field dose calculations and exhibit significant discrepancies when compared to experimental measurements, reaching up to 100% in the "near" OOF region [5, 6]. Consequently, several research initiatives focused on improving dose estimation in the OOF regions, employing analytical calculations, as reviewed in [7], or Monte Carlo (MC) simulations [8]. While the former method is relatively fast (taking several minutes), its precision can be outperformed by MC simulations. However, the latter approach is time-consuming, and the statistical precision to achieve is often defined from in-field simulations.
In the following, we present the statistical errors associated with the OOF deposited dose for the Elekta Versa HD, as a function of the simulation running time and introduce a Variance Reduction Method (VRM) named Compton Splitting to speed up the simulation.

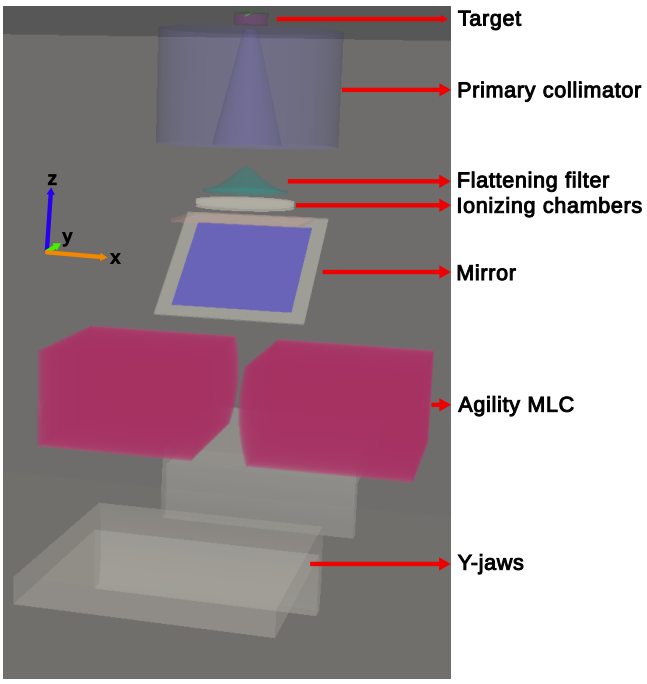

Figure 1: Simulation view of the different parts of the LINAC head. The jaws representation is here simplified. A phase space is inserted between the mirror and the MLC and acts as a particle source.

2 Materials and Methods

The MC simulation work is performed using GATE [9], an open-source software based on the GEANT4 toolkit [10], to model a LINAC head based on available information about Elekta Versa HD (Figure 1). The physics list used for the MC simulations was *G4EmStandardPhysics option3*.
The LINAC head simulation is divided into two parts. The

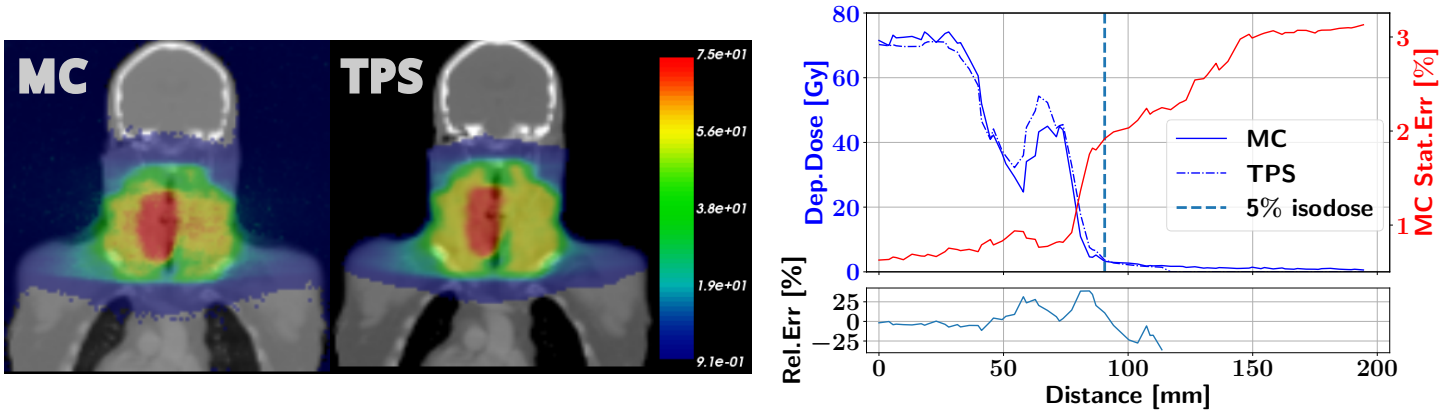

Figure 2: Left: Comparison, between the MC simulation (left) and Monaco TPS (right), of deposited doses, on a coronal plan, generated according to a DICOM RT plan. The dose is normalised at 70 Gy corresponding to the deposited dose at the LINAC isocenter position. The colormap scale is in Gray. Right: Comparison between the TPS and the MC simulation of deposited dose 1D profiles along a path starting from the isocenter to the minimum deposited dose value within the patient. The start of the OOF region (5% isodose) is depicted for visualisation purposes.

first part encompasses all patient-independent devices, including the electron target, primary collimator, flattening filter, ionizing chambers, and mirror. Particles exiting this part are stored in a phase space file and subsequently used as a particle source for the second simulation part. This part involves target-specific components, the Agility™ Multi-Leaf Collimator (MLC) and Y-jaws. The simulated LINAC head irradiates either a water tank or a voxelized CT-scan, on which a *dose actor* is attached. It enables to store of both the deposited dose and corresponding statistical uncertainties in $4\times4\times4$ mm^3 dose scoring voxels. The simulated accelerator parameters were fine-tuned to reproduce the dose deposition experimentally measured, i.e percentage depth-dose curves and dose profiles in X and Y-axis. The simulated dose well reproduces experimental data, and ongoing work involves refining simulation parameters.

The statistical assessment was conducted in a two-step process. The first step investigated, for MLC apertures from 2 to 11 cm in both axis, the impact of the three main mechanisms generating the OOF dose: (1) low-energy scattered photons within the target (patient-scattered photons, or PS photons), (2) scattered photons at the MLC/Y-jaws tips, or in the flattening filter (head-scattered photons or HS photons), and (3) photons crossing the MLC/Y-jaws (head leakage photons, or HL photons). The second step assessed deposited dose and its uncertainty as a function of the OOF distance, starting from the 5% isodose curve. The required simulation time was defined as the simulation duration, on a single thread (Intel® Core™ i9-13950HX), to achieve mean statistical uncertainties of 5% on a given dose scoring voxel. We also devised a method that reads any DICOM RT Plan to replicate a whole volumetric irradiation (e.g. few arcs, several hundreds of control points). It allows us to compute an entirely MC-based patient absorbed dose distribution, which is compared afterwards to the one obtained from Monaco TPS. Photons responsible for the OOF dose deposition (mainly HS and HL photons) are relatively rare compared to photons going in the field. Since they are mostly generated by photons undergoing Compton processes within the MLC/jaws before interacting within the patient, we decided to split Compton events occurring in the MLC/jaws regions. This splitting, coupled with Russian roulette for scattered photons with backward direction angles relative to the patient, is confined to the first two Compton processes of the particle (either primary or split). Each split particle is then conventionally tracked, with an associated weight bias. The simulation acceleration was assessed by computing the efficiency, denoted as ε, where $\varepsilon = \frac{1}{\sigma^2 t}$. σ^2 represents the total deposited dose variance, and t corresponds to the simulation running time. This efficiency was calculated from a box-shaped phase-space placed in the far OOF area. This efficiency is subsequently compared to the one obtained with a reference simulation without any applied bias.

3 Results

Figure 2 (left) illustrates the deposited dose within the patient according to the MC simulation (left) and the TPS (right). The MC simulation effectively reproduces a VMAT session, despite observable discrepancies in the deposited dose between the two images. A quantitative comparison is presented in Figure 2 (right), highlighting the deposited dose along a path starting from the isocenter to the coordinates of the minimum deposited dose, within the patient. Along this path, the difference in the in-field dose deposition is less than 5% near the isocenter but can reach up to 35% in the dose gradient. It has to be noted that here, below 1 Gy, the TPS no longer calculates the deposited dose.

The phase space emits $\sim 10^{11}$ γ, with $\sim$ 50000 particles per second simulated, requiring 23 days of simulation on a single thread. The resulting OOF deposited dose uncertainties, 10 cm beyond the 5% dose limit, remain low, around 3%.

Figure 3 provides a summary of the required simulation running time to achieve a 5% statistical uncertainty in $4\times4\times4$

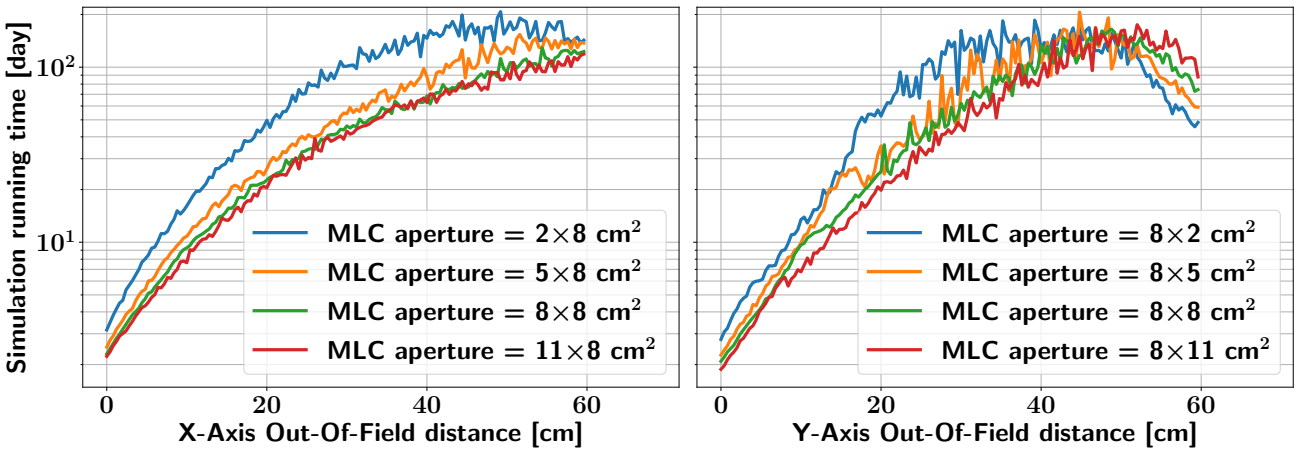

Figure 3: Required simulation running time to achieve 5% of statistical uncertainties within the OOF region, as a function of the MLC aperture and OOF distance from the 5% isodose curve, along the X-axis (left) and the Y-axis (right).

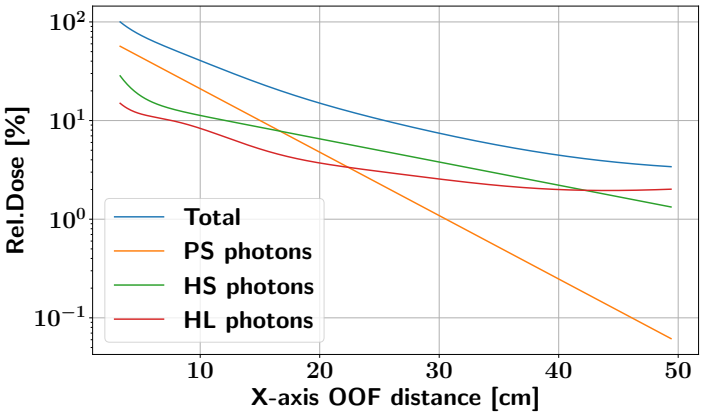

Figure 4: Individual component contributions to the OOF deposited dose plotted against the X-axis OOF distance for a MLC aperture of 8×8 cm^2. Each process is fitted based on its distinct behavior and the fit is presented solely to illustrate the trends within each process. The patient-scattered (PS) contribution is represented in orange, the head-scattered (HS) contribution in green, and the head-leakage (HL) contribution in red.

mm^3 voxels. The required time is plotted against the out-of-field (OOF) distance along the X-axis (left plot) and the Y-axis (right plot). The results are presented for the different MLC apertures simulated (from 2 to 11 cm). As expected, the simulation running time depends on the OOF distance (Figure 3).

In the near OOF region (approximately 0 - 15 cm), the dominant contribution comes from patient-scattered photons and the simulation duration peaks at a maximum of around 10 days (Figure 4). In the middle OOF region (approximately 15-40 cm), PS photons are primarily absorbed within the patient, and the dose is deposited through head-scattered photons and head-leakage photons. The deposited dose decreases and leads to an augmentation of the simulation running time to a maximum of 100 days. In the far OOF region (> 40 cm), the deposited dose increases because of photons passing beyond the collimation system. Since they are not interacting in the collimation system, they enhance the photon statistics, potentially reducing the simulation running time.

Splitting factor	q_D	$\frac{\varepsilon}{\varepsilon_{ref}}$
5	0.97 ± 0.08	1.33 ± 0.04
10	0.98 ± 0.07	1.39 ± 0.04
20	0.98 ± 0.06	1.44 ± 0.04
100	0.95 ± 0.11	1.43 ± 0.06

Table 1: Efficiency gain of the Compton splitting method for far OOF deposited dose. q_D is the quality in terms of deposited dose. q_D = 1 means that the deposited dose estimator is unbiased. ε_{ref} is the efficiency of the reference simulation.

Table 1 presents an unbiased deposited dose estimator (q_D close to one), with a modest simulation efficiency improvement, reaching up to 44%, in comparison to the reference simulation. The efficiency plateaus around a splitting factor of 10.

For higher values, all photons entering the collimation system consistently pass through it, ensuring no waste in tracking primary photons stopped by the collimators. As a result, all simulated events have the potential to attain the OOF region, contributing to the deposited dose. While a further increase in the splitting factor augment the number of split tracks passing through the collimation system, it concurrently extends the time spent in the collimation system per event. Hence, increasing the splitting factor does not enhance simulation efficiency further.

4 Discussion

We presented a model to evaluate the simulation running time required to achieve a specific statistical uncertainty (5%) in the OOF region. The trend of the curves aligns with the current state-of-the-art [11, 12].

The dose distribution generated by the MC simulation, which

replicates the radiotherapy session, exhibits differences when compared to the dose map calculated by the TPS, and suggesting a potential need for further refinement in the MC model. However, even though a simulation is fine-tuned according experimental data, previous research highlighted that large discrepancies peaking to 30% may remain with respect to the TPS [13].

In the far OOF regions, the required simulation running time peaks at 200 days for a single thread. This time can be significantly reduced, by employing multi-job simulations (about one day on our cluster). Despite this acceleration, training a deep-learning algorithm still demands the computation of around hundred images. Creating such a patient dataset, even with the support of a cluster, remains a time-consuming process taking several months. This highlights the need to strive for efficiency improvements in Monte Carlo simulation performance.

This statistical assessment will also provide a reference for calculation efficiency in OOF regions. This efficiency will serve as a ground truth for estimating potential gains in efficiency through the application of variance reduction methods [14]. A preliminary evaluation indicates that, even if allowing a 1.4 efficiency gain, Compton splitting alone may not be dedicated or sufficiently effective to enhance simulation efficiency. Alternative pseudo-deterministic VRMs, as SeTLE [15], or deep learning-based techniques to denoise low-statistic Monte Carlo dose distribution maps [16] could improve further simulations efficiency.

5 Conclusion

This study introduces a MC simulation model for the Elekta Versa HD LINAC using GATE. The model is used to generate a dose map according to a DICOM RT-plan, and is then employed to estimate simulation running times in the OOF region for various collimation system apertures. It was shown that achieving a precise simulation with a 5% statistical uncertainty demands around 200 days of simulation on a single thread. The proposed Compton splitting method allowed to 1.4 efficiency gain. These data can serve as a benchmark to improve MC simulation efficiency or for dataset creation to train deep-learning algorithms tailored to LINAC applications.

Abstract

Purpose: To account for dynamically deforming anatomy during photon and electron dose calculation by implementing and validating a deformable voxel geometry for Monte Carlo dose calculations: DefVoxMC.
Materials and Methods: DefVoxMC is implemented in the Swiss Monte Carlo Plan framework and validated for non-rigid deformations for photon and electron beams with a compression test and a Fano test. DefVoxMC is used for a clinically motivated case with a breathing motion, and the dose differences between the reference (static) and deformed situations are assessed.
Results: The compression and Fano tests were successful. For the clinically motivated case, areas with dose differences of up to 1.4 Gy for electron beams and 6.9 Gy for photon beams are observed between the static and deformed situations with a prescribed dose of 50 Gy.
Conclusion: DefVoxMC is successfully implemented and validated for photons and electrons and can be used to consider deformations in clinically motivated cases.

1 Introduction

A crucial aspect of radiation therapy is dose calculation, aiming to accurately estimate the delivered dose. However, the dose calculation is usually performed using a static CT, while the dose is delivered to a patient with a dynamically deforming anatomy. Deformations can happen during the dose delivery, e.g. breathing motion, or between fractions, e.g. weight loss, tumor regression or progression.

A promising approach to consider deformations for dose calculations is to use a deformable voxel geometry for Monte Carlo (MC) simulations. MC simulations are considered the gold standard for dose calculation in radiation therapy [1]. The deformable voxel geometry consists of dodecahedron-shaped voxels (Figure 1) designed so that each voxel can be approximately deformed according to the deformation in the anatomy, quantified by a deformation vector field (DVF) [2]. The underlying assumption is that each voxel corresponds to the same mass element in every anatomical shape. Using this method, the geometry of the planning CT can be deformed to match the anatomical shape at other time points during the treatment as investigated by Heath et al. [3]

In this work, we implemented and validated a deformable voxel geometry for MC dose calculations to consider dynamically deforming anatomy during photon and electron dose calculations. The deformable voxel geometry extends the in-house Swiss Monte Carlo Plan (SMCP) [4,5], a framework that can be used for different particle transport algorithms for photon and electron beams.

2 Materials and Methods

2.1 Implementation and Validation

For the deformable voxel geometry, the six rectangular sides of regular voxels are divided into two triangles, resulting in a dodecahedron-shaped voxel as in Peterhans et al. [2] This shape allows independent shifting of every corner point, as depicted in Figure 1.

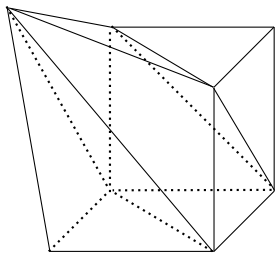

Figure 1: Dodecahedron-shaped voxel with one corner point shifted.

The mass and material of the voxels are set to be conserved with deformation. Therefore, as the volume of the voxels changes with deformations, the density is adapted. Within SMCP different particle transport algorithms can be used with any geometry. Available transport algorithms are VMC++ [6], EGSnrc [7], and other algorithms; in this work, the results are calculated with VMC++ except for the Fano test, which is calculated with EGSnrc. While the particle transport code simulates the interactions, it relies on the geometry code to calculate the path of the particles through the geometry. The geometry code is adapted for the deformable voxel geometry, considering the more complicated dodecahedron-shaped voxels.
The particle transport takes place in the deformed geometry, simulating the dose calculation in the deformed situation while scoring the dose in the geometry of the original situation. This MC dose calculation, using the deformable voxel geometry, is referred to as DefVoxMC in this work.

DefVoxMC is validated with a compression test, using non-rigid deformations on a cubic phantom with a density of 1.0 g/cm^3 for photons (0.2 g/cm^3 for electrons, as otherwise their range is too short). The compressed phantom has a density of 1.25 g/cm^3 for photons (0.25 g/cm^3 for electrons). Dose calculations are performed for a 6 MV photon field and a 6 MeV electron field using a voxel size of 0.125^3 cm^3. A first MC dose calculation is performed on both phantoms

using a regular voxel geometry. Next, the geometry of the original phantom is deformed to match the compressed phantom during the dose calculation using DefVoxMC. In both cases, the depth dose profile is calculated along the beam direction. The compression test is successful if the depth dose profile calculated with DefVoxMC on the deformed original phantom and calculated with a regular voxel geometry on the compressed phantom correspond.

Another test for the deformable voxel geometry is the Fano test [8]. The Fano Theorem states that if the atomic properties per unit mass are uniform and a uniform source (per unit mass) is used, then the fluence is also uniform. In this work, the Fano test is used with the specific conditions outlined by Tessier [8]. A homogeneous water phantom is used, and density changes are introduced by applying a deformation vector field (DVF). This DVF stretches voxels in the center of the x-direction while uniformly compressing the other voxels, conserving the overall size and ensuring a uniform atomic interaction cross-section. A uniform, isotropic, and density-scaled source with an energy of 15 MeV is used. Finally, an infinite simulation space is ensured by creating a new particle with the same direction and energy as the departing one on the opposite side of the geometry. The theoretical Fano value is calculated according to the following equation:

$$D_{Fano} = n\frac{E_0}{m}$$

Where n is the number of particle histories simulated, m is the mass of the phantom, and E_0 is the energy of the particles [8]. For the phantom with a mass of 1000 kg and 2.0×10^8 simulated particle histories, the Fano value is 4.81×10^{-7} Gy. The Fano test is successful if the resulting dose distribution is uniform and matches the theoretical Fano value.

2.2 Clinically Motivated Case

DefVoxMC is used for a clinically motivated case from the 4D Lung data set [9]. A breast case is simulated by contouring the left breast as the planning target volume (PTV). An arc mixed-beam radiotherapy (arc-MBRT) [10–12] plan is generated with two 6 MV photon arcs and two non-isocentric 9 and 12 MeV electron arcs. The dose distribution is calculated on a regular voxel grid and using DefVoxMC under breathing motion from the 4DCT.

The CT at the breathing phase 0% is chosen as the planning CT. Deformable image registration (DIR) is applied between the planning CT and the remaining nine breathing phases. This work uses the B-Splines image registration of plastimatch [13] for DIR. Additionally, DIR is applied between the neighboring phases, those DVFs are used for interpolation. The schematic of the resulting DVFs with one interpolation point between phases is shown in Figure 2, but more interpolation points between the phases are possible for a higher time resolution.

The vectors of the resulting DVFs are applied to shift the corner points of the deformable voxel geometry of the planning CT to match the deformed situation at every time point. In the particle simulation, the monitor unit (MU)-fraction of a particle is sampled, as the beam parameters are given as a function of MU-fraction. To match the breathing motion to the beam parameters, the number of MUs delivered per time is estimated. This is done using the limiting linac axes, such as gantry speed, maximum dose rate, etc. Using this information the timestamp of each sampled particle is determined. The closest neighboring DVF is used to deform the geometry, and the whole particle history is simulated. This process is repeated for each sampled particle and is depicted schematically in Figure 2. The resulting dose distribution is on the planning CT (CT at phase 0%).

The difference between the dose distributions with a breathing motion and for the static situation is evaluated. The calculation times and RAM usage are assessed for one electron and one photon arc.

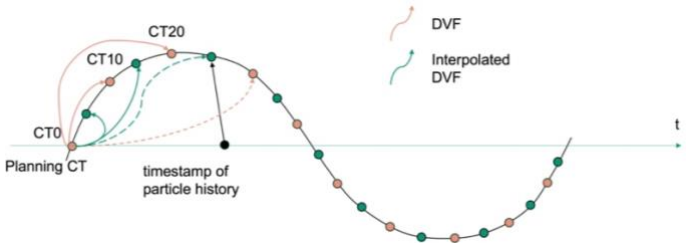

Figure 2: Schematic of DefVoxMC. Light red dots depict the original 4DCT, while green dots are interpolated CTs. The CT at phase 0% is chosen as the planning CT, and the DVFs point from this CT to the remaining CTs. The black dot represents the timestamp of a sampled particle, and the geometry is deformed with the nearest DVF. The y-axis represents the deformation due to the breathing motion. The arrows depict the DVFs.

3 Results

The results of the compression test are shown in Figure 3. The relative dose differences between the dose on the compressed phantom and the deformed original phantom are within 1% for electron and photon fields, indicating that DefVoxMC dose calculations in deformed phantoms are accurate for both particle types.

The results of the Fano test are shown in Figure 4. The dose is averaged over the y- and z-direction so that the difference in mean dose along the direction of the deformation can be evaluated. The relative dose difference to the theoretical Fano value is less than 1‰, indicating that the dose calculation with DefVoxMC is performed correctly.

The absolute dose difference between the dose distribution with a breathing motion and the static situation for the clinically motivated case is shown in Figure 5. The figure shows the electron (left) and photon (right) contributions of the arc-MBRT plan separately. The overall dose distribution is normalized to cover 50% of the PTV with the prescribed dose of 50 Gy. It is important to note that the

electron and photon contributions differ. The electrons contribute 28% to the target coverage, while the photons contribute 72%. There are areas with absolute dose difference of up to 1.4 Gy for the electrons and 6.9 Gy for the photons.

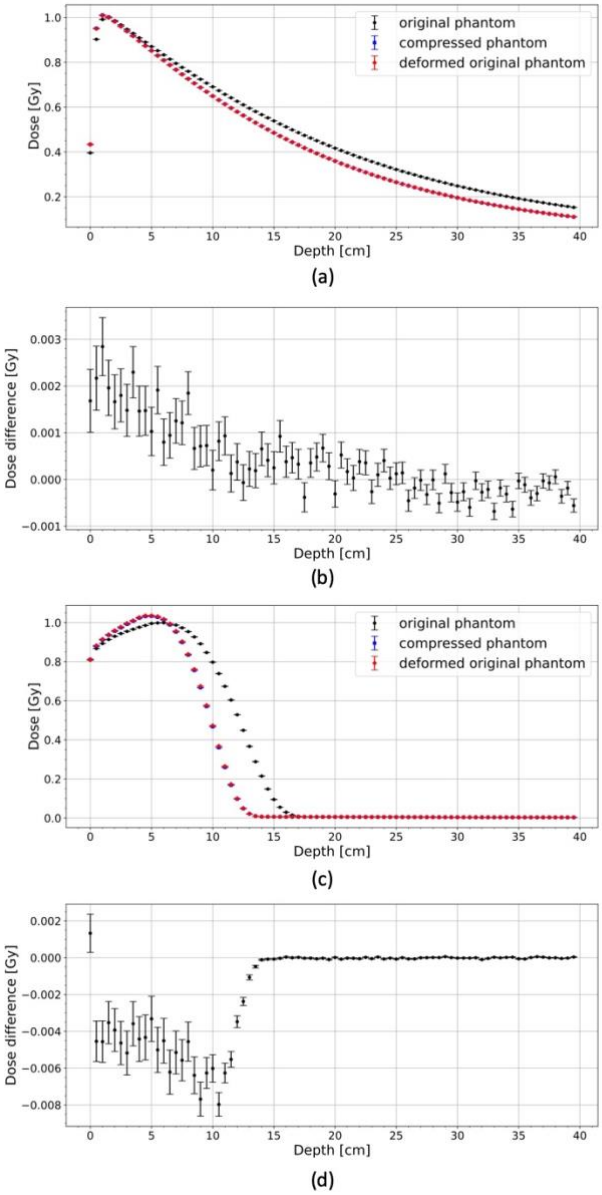

Figure 3: Results for dose calculations on phantoms with different densities. Only every fourth data point is depicted for readability. Error bars represent the standard deviation of the mean. (a) Depth dose profile of 6 MV photon field. (c) Depth dose profile of 6 MeV electron field. (b), (d) Difference between dose on compressed phantom and deformed original phantom.

The dose calculation is parallelized on the UBELIX HPC cluster, and 10^8 particle histories are simulated for the results above. The mean relative dose error for voxels with a relative dose bigger than 50% is 0.59%.

To compare calculation times only one CPU is used, and 10^5 particle histories are simulated. Table 1 shows the calculation times for one electron and one photon beam to compare the performance of DefVoxMC to a regular voxel geometry. The preparation includes the loading and interpolation of the DVFs. The particle simulation time for electron beams is 1.2 times longer for deformable compared to regular voxel geometry; for photon beams, it is 1.8 times longer. For the clinically motivated case, 6 GB of RAM was needed to store 50 DVFs for the 10 phases and 4 interpolation points between the phases.

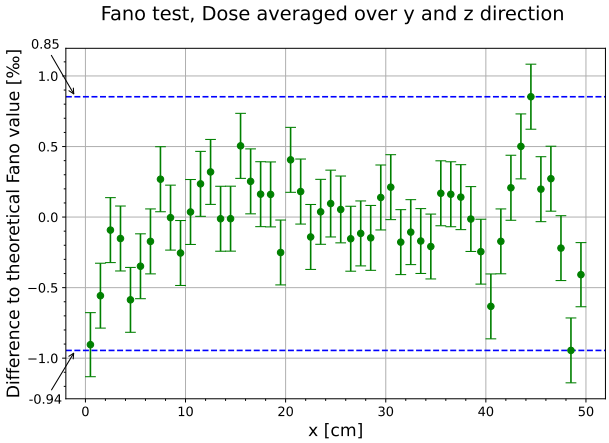

Figure 4: Dose difference along the x-direction averaged over y- and z-direction for the Fano test. The blue lines indicate the maximal dose difference to the theoretical Fano value. Error bars represent the standard deviation of the mean.

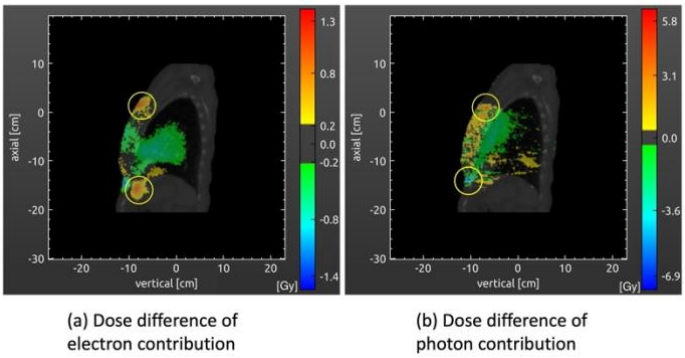

Figure 5: Absolute dose difference between the dose distribution with a breathing motion and the static situation in Gy in a sagittal slice. The mean relative dose error for voxels with a relative dose bigger than 50% is 0.76% for the photon contribution and 0.53% for the electron contribution. Yellow circles highlight areas with the largest absolute dose difference.

Table 1: Calculation times for photon and electron beams

	Preparation [min]	DefVoxMC [min]	Regular Voxel [min]
Electrons	3:10	2:45	2:15
Photons	3:10	1:55	1:05

4 Discussion

A deformable voxel geometry, DefVoxMC is successfully implemented and integrated within the SMCP framework. DefVoxMC is validated for non-rigid deformation with a compression test and a Fano test. The agreement of the compression test is within 1%, similar to the results of Heath et al. [3] In this work, the deformable voxel geometry approach is applied to electron beams for the first time. We further demonstrate the application of DefVoxMC to a

dynamically deforming situation for a clinically motivated treatment plan combining photon and electron arcs.
The calculation time compared to MC with a regular voxel geometry is increased due to the more complicated geometry methods of DefVoxMC. The geometry methods are called less often for electrons than for photons because electrons have a limited range. Therefore, the time increase between regular voxel geometry and DefVoxMC is smaller for electron than for photon beams.

The underlying assumption of the deformable voxel geometry is that each voxel corresponds to the same mass element in the original and the deformed situation. Other approaches like dose warping [14,15] and energy remapping [16] calculate the dose distribution on the deformed situation and apply the DVF to the dose or energy, mapping it back to the planning CT. However, the DVF holds the information of how the anatomy deforms and not the dose distribution. Unlike dose warping and energy remapping, for DefVoxMC, the DVF directly deforms the anatomy.
As a limitation of the study, the underlying assumption of each voxel corresponding to the same mass element in the original and deformed situation may not be fulfilled in certain situations. DefVoxMC could be used for adaptive radiotherapy to accumulate the daily dose on the planning CT by performing DIR on the daily CT. However, if the patient loses weight and some mass elements disappear, the assumption is not fulfilled anymore. Also, for the breathing motion, the mass of the inhaled air might influence the results. Another limitation is the DIR itself. DefVoxMC strongly relies on the quality of the DVF, but it is known that different DIR algorithms produce different DVFs [17], ultimately resulting in differences in the calculated dose distributions. To have accurate results on clinical cases, the quality of the DVF must be further investigated.

5 Conclusion

The SMCP framework is successfully extended with a deformable voxel geometry for dose calculations on deforming anatomy. DefVoxMC is validated with a compression test and a Fano test for photon and electron beams.
DefVoxMC can be used for clinical cases to consider dynamically deforming anatomies.

Acknowledgments

This work was supported by Varian, a Siemens Healthineers Company. Dose calculations and optimizations were performed on UBELIX (wwww.id.unibe.ch/hpc), the high-performance cluster at the University of Bern.

[1]Département de physique, de génie physique et d'optique, Université Laval, Québec, Canada
[2]Service de radio-oncologie et Centre de recherche CHU de Québec-Université Laval, Québec, Canada

Abstract The continuous growth of Computed Tomography (CT) examinations underscores the pressing need for enhanced personalized dose estimation in medical imaging. Existing methodologies, reliant on either the CT Dose Index (CTDI) or anthropomorphic models, provide estimations with limited consideration of the patient's anatomy. While patient specific Monte Carlo simulations are recognized as the gold standard, they remain prohibitively time-consuming and remain unfit for massive, population-scale calculations. This study aims to extend the GPU Monte Carlo Dose (GPUMCD) software for clinical CT acquisitions and showcasing fast dose-to-organ extraction facilitated by automated segmentation tools. Doses simulated within anthropomorphic phantoms closely approximated measured values (within 7%) for various scenarios. Study of an open-access CT dataset of 58 patients showed a mean organ dose variation of up to 50% from the cohort average with identical scanning parameters. The personalized dose pipeline was executed on a single A100 40GB GPU for a runtime of 5 to 7 minutes. Notably, the segmentation task took an average of 140 seconds and the GPUMCD simulation, 71 seconds. The runtime was further reduced to an average of 4 minutes when employing 2 GPUs in parallel, use of more GPUs provided limited improvement to the pipeline as the CPU bound pre- and post-pocessing steps became the predominant computation cost. This works demonstrates the ability to generate a DICOM compliant, three-dimensional dose distributions, segmentations, and dose reports for CT acquisitions within minutes. This pipeline lays the groundwork for swift, personalized CT dosimetry and facilitates large-scale dose-to-organ studies.

1 Introduction

X-ray Computed Tomography (CT) is a diagnostic imaging method with relatively high radiation exposure to the patient. The clinical usage of CT machines has seen a rapid increase in use, causing a significant increase in medical radiation exposure per capita. Current means of dose estimations are performed through indices such as the Dose Length Product (DLP). Such indices were designed to be a standardized measure of the radiation output of a CT system and not a measure of individual patient dose. Studies have outlined that estimations of patient dose and cancer risks through such generic representations can carry an uncertainty of ±40% and may grow to a factor of ±5 when used to determine any one individual's effective dose or cancer risk [1, 2].
MC simulations are notoriously slow to reach an adequate level of accuracy due to the significant amount of required calculations (histories). Such tools have previously been validated for tasks such as CT imaging simulations. However, due to the long computation time, MC simulations have not been used in routine operations despite various improvements to MC calculations. Since the turn of the century, new adaptations of MC software have been developed for the Graphics Processing Unit (GPU) offering significant improvement in computation time. The GPU Monte Carlo Dose (GPUMCD) [3, 4] software platform, for example, was utilized for External Beam Radiation Therapy [3, 4], Low Dose Rate (LDR) and High Dose rate (HDR) brachytherapy [5–7], Internal Radiation Therapy (IRT) [8], and proton therapy [9].

At the core of any dose-to-organ examination is the need to have accurate and precise organ/region segmentation. This contouring task is typically done by experts, and remains a very time-consuming and highly repetitive task. Organ identification in CT modality is done through anatomical knowledge and recognition of image contrast values. Contrary to other types of images, the gray values on CT images carry a physical meaning. Due to the very similar atomic composition of many organs, the Hounsfield Units (HU) values often fall within the same range, that is, between 0 and 100 HU [10]. In scenarios where such organs are nearby, or where their boundaries are unclear, it becomes increasingly difficult to have a clean and consistent contour.

Despite this ever-increasing need for quality contouring, a proper standard of validation for organ delimitation has yet to be developed [11]. A previous study on inter-observer variation in segmentation of brain ROI showed inter-observer scoring of as low as 0.4 Dice score (DSC) for the chiasm and nerves, but above 0.8 DSC for the brainstem and eyes [12]. This broad variation in segmentation brings in turn significant variations in measurements or metrics which derive from the volume definition. Metrics of organ dose would be affected, as these are typically reported as a measure of the volume of the ROI, as in the case of the Dose Volume Histogram (DVH).

This study aims to present a new software pipeline, exploiting the power of automatic segmentation tools to provide consistent and accurate organ segmentations, and a GPU-enabled MC simulation through GPUMCD for patient-specific dose deposition originating from CT imaging. This pipeline allows patient-specific dose-to-organ measurements to be performed in a completely automated fashion, utilizing only the parameters present within the provided DICOM study.

2 Methods

A new CT extension was developed for GPUMCD, incorporating parameters such as direction, pitch, and current of the X-ray source, originating directly from the DICOM CT-examination files. Material and density assignment of the simulated patient volume were performed using standard calibration procedure for CT volumes.
Experimental validation of the new GPUMCD extension involved standard weighted CT Dose index ($CTDI_w$) and in-air ($CTDI_{100,air}$) measurements under known conditions, comparing results to simulation outcomes. Measurements were conducted with varied pitch factors and volume sizes. A series of complete CT acquisitions were additionally taken to perform dose calibration. Anthropomorphic head volume measurements were also performed using the Stereotactic End-to-End Verification Phantom (STEEV), (CIRS, Norfolk, USA) to assess dose deposition in more intricate geometries.
To assess GPUMCD's performance, 58 chest CT studies from the open dataset *Lung CT Segmentation Challenge 2017* (LCTSC) were simulated using three different NVIDIA GPUs: RTX 2070 super, RTX 3090, A100-SXM4-40GB. The recorded metrics included the average time required for 10^6 histories and a requirement of achieving a maximum uncertainty of 2% within the volume. Each study was run with 10^{10} primary histories, and a subsequent average runtime for 10^6 primary histories was determined. Additionally, the simulations were tested on an NVIDIA DGX platform equipped with multiple A100 (40GB) GPUs, leveraging GPUMCD's parallel GPU computation capabilities.
GPUMCD was containerized in a Docker [13] image, requiring as input a single DICOM CT series. Dose depositions were simulated with GPUMCD for each CT series in the LCTSC dataset [14] until the maximum uncertainty reached 2% (excluding in-air dose). An additional layer of data pre- and post-processing was added to the Docker images. The pre-processing steps extract simulation parameters from the DICOM study headers such as the kVp, tube current and modulation, collimation, pitch, and imaged volume size and resolution. The imaged volume is also converted into an egsphant compliant file format for ingestion by GPUMCD. The resulting dose and uncertainty volumes from the simulation were stored in associated DICOM RTDOSE files and a DICOM SR was produced with simulation parameters, GPUMCD version, and console logs as part of the post-processing steps.
Within the DICOM tags of the LCTSC study, the information for the tube current, tube potential, and spiral pitch factor were absent. In order to perform an initial analysis on a small cohort, the simulations for this dataset were all set to have a tube potential of 120 kVp and a constant tube current of 100 mAs with a pitch factor of 1. Hard-coding these values for these 58 patients made a *true* measure of deposited dose impossible, but enabled a cursory examination of dose deposition independent of the typical major dose drivers from scanning parameters and dependent on mainly patient anatomy and positioning.
The segmentation tools, TotalSegmentator V2 [15, 16] and Lungmask [17] were similarly containerized in individual Docker images. Each image was in turn used to segment LCTSC dataset. The resulting segmentations were stored in DICOM SEG or RTStruct format, and a DICOM Structured Report (SR) was generated for each segmentation task with detailed information on the provided parameters, segmentation tool and version, and application console logs.
For each CT study the associated segmentation and dose grids were overlaid in order to extract dose-to-organ metrics. The resulting metrics were stored in a DICOM SR file.

3 Results

3.1 Phantoms

The simulated and measured doses for a full abdomen protocol of a 32 cm PMMA CTDI volume are displayed in Table 1 along with the two measurement positions within the STEEV phantom. Simulated values varied by a maximum of 6.6% from measurement values. This falls within the experimental measurement uncertainties of 7.4%, following scenario 2 of IAEA-TRS 457 section 8.3.2 [18]. Similar comparisons were observed in the STEEV phantom with 80 kVp, 100 kVp, and 140 kVp tube potentials with a maximum of 7.2%, 6.4%, and 6.8% difference respectively.

Phantom	Measured (mGy)	Simulated (mGy)	Δ_{dose} (%)
PMMA 32cm center	5.22	5.26	0.6
PMMA 32cm mean periphery	14.75	15.58	5.5
STEEV isocenter	20.56	21.84	6.2
STEEV anterior	20.43	21.79	6.6

Table 1: Simulated and measured average dose values for a constant 100 mA tube current over a full volume scan for 120 kVp tube potential. A spiral pitch factor of 1 was used for the PMMA volumes, and 0.6 for STEEV.

3.2 Patients

Mean organ dose values are shown in Figure 1, illustrating results obtained using the LungMask and TotalSegmentator segmentation tools, alongside the ground truths from the LCTSC dataset. Only organs segmented by at least two of the methods are presented in the figures. Notably, a consistent mean organ dose is observed for either lung, with the maximum difference not exceeding 0.5 mGy.
Clear differences were observed when comparing the segmentations of the heart and spinal cord provided by the ground

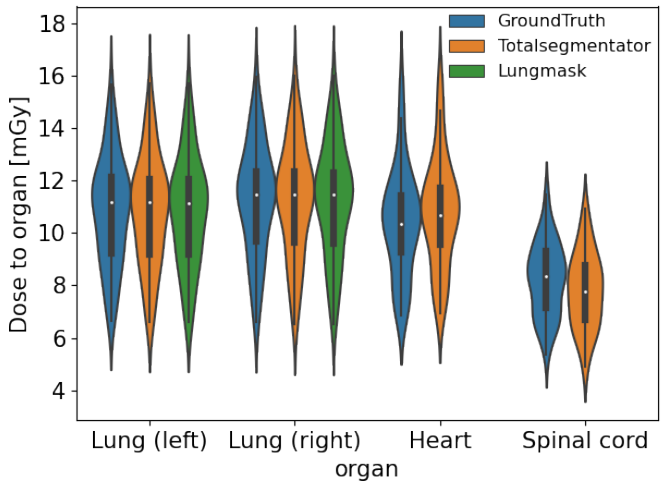

Figure 1: Mean dose to organ using GPUMCD and various segmentations.

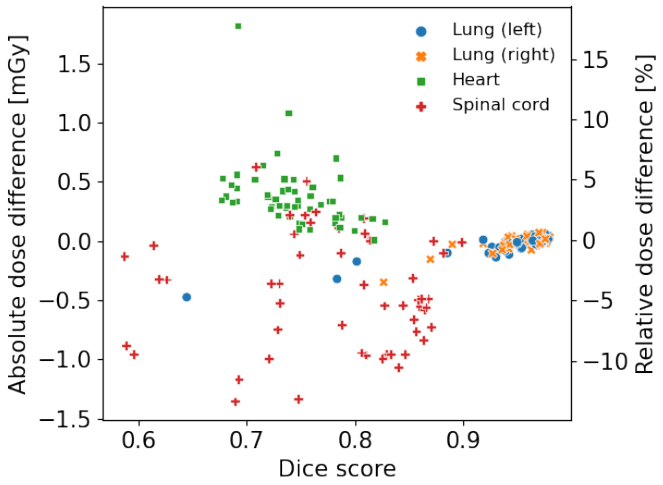

Figure 2: Mean organ dose differences yielded by Totalsegment versus LCTSC ground truth segmentations.

truth and TotalSegmentator. The spinal cord segmentations extended throughout the whole CT volume for TotalSegmentator, but were not present within the first and last few slices within the ground truth. The heart segmentation for the ground truth was a very simplified shape as compared to that provided through TotalSegmentator. These significant variations in segmentation volumes produced a maximum difference in mean dose for the heart and spinal cord of 14% and -17% respectively, with an average deviation of 3.5% and -5.5% mGy respectively.

The execution time for the pipeline's data pre-processing took on average 65 seconds; the main cause of this variation being the total amount of slices within the series. Utilizing a single A100 40GB GPU, the segmentation pipeline took an average of 140 seconds for the TotalSegmentator tool and 16 seconds for LungMask. The time to perform the simulation through GPUMCD for a maximum 2% uncertainty was on average 36 seconds. Reading parameter files and writing results for GPUMCD took an average of 34s. The extraction of organ dose values from the resulting DICOM files was performed in 8 seconds. The average runtime of the entire pipeline while operating in series ranged from 5 to 7 minutes. Utilizing 2 GPUs in parallel, the pipeline completed in an average of 4 minutes. Further GPU-parallelizing of the task will reduce the computation time of both the simulation and segmentation tasks to under a minute.

Operating the pipeline on RTX 3090 and RTX 2070S GPUs was on average 35% and 330% slower respectively, with a total computation time ranging from 7 to 10 minutes and 16 to 23 minutes respectively.

4 Discussion

In this study, an extension of the existing Monte Carlo tool, GPUMCD, was developed to accommodate modern CT machines. This extension was validated through a comprehensive comparison between simulated outcomes and measured results across diverse scenarios. Simulations were conducted for various homogeneous volume configurations, and an anthropomorphic volume was employed in the analyses.

The distribution of dose to various organs for the LCTSC patient cohort is presented in Figure 1. The figure demonstrates significant inter-patient dose variations. Organ volume and patient sex were not identified as primary sources of variation. As the pitch, tube current, and tube potential were kept constant across all patients of the LCTSC dataset, variations were predominantly attributed to factors such as patient positioning (e.g., lowered or raised arm(s)) and patient anatomy. Organ doses exhibited variations of up to $\pm 50\%$ from the cohort average. Comparisons with anthropomorphic organ dose calculations typically align with the cohort average, emphasizing the utility of such models in representing an average patient. However, these models fail to account for the unique characteristics not only of each patient but also their position during the CT examination.

The impact of the segmentation tool on the obtained mean organ dose is demonstrated in Figure 1 and Figure 2. The mean organ dose values for both lungs presented minimal dependence on the segmentation tool. However, the amount of CT slices segmented, and contour simplicity varied significantly between TotalSegmentator and the ground truth for the heart and spinal cord. This significant segmentation variation, presenting Dice scores between 0.6 and 0.9, showed greater dose variations, typically under 0.5 mGy (5%) but reaching 1.7 mGy (17%) in extreme cases.

A significant constraint in establishing a tool to consistently and accurately calculate patient dose in CT exposures has been computation time. The presented pipeline in this project addresses this challenge, making it feasible to perform hundreds of organ-dose calculations daily with reasonable hardware requirements. Each component of this pipeline is encapsulated in a self-contained Docker container, facilitating

straightforward and independent execution if needed.
This pipeline is presented with a runtime of under 7 minutes on an A100 40GB GPU with the ability to further reduce the simulation time of GPUMCD can be achieved by leveraging multiple GPUs with minimal associated overhead. With a total of 2 GPUs the runtime is reduced to an average of 4 minutes, however the use of more GPUs provides little reduced runtime. Within both the segmentation and simulation, along with the pre- and post-processing steps, are CPU bound processes which are not sped-up by additional GPUs. These CPU processes present a 1 to 2 minutes of computation time, leading to a bottleneck. While optimization and parallelization of these subtasks have the potential to enhance performance, such endeavors fall outside the scope of the present project.

5 Conclusion

The results presented in this study showcase a fast pipeline capable of leveraging diverse segmentation software and a new GPUMCD extension for CT simulation, enabling the calculation of personalized organ doses in CT examinations in under 7 minutes on a commodity GPU. The mean organ dose exhibits considerable variability between patients with identical scanning parameters, varying between 5 mGy and 18 mGy for the lungs and heart, and between 3 mGy and 12 mGy for the spinal cord.
Inter-segmentation dose variation for lungs was consistently within 0.3% with dice scores above 0.9. Segmentations for the heart and spinal cord had Dice scores varying between 0.6 and 0.9, with an organ dose variation of up to 17%.
The capability of this pipeline to rapidly generate quantitative 3D dose distributions for individual patients holds great potential for personalized protocol optimization and facilitates large-scale epidemiological studies.

Accuracy comparison between GATE and TOPAS for 6MV Varian CLINAC IX

Zakaria Ait Elcadi[1] and Othmane Bouhali[1]

[1]Electrical and Computer Engineering, Texas A&M University at Qatar, Doha, 23874, Qatar.

Abstract Monte Carlo simulations in radiation therapy often face CPU timing challenges, prompting the development of various Geant4-based platforms for optimization. Our study compares GATE and TOPAS, both Geant4-rooted, aiming to guide users toward platforms offering optimal CPU tools and high precision.
The assessment involves CPU timing and electron beam configuration comparisons. Firstly, exploring platform-specific physics, phase space, and variance reduction techniques; secondly, scrutinizing electron beam configurations using stringent criteria.
Results show GATE's 7% efficiency edge over TOPAS in CPU timing, attributed to distinct techniques. However, electron beam assessments reveal discrepancies in mean energy and spot size. TOPAS excels in agreement with measurement percentage dose points due to its advanced physics configuration.
This analysis emphasizes GATE's computational efficiency and TOPAS's electron source modeling precision. It stresses the importance of platform-specific capabilities when selecting radiation therapy simulation tools.

1 Introduction

Clinical linear accelerators (LINACS) allow the production of electrons or photons with energy of several MeV, commonly used for the treatment of cancer. These LINACS are based on the principle of acceleration of electrons by high frequency electromagnetic waves. The goal of this therapeutic weapon is to deliver the highest possible dose of radiation to the tumor volume while limiting the irradiation of surrounding healthy tissues to reduce the risk of complications. MC methods are based on a microscopic modeling of particle transport resulting in a 1D, 2D and 3D simulation. The trajectories of the particles are simulated individually from a series of random numbers and cross sections responsible for reproducing the physical phenomenon. The solution is derived from the statistical mean of the quantities obtained from the simulation of a large number of primary particles. Despite this precision, they are difficult to apply in clinical routine because of excessive computation times. Several Monte Carlo simulation software [1–5] have been developed for Over time, several platforms have emerged, leveraging Geant4-based tools, each striving to optimize CPU performance. Yet, within this cohort, disparities in options and their consequential impact on CPU timing endure as a persistent issue. In this context, our study assumes a critical role, aiming to meticulously compare and contrast two prominent platforms, GATE and TOPAS, both deeply rooted in the Geant4 framework. By elucidating the nuances and performance benchmarks of GATE and TOPAS, our study endeavors to offer a guiding compass, ensuring practitioners can navigate the complexities of Monte Carlo simulations in radiation therapy with a judicious amalgamation of computational efficiency and unparalleled accuracy. [6–10].

2 Materials and Methods

GATE (Geant4 Application for Tomographic Emission) is an open-source Monte Carlo simulation based on Geant4. The GATE/Geant4 v9.1 using Geant4 v10.7, brings faster simulation times, better tracking algorithms, and enhanced visualization. TOPAS (TOol for PArticle Simulation) is a Monte Carlo platform for proton and carbon ion therapy. TOPAS v3.9 based on Geant4 v10.7 offers new features like simulating spot scanning proton therapy for more precise tumor targeting. The Varianc Clinac IX were modeled (figure 1) based on data provided by the manufacturer [11]. Our simulations were conducted on a $30 \times 30 \times 30\ cm^3$ water tank divided into small voxels of $5 \times\ 5 \times\ 5\ mm^3$ for the standard field size of $10 \times\ 10\ cm^2$. Because the profile measurements were all taken along an axis (the axis of movement of the jaws closer to the beam, which we call the Y axis), we only use one voxel in the orthogonal direction, X. The number of voxels along the Y axis will cover the central region and the penumbra.

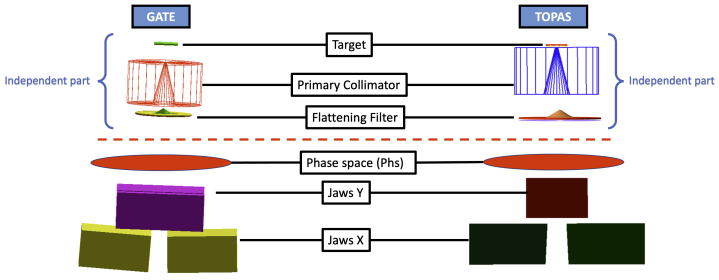

Figure 1: GATE and TOPAS modeling of Varian CLINAC IX head components for 6 MV photon beam

We used the high performance computing facility at Texas AM University in Qatar to reduce simulation computing time [12]. It is a Linux-based system outfitted with cutting-edge blade servers and a total of 4,128 traditional Intel Haswell CPU cores. All compute nodes are equipped with two 12-core processors and 128GB of RAM. It is linked to a 1PB storage system. The simulations were carried out initially with one node, and then we increased the number of nodes

from two to 94 to investigate the effect of nodes number on calculation time. TOPAS, in contrast to GATE, fully supports Geant4's multithreading simulation capability. We used the thread values from 2 to 94 in parallel to study the effect of varying the threads value on CPU timing.

2.1 Phase space

A phase space (PhS) encapsulates all potential states of a system as points in a space, defined by particles' attributes like energy, type, position, and direction. Collected by a surface in a specific geometry, this data is stored digitally for simulations [13]. Using a PhS streamlines initial simulation by needing only secondary collimation specifics for a fixed photon beam. It saves time by doing electron transport calculations just once.
PhSs are widely used in dosimetric applications. Modeling a photon beam with a PhS involves creating the PhS by collecting particles passing through a plane at the flattening filter exit and saving that data for reuse. While efficient, PhS files can become large and inflexible once made.
They come in formats like ROOT [14] or PHPS [15] and are created using software such as GATE and TOPAS. When optimizing multiple parameters, starting with less interdependent ones helps avoid biases. Adjustments in the optimization process may enhance the accuracy of final estimates.

2.2 Physics cuts

There are two kinds of physics cuts that can have a significant impact on CPU time. The first are production thresholds, which aim to avoid the generation of unnecessary low-energy secondary particles by ionization and bremsstrahlung processes. The minimum remaining kinetic energy for a track, that is, the energy below which particles are no longer transported, is the second type of physical cut that can help optimize the processus. The cutting energy prevents particle traces and thus reduces the time per history. The cut-off energy can be defined in two ways: either once for all the world or by a specfic modeled geometry. The user should define the production thresholds in GATE and TOPAS. This threshold should be defined as a distance or limit distance for individual materials, which is internally converted into energy. A region's production thresholds are established. Each volume is treated as a geometric region in GATE. TOPAS, unlike GATE, allows users to define the lower and upper edge production thresholds in terms of energy.

2.3 Variance reduction technics

Significant CPU time simulating an accelerator head involves tracking initial electrons to produce bremsstrahlung gammas. Bremsstrahlung splitting reduces time spent on electrons, favoring gamma tracking for better phantom reach. A secondary threshold is needed for particulate matter generation above the production threshold. Calculation precision affects time; "StepFunction" based on voxel size limits step size [16].
Choosing step size in Monte Carlo tracking is tough; TOPAS decides based on local factors, physics, and user input. Experimenting with different max sizes determines optimal precision. GATE Special Slices set limits on particle tracking. "KillActor" in GATE stops tracking particles outside a volume, saving computation. TOPAS filters particles upon creation for efficiency but caution is advised, as it's not a variance-reduction method.

3 Results

The need for long computation times in Monte Carlo (MC) simulations necessitates the use of various tools to reduce computation time while ensuring the accuracy of the final results. As described in section 2 , we utilized GATE and TOPAS to study different optimization techniques, prioritizing those that are less dependent on others. Unless otherwise specified, all results were obtained using 12×10^9 initial electrons with 6.0 MeV energy and a zero-width beam, 10×10 cm^2 field size and a division number of 100 for Bremsstrahlung splitting. The simulations used the Standard EM model opt3 for GATE, while opt4 was chosen for TOPAS with default parameters.
To initiate the optimization process, we analyzed the execution time at different locations of the accelerator head to gain insights into possible optimization factors. Initially, the entire accelerator head was simulated in a single step, enabling the simulation of particles interacting with various components until they reach the phantom located 100 cm away from the target. The entire Linac geometry was simulated with an initial electron energy of 6 MeV, a production threshold of 0.1 mm, and a reference field size of 10×10 cm^2. Subsequently, a phase file was added under each component of the Linac to calculate the computation time consumed by each component. The obtained results depicted in table 1 were as expected, indicating that most of the time was spent tracking electrons, especially in the target.

3.1 Phase space

The process of optimizing computation time began by utilizing the maximum number of nodes available to the user. To speed up simulations, a parallelization script was introduced to divide the simulation into 200 parallel tasks, each job containing 6×10^7 particles, and associated with the maximum number of nodes. This resulted in a 25% for TOPAS and 27% for GATE optimization when compared to the use of a single node.
Next, the PhS was used to divide the geometry into two parts: a dependent part and an independent part (figure 1). The PhS in this work was modeled as a cylinder with a diameter of 10 cm and a thickness of 1 nm in the z-direction,

Particle/Geometry region	Time/Time total (%)
e-/Target	81
e-/Primary collimator	1.1
e-/Flattening filter	1.2
e-/Jaws	1.1
e-/Outside	0.3
e-/Total	84.7
γ/Target	6.7
γ/Primary collimator	1.2
γ/Flattening filter	1.2
γ/Jaws	0.9
γ/Outside	5.1
γ/Total	15.1
e+/Total	0.2

Table 1: Fraction of time spent in each Varian CLINAC IX head components by particle type

located 7 cm above the secondary collimator or Y-jaws. The PhS format differs between GATE and TOPAS: in GATE, there is the phase space actor, which can be in PHPS, or ROOT format to avoid large format files; in TOPAS, the ROOT format cannot be used as a source for the second accelerator head module. Each PhS associated with a 6.10^7 particle job is three times larger than the one in root format. By considering only the dependent part and using the PhS as the beam source, the simulations were simplified. The calculation time was reduced by 66% for TOPAS and 68% for GATE when compared to the simulation of the entire accelerator head.

3.2 Physics cuts in the phantom

The use of a 0.1 mm cut-off in the phantom and throughout the entire geometry allows for the assumption that the deposited energy threshold is confined to the corresponding dose grid voxel. To verify this assumption, a PhS file was generated with a $10 \times 10\ cm^2$ field, which stopped at an XY plane located 1 cm before the phantom. Using various production threshold values, particles were eliminated, and the integral of the dose outside the creation voxel was calculated and compared to the CPU time gain. Table 2 summarizes the results, indicating that a production threshold value of 0.1 mm in the water phantom would not significantly affect the dose. The negligible impact on the dose is likely due to the fact that the energy threshold is confined to the corresponding dose grid voxel, as assumed, and because the phantom's cut-off is consistent with the world's cut-off .

3.3 Variance reduction techniques

Multiple simulations were conducted using variance reduction techniques. A division factor of 100 was utilized, and an energy slice of 1 mm, which corresponds to 1/5 of the

Cut in phantom (mm)	CPU time gain (%)
0.01	-24
0.05	-5
0.1	0
0.2	2
0.5	4
1	8

Table 2: CPU time gain when implementing a specific production threshold in the water phantom, utilizing the default GATE & TOPAS value of 0.1mm.

voxel dimension, was assigned. The step function was set to 0.1 mm. Furthermore, the software programs GATE and TOPAS have parameters called "setMaxStepSizeInRegion" and "MaxStepSize" for electrons, respectively, which allow for limiting the maximum step for a particle in a given region. To identify the optimal value for this parameter, various values ranging from 10 to 50 μm, with a pitch of 10 μm, were investigated. The chosen value was selected based on the recommended cut-off energy value and a reasonable calculation time, as presented in the table 3 [17].

Max Step (μm)	CPU Time gain (%)
10	10
20	-5
30	-15
40	-34
50	-71

Table 3: CPU time gain for different values of "setMaxStepSizeInRegion" in GATE and "MaxStepSize" in TOPAS.

The selection of the thread number is a variance reduction technique offered by TOPAS. To analyze the impact of this technique on execution time, several simulations were conducted using 2 to 64 threads. The results indicated that using more than 32 threads in a single simulation did not result in any significant improvement in the total CPU timing. One of the actors that GATE offer to contributes to variance reduction is the "KILL" actor, which is attached to a cylindrical geometry surrounding all of the other geometry and two boxes, one above the target and one below the water phantom. Table 4 summarizes the computational time savings for both TOPAS and GATE after implementing all processes (the first process is simulating the entire geometry), including PhS, cuts, and variance reduction techniques.

4 Discussion

The study explores efficient strategies in Monte Carlo simulations, emphasizing the need for optimization. Using GATE and TOPAS, it focuses on independence and reveals intriguing insights from simulations. Initial analysis showed electron tracking as a major time-consuming task, emphasizing

Process	CPU time gain (%) TOPAS	GATE
Jobs splitting	25.2	26.9
PhS (as a source)	65.82	67.82
Cuts	70	73.24
Variance reduction techniques	88.99	94.47

Table 4: CPU gain time for TOPAS and GATE after appliying all CPU optimization process

optimization importance. Fragmenting tasks led to faster CPU times. Parallelization scripts boosted optimization by 25-27%, and intelligent use of phase space reduced calculation time by 66-68%. Fine-tuning physics cuts and variance reduction techniques, like adjusting step sizes and using "KILL" in GATE, significantly cut computation time. GATE showed a 7% CPU optimization edge over TOPAS due to its adept use of Phase Space and Variance Reduction techniques.

5 Conclusion

This study underscores the vital need for efficient Monte Carlo simulations without compromising accuracy. By exploring GATE and TOPAS optimization tools, it unveiled crucial pathways for precision while minimizing computational expenses.

Identifying time-consuming aspects like electron tracking and utilizing fragmentation, parallelization, and phase space segmentation significantly reduced computation times.

Fine-tuning physics settings in the phantom highlighted the balance between computation time and accuracy, aiding in optimal parameter selection.

Notably, GATE's advantage over TOPAS by 7% in CPU optimization, thanks to its Phase Space and variance reduction techniques, offers users a choice. They can prioritize their platform based on specific needs while ensuring both accuracy and efficiency in their work.

Can Low-Cost Magnetic Resonance Distortion Phantoms be 3D Printed?

Haley Clark[1,2]

[1]Department of Radiation Oncology, BC Cancer, Surrey, Canada
[2]Department of Physics and Astronomy, University of British Columbia, Vancouver, Canada

Abstract Expanding use of diagnostic MR fusion, MR-simulation, and MR-linacs in radiotherapy has increased awareness of the quality assurance challenges associated with spatial distortions. While precise and effective commercial phantoms exist, they are costly and can present challenges when monitoring multiple MR scanners. In this work, we evaluate whether extremely low-cost 3D printed phantoms exhibit the spatial accuracy needed to monitor spatial distortions. Using several printed variations, we find that clinically sufficient accuracy is possible for up to four orders of magnitude cheaper cost than a commercial phantom.

1 Introduction

Spatial distortions in magnetic resonance (MR) images used for radiotherapy planning can negatively impact tumour and organ-at-risk localization [1]. Recently, quality assurance guidelines have emerged recommending routine monitoring of spatial distortions for MR scanners [2, 3].

Commercial phantoms made of high-grade materials can be used to monitor distortions, but they are generally expensive and bulky. BC Cancer radiotherapy makes use of a network of numerous external MR scanners, so use of commercial phantoms for each individual site would be not ideal. 3D printed phantoms, on the other hand, are lightweight and rigid, so could be more easily transported. Low production costs mean distributing phantoms to numerous MR scanners would be more cost effective with 3D printed phantoms, and the low-complexity construction means phantoms could, in principle, be made on-site as needed. However, spatial characteristics of such phantoms must be both accurate and consistent enough so that clinically relevant distortions remain detectable (i.e., ≤1-2 mm) [2].

In this work we investigate whether lightweight, low-cost phantoms can be 3D printed with sufficient accuracy for routine MR distortion monitoring.

2 Materials and Methods

A computer program was developed to generate $\mathbb{R}^3$ manifold surface meshes of rectilinear lattice phantoms with arbitrary cell dimensions and edge thickness. Four phantoms (one ‘small’ with 2x3x4 cells; two ‘medium’ with 4x4x8 cells; and one ‘large’ with 4x4x16 cells) were 3D printed using 1.75 mm diameter polylactic acid (PLA) filament (MakerBot MP05778). (See fig. 1.) Cells were isotropic with 15 mm extents. Edges were 3 mm in diameter.

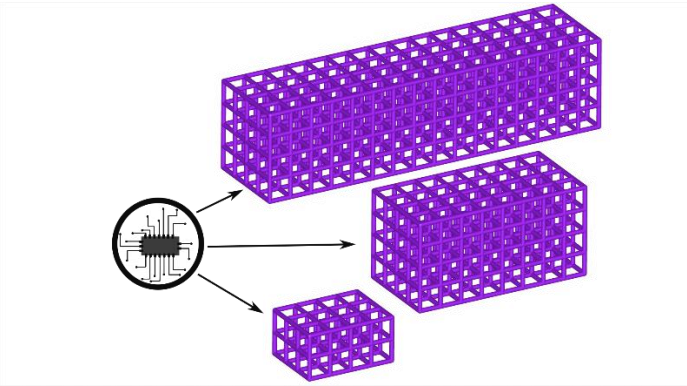

Figure 1: Small, medium, and large rectilinear lattice phantom models [4]. The regular structure can be used to monitor MR image distortions.

Two 3D printers were evaluated: a MakerBot Replicator Z18 and a Creality Ender 3. Print times spanned 3 - 12 hours, varying with phantom size. Medium and large phantoms analyzed in this study were printed with vertical supports and base-layer rafts to improve adhesion and print accuracy; the small phantom was printed with neither. Edge element thicknesses, cell inner and outer widths, and total phantom extents were each measured in 12 places with a caliper accurate to 0.02 mm. (See fig. 2.)

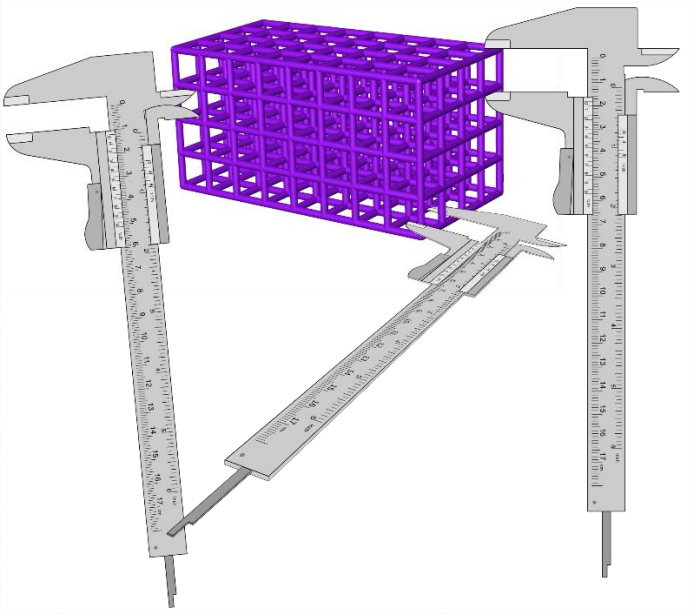

Figure 2: Schematic of caliper [5] measurements performed on all four phantoms. Lattice cell widths, edge diameters, and phantom extents were sampled in 12 places. Distortion (see fig. 4) was assessed with a square.

3 Results

All phantom variants printed without issues or failures. Printing supports were sufficiently thin (≤ 0.1 mm) that they could either be safely ignored or reliably eliminated during analysis of CT or MR images with a top-hat morphological transform [6]. Alternatively, even the largest phantom was able to be printed without the use of supports by bridging. (See fig. 3.)

Mean edge diameters for all phantoms were 3.04 mm (ideal: 3.0 mm, worst: 3.45 mm); mean cell inner widths were 11.91 (12.0 mm, 11.37 mm); mean cell outer widths were 17.88 mm (18.0 mm, 17.18 mm); mean total phantom extents near the extrema were 62.72 mm (63.0 mm, 62.69 mm); and mean total phantom extents near the middle were 62.04 mm (63.0 mm, 62.04 mm). Deflection and accuracy degraded worst along the printing axis. (See fig. 4.)

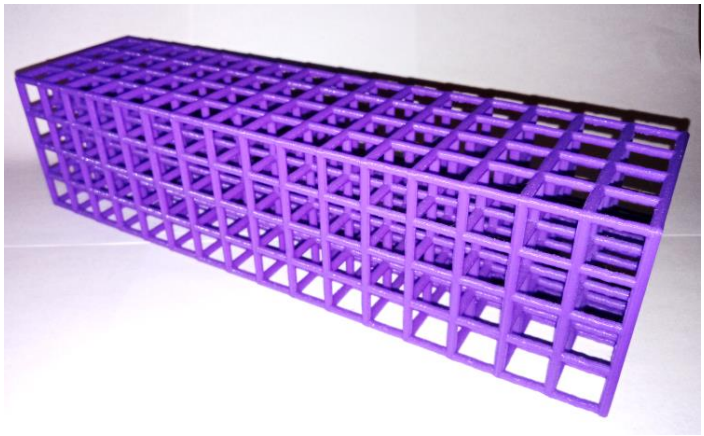

Figure 3: Example of a 3D printed 4x4x16 grid phantom, printed on a Creality Ender 3 printer.

The small phantom was the most accurate overall; the average discrepancy for all characteristics were ≤ 0.20 mm from ideal.

The medium (large) phantoms had average discrepancies ≤ 0.74 mm (≤ 0.76 mm) from ideal for all characteristics. The small phantom was printed without supports or a raft, yet still demonstrated excellent accuracy, minimal bridging artifacts, and good print adhesion.

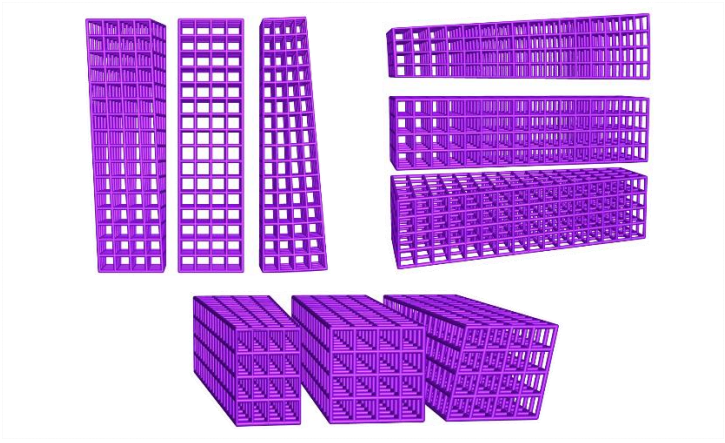

Figure 4: Exaggerated phantom warps that can result during printing, including skew, keystoning, and twists. Warps will confound distortion analysis. All can be ameliorated via use supports when printing, use of rafts if the printer bed exhibits adhesion issues, accurate bed leveling, and calibration of extrusion rates and printer bed temperatures.

4 Discussion

The 3D printed phantoms investigated in this work were all found to be sufficiently accurate for routine distortion monitoring purposes [3]. Commercial phantoms vary in cost but are typically $10,000 - $80,000 CAD. In contrast, the phantoms 3D printed for this study cost less than $300 CAD altogether, including the cost of the printer – a price difference of *two orders of magnitude*.

Material costs for printing a single phantom was approximately $5 CAD, or *four orders of magnitude cheaper* than a proprietary phantom. (See fig. 5.) While commercial phantoms are precision devices designed to accurately emulate clinical scenarios, use of low-cost 3D printed phantoms could conceivably assure greater quality through improving access to necessary equipment.

The limited spatial extent of the phantoms printed in this study presents a hindrance to whole-bore distortion checks. This can be overcome by chaining several phantoms together with interlocking connectors. Since the smallest phantom exhibited the most accurate dimensions, chaining small phantoms together might provide the best overall geometric accuracy. Additionally, this idea could be extended to create interlocking phantoms custom-fit for a specific MR scanner, patient immobilization device, coil, or support devices. However, further work is required to evaluate feasibility.

Note that while typical 3D printed materials will not directly produce signal in an MR scanner, the phantoms presented here can be imaged by submerging in liquid. Many MR-compatible 3D printed materials are not water soluble, so can withstand being submerged indefinitely, and air bubble

contamination can be countered with surfactants or ultrasonic vibration.

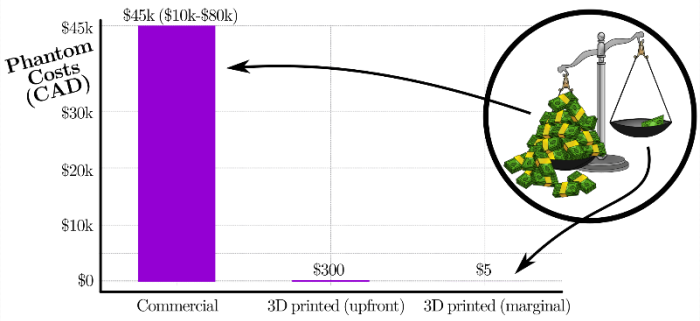

Figure 5: Quantitative cost comparison for commercial phantoms, 3D printed phantoms (+upfront costs), and 3D printed phantoms (marginal costs only). All are approximate. Inset: qualitative depiction of phantom costs; commercial on left, 3D printed (marginal costs only) on right.

5 Conclusion

3D printed MR distortion phantoms offer a compelling low-cost option for routine quality assurance when MR scanners will be used for radiotherapy. The phantoms presented in this work are straightforward to 3D print and can be done so quickly. Design files and surface meshes for these phantoms are open source.

Abstract One of the main bottlenecks in implementing online adaptive radiotherapy is the time required to contour and approve the daily contours. Quality assurance (QA) to identify those automatically generated contours that would benefit from manual revision would save a lot of time. This study aimed to develop a contour QA workflow for adaptive proton therapy for head and neck cancer. For the daily optimization, propagated organ-at-risk (OAR) contours are used. The proposed automatic contour QA (CAT-QA) uses geometrical and dosimetric tests to identify structures for manual re-contouring. It is split in two phases: an offline phase conducted before the treatment and an online phase conducted after acquiring the daily image. We applied this workflow to nine patients with multiple repeated CTs. Over all cases, maximum three structures were selected for manual revision. Using CAT-QA ensures to follow the initial prescription and avoids dose increase in OARs due to uncertainties of the propagated contours. In conclusion, although more validation is required, the defined workflow could enable safe use of auto contouring for adaptive radiotherapy whilst reducing time spent on manual contouring.

1 Introduction

Online adaptive radiotherapy aims to optimally conform the dose to the target by planning on daily anatomy ([1]). Using adaptation has shown to reduce the dose to healthy tissue for head and neck cancer (H&N) patients [2]. A daily adaptive workflow has to be fast to avoid anatomical changes between the acquisition of the daily image and the start of treatment. One of the main bottlenecks for clinical implementation of online adaptive is the time and human resources required to contour and approve the daily contours. These daily contours are essential to re-optimize the treatment plan on the daily anatomy, and, because of time limitations, need to be generated automatically by either automated segmentation and/or propagation.

Whereas it has been suggested that manual recontouring is often not necessary, especially for the organs-at-risk (OARs) [3], automatic algorithms can still yield unexpected results and therefore need quality assurance (QA). Including an automatic QA workflow that identifies those structures that need to be recontoured is an important step towards speeding up the daily recontouring task. Some work has been done in this direction [4–8], developing QA methods based on geometric differences. However, geometric differences do not necessarily result in clinically relevant dosimetric variations. Thus, correcting OAR-contours for which potential dose variations have little clinical impact only takes up time without improving treatment quality. In this study, we develop a contour QA workflow for adaptive proton therapy for head and neck cancer that identifies only the structures that benefit from manual revision, taking into account both geometric and dosimetric parameters.

2 Materials and Methods

Nine H&N patients, with on average four repeated CTs, have been used to investigate the proposed contour QA. Manual contours were delineated by radiation oncologists on all available CTs and are used as reference structures for the analysis outlined below. All cases were optimized on each of the available images with an IMPT plan with a SIB approach with two dose levels, mimicking a clinically plausible treatment plan. The automatic contour QA, CAT-QA, described below is tested retrospectively by simulating an online adapted workflow, using the available repeated CTs as potential daily images.

2.1 CAT-QA Workflow

The proposed contour-QA worklfow, CAT-QA, is split into two phases: an *offline* and an *online* phase (Fig. 1). During the offline phase, which is performed before the treatment, the sensitivity of the structures is assessed both geometrically and dosimetrically on the planning image. Non-sensitive structures identified during the offline phase are excluded from further evaluation in the online phase. In the online phase, the geometric and dosimetric sensitivity of only a subset of the initial structures is further evaluated on the daily anatomy. By reducing the number of structures to be evaluated online, the online QA workflow is more efficient and potentially suitable for an online adaptive workflow.

2.1.1 Offline phase

For the offline part, the planning CT, manual contours and the planned dose are used as input data (input data 1, fig 1). To assess the quality and sensitivity of the contours, we compare the manual contours to another structure set. Here, these alternative contours are generated with the deep-learning

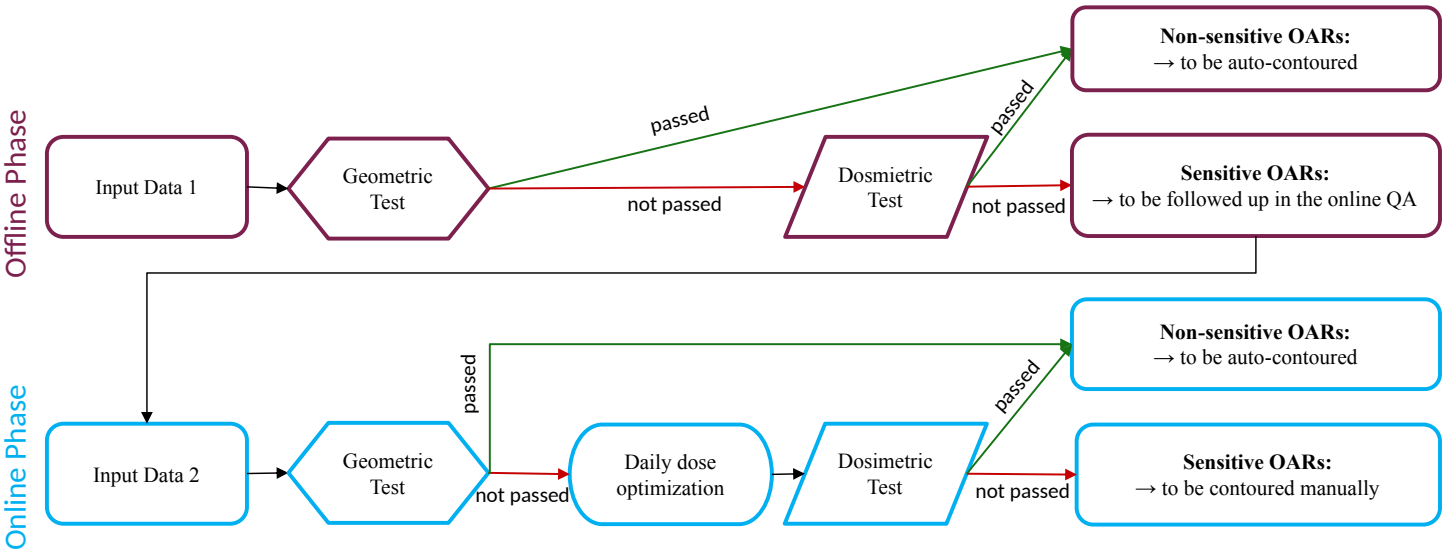

Figure 1: The offline phase is conducted after acquiring and generating the input data 1: the planning CT, the planned dose, the manual contours, and generating the auto-contours. The online phase is conducted after acquiring and generating the input data 2: the planning CT, manual contours of planning CT, planned dose on planning CT, the daily CT, the propagated contours. The daily dose is calculated by optimizing the dose using the propagated contours.

segmentation in Raystation (Raysearch AB, Stockholm, Sweden). First, the sensitivities of the structures are checked by carrying out 4 different geometric tests (described in detail in 2.1.3) by comparing the manual contours with the auto-contours. All OARs for which their auto-contour passed the geometric test are labeled as non-sensitive. These contours are not further considered in the offline or online workflow. The remaining OARs undergo a dosimetric sensitivity analysis. This is done by comparing the plan optimised with the auto-contours with the one optimised with the manual contours (described in detail in section 2.1.4). OARs that successfully pass the dosimetric test are deemed to have a low influence on the dose and are consequently excluded from further investigation in the online phase

2.1.2 Online Phase

For the online part, the planning CT, the manual contours of the planning CT, the planned dose and the daily CT are used as input data (input data 2, Fig. 1). Daily contours are propagated by registering the daily CT with the planning CT using plastimatch b-spline. Firstly, the sensitivity of the structures on the daily image is checked by performing four different geometric tests (see details in section 2.1.3). All OARs that pass the geometric test are marked as non-sensitive. This means that the automatically generated contours can be used to optimise the daily plan. The structures that did not pass the geometric tests are further evaluated to assess their dosimetric sensitivity (see 2.1.4). All OAR contours that passed this dosimetric test are also flagged as non-sensitive and all the others flagged as sensitive. For these finally flagged sensitive contours, manual revision is needed to proceed with the online adaptive workflow. For all the non-sensitive structures the b-spline contours are further used for the online adaptive workflow.

2.1.3 Geometric test

Both offline and online, four geometric tests are performed.
1. **Mean Hounsfield unit (HU):** Mean HU values are compared between the structure on the planning CT and the automatically generated one either on the planning CT for the offline part or on the daily CT for the online part. For the online part, the b-spline generated contours are used for the comparison of the HU values.Differences up to 100HU are accepted.
2. **HU range in contours:** The range of the HU values in the contours are tested. If the range changes are not more than $\pm$ 200 HU, the geometry of the structures is further evaluated by the third and fourth step.
3./4. **Dice similarity coefficient (DSC)/surface dice** are evaluated. For this, in the online workflow instead of the manual contours from the planning CT, a second set of auto-contours (this time generated using plastimatch demons) are used to take into account the anatomical deformations of the structures over the course of the treatment. If the DSC and the surface dice are higher than 0.8 (see AAPM report [9]), the contour has passed the geometric test.

2.1.4 Dosimetric test

The dosimetric test assesses the clinical endpoints outlined in the prescription for plans optimized with automatic contours in comparison to the reference plan optimized with manual contours. Offline, it compares the planned dose endpoint with the same endpoint in the dose reoptimized with the auto-contours, but with both evaluated on the manual contours. Online, these planned dose endpoints are compared to

the daily dose endpoints, evaluated in the b-spline contours themselves.Any dosimetric differences surpassing 20% (as suggested by [10]) or exceeding OAR tolerance categorize the structure as sensitive.

2.2 Evaluation of CAT-QA

The performance of CAT-QA is assessed by comparing the dosimetric differences between three plans: the plan optimised on the daily CT using manual contours (*daily reference plan*), the plan optimised using all automatic OAR contours (*fully automated plan*), and the plan optimised using a combination of the automatic OAR contours and the manual OAR contours selected as sensitive from the CAT-QA (*CAT-QA plan*). For each plan, the deviations of the prescription endpoints of the most relevant OARs and clinical target volumes (CTVs) from the reference plan are reported.

3 Results

For most OARs, the CAT-QA ensures that clinical endpoints defined in the prescription are within a 5% dose difference compared to the values achieved with the reference plan optimized on manual contours (Fig. 2). Seven out of 273 OAR structures have a dose difference larger than 5%. Our results show that by optimizing the plan with ALL automatic OAR structures, 21 structures would exceed the prescription value by more than 5% compared to the reference plan. Moreover increases in dose to healthy tissue of up to 26% of the prescribed dose would be detected in single fractions. As such, the workflow proposed here is an efficient tool to mitigate severe increases in the dose to the normal tissue. Nonetheless, the proposed workflow may not be sufficient to limit differences to less than 5% for all structures over all fractions. Indeed, for small organs, differences of up to 12% are detected for individual structures (e.g. right parotid in Fig. 2) with the defined tolerances used in the CAT-QA.
Similar considerations apply to target coverage, where, in

	total	offline sensitive	online sensitive
Case 1	37	16	1-3
Case 2	34	26	0-1
Case 3	42	32	0
Case 4	29	19	0
Case 5	15	2	0
Case 6	14	3	0-1
Case 7	15	0	0
Case 8	15	0	0
Case 9	15	2	0

Table 1: Number of structures selected by the workflow as sensitive in the offline and online phase. All OARs for which there is no automatic contour in the offline phase, are considered sensitive as well.

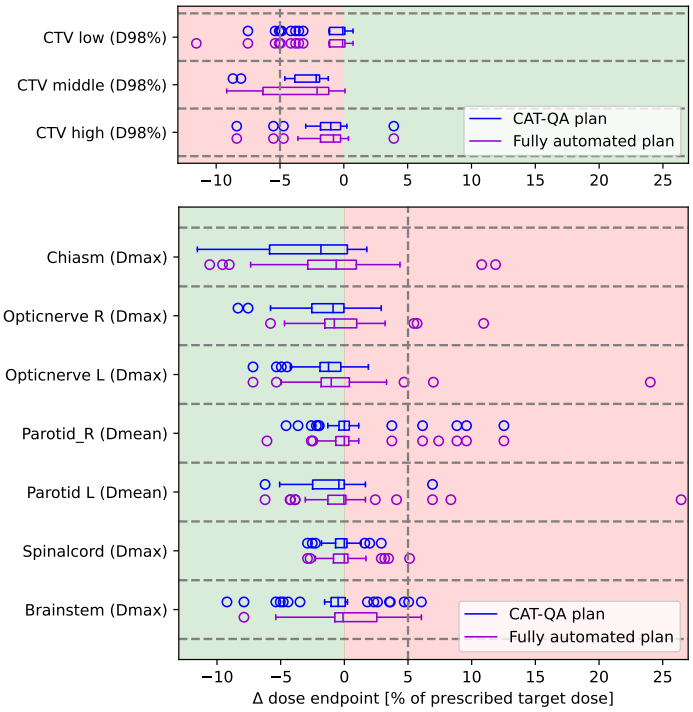

Figure 2: CAT-QA plan: Dose difference between the optimized dose using the manual contours and the optimized dose using the propagated contours combined with the manual contours for the structures selected by the workflow. Fully automated plan: Dose difference between the optimized dose using the manual contours and the optimized dose using the propagated contours.

most cases, the QA-Contour workflow is sufficient to limit the dose difference to below 5% for the daily plans However, higher differences are found for seven out of 89 target points evaluated (Fig. 2).
Nevertheless, the sensitivity analysis performed in the offline phase is an effective way to reduce the number of structures, to be further evaluated online, thus reducing the time needed for the execution of the QA tests in the online phase (Table 1). Indeed, on average, more than 60% (from 23% to 100%) of the initially defined structures are flagged as non-sensitive and are not analysed any further in the online phase.

4 Discussion

In this study, we present the framework of a automatic contour-QA workflow incorporating both geometric and dosimetric tests. The proposed workflow significantly reduces the number of structures requiring manual re-contouring, ensuring low doses to healthy tissue and high target coverage. Following the online phase, fewer than 3 structures, on average, are flagged as sensitive, necessitating manual contouring for the adaptive process. The workflow's effectiveness is highlighted by the substantial increase in doses (up to 26%) detected in OARs when not utilizing it.
While the CAT-QA workflow demonstrates positive results for most OARs, some outliers were not well detected, possibly due to uniform thresholds for geometric and dosimetric

deviations across all structures. Future improvements may involve OAR-specific tests to enhance results based on individual characteristics.
This study did not consider QA for propagation of target structures in the workflow, assuming they would be manually revised before daily optimization. A follow-up study will extend the workflow to include target contour QA.

5 Conclusion

The CAT-QA workflow, which considers both geometric and dosimetric parameters, shows promising utility for the safe integration of auto-contouring in online adaptive radiotherapy, while concurrently reducing the time dedicated to manual contouring. However, further refinement is required to minimize differences wih manually optimized plans below 2% before clinical implementation.

QATrack+: An open-source routine quality assurance platform

Randle Taylor[1] and James Kerns[1]

[1]Radformation, New York, NY, United States of America

Abstract QATrack+ is an open-source quality assurance platform able to record data, attach relevant files, and perform custom calculations. The software is extensible and allows users to write their own scripts for advanced data processing. Service events, reporting, and charting are all built-in and work seamlessly with data inputs. Advanced permissions also allow for specialized permissions and multi-role environments.

1 Introduction

Within the radiotherapy and clinical domains, handling routine quality assurance (QA) for all equipment within a clinic can be an arduous task. Such QA includes daily, weekly, monthly, quarterly, and annual requirements. [1, 2] Traditionally, this has been handled via spreadsheets or simple documents. The task of remembering the upcoming due dates, archiving binary data such as images or reference files alongside a spreadsheet, and performing any specialized tasks such as image analysis can have the clinician interfacing with multiple programs for even the most rote of tasks.

QATrack+ was developed at the the Ottawa Cancer Center as a customized solution for these problems, specifically for diagnostic [3] and regulatory requirements of QA [4]. It has since been open-sourced and used across numerous clinics worldwide.

2 Materials and Methods

The QATrack+ platform is written in the Python programming language [5] and built on the Django web framework library [6]. It is server-based and interfaced through a web browser; this means QATrack+ is deployable to the cloud or locally, depending on clinic needs.

The platform revolves around the concept of a test, which is an input or output item, within a "test list" which is a collection of tests. An example would be a daily high-dose-rate afterloader check-out with a 10-20 items to complete. The input-type tests can be entered by the user and the values can be compared with a reference value as well as a tolerance range. Each test can have independent references and tolerances. Output-type tests can also be created and linked to input tests, such as a dose calculation from ion chamber readings. These output tests can also have references and tolerances attached. Completing a test list creates an instance of that test list with all the values attached, hereafter called a session, including the performer, timestamp and other relevant details.

One of the most powerful features of the platform is being able to write Python scripts to calculate complicated output for a test. The special calculation test type can use inputs of other tests to perform basic math comparable to a spreadsheet, but also complicated calculations such as statistical variations, regression fitting or testing, retrieving data from another database, or performing image analysis such as with Pylinac [7]. The ability to write scripts within the context of other simple data records mean the user is not required to use multiple applications to perform all aspects of routine QA.

The advantages of a platform vs a spreadsheet or set of spreadsheets are several, including the ability to attach files to the session such as screenshots, log data, or reference materials. QA sessions can be reviewed by the appropriate authority later on, due to the multi-role paradigm. Data from the QA sessions can be charted over time to show intra-test trends and can also show inter-test correlations. Reports can be created within the browser and downloaded to a PDF, CSV, or Excel document so that a set of hard copies of all data is available, adding to redundancy. Email notifications can be configured to alert users about tests that had values out of tolerance, tests awaiting review, upcoming due dates, and more. A web application programming interface (API) also exists, allowing users to interact programmatically with the application, allowing for in-house applications to communicate with the server.

The platform is deployable to a number of different operating systems and compatible with a majority of the commonly-used databases including PostgreSQL [8], MySQL [9], and MSSQL. Being server-based, the platform only requires a browser to use, reducing the requirements of local resources.

3 Results

An example of entering data in QATrack+ is shown in Figure 1. Feedback from inputs is immediate and will render a red or amber warning if the value is outside the respective tolerance.

Reviewing data is a separate task in QATrack+ and allows the appropriate authority to approve, reject, and/or comment on the data session as well as attach further documentation or files, shown in 2

A chart of acquired data for several tests is shown in Figure 3. The timescale is configurable as well as the tests to display, allowing the user to compare the results of arbitrary

Figure 2: Reviewing a QA session in QATrack+. Reference and historical values give contextual meaning to the current values.

tests across multiple machines.

The role-based permissions allow for composite and multi-role users including therapists, physicists, service engineers, and administrators to all use the platform with granular permission sets controlled by the clinic. Integration with Active Directory is also supported and allows users to log into QATrack+ via their network login, eliminating the need for local credentials.

4 Discussion

The intent of the platform is to provide a singular, comprehensive way to perform, manage, and track routine QA data. QATrack+ has been in use in numerous clinics around the world and has seen adoption particularly in budget-constrained clinics. The ability to enter data, perform calculations on that data, as well as record related data such as screenshots or reference materials all in one application reduces necessary cognitive load on the user.

Given that the platform is open-source, clinics can choose to adopt and adapt the platform to their own needs as desired and host locally in the clinic or on the cloud and invites validation from the community as well as enables budget-constrained clinics to leverage a powerful, state-of-the-field platform.

5 Disclosures

The authors are employed by Radformation, which uses QATrack+ as the base for a commercial product.

Abstract
Computed Tomography is the principal contributor to ionizing radiation exposure of medical origin for the Canadian population. The Canadian Computed Tomography Survey by Health Canada provides guidance in the safe use of radiation-emitting devices, notably by proposing Diagnostic Reference Levels (DRLs) for typical CT exams (e.g. head, chest, abdomen). Dose associated with typical studies can be compared to DRLs, but this remains a periodic one-off procedure that, although part of a quality assurance program, might fail to capture the reality of clinical activities. There is a need to monitor more closely and continuously the use of ionizing radiation in CT, as increasingly demanded by regulatory authorities. This project aims to implement big data methods to provide CT dose visualization and analytic tools to managers and technical personnel in a large institution. For instance, dashboards were deployed to provide an overview of radiation usage in CT, leading to opportunities to study clinical practice trends and facilitating the identification of outliers to improve heath care. The technology used was found to be well adapted to the analysis of massive datasets without interfering with clinical activities.

1 Introduction

Computed Tomography is currently the principal contributor to ionizing radiation exposure of medical origin for the Canadian population [1], a situation that typically prevails in developed and developing countries. CT examination requests are also on the rise, with an increase of 30% from 2010-2020 and an additional expected increase of 18% within the next twenty years [2]. The Canadian Computed Tomography Survey by Health Canada provides guidance in the safe use of radiation-emitting devices, notably by proposing Diagnostic Reference Levels (DRLs) for typical CT exams (e.g. head, chest, abdomen). Further dosimetric recommendations are also given by the Safety Code 35 to promote better radiation exposition management within health institutions [3]. Proper quality assurance programs respect such guidelines, but might still fail to capture the reality of clinical activities.

In 2016, authorities in Quebec (Canada) surveyed current dosimetric practices within the province and demanded both to better conform to Health Canada guidelines, and to monitor more closely the use of ionizing radiation in CT. Currently, no clear guidelines or best practices are proposed to health institutions in Québec for radiation exposure monitoring. Therefore, this project aims at developing a dashboard to provide visualization and analytic tools to managers and technical personnel to monitor radiation usage in CT.

2 Methods

2.1 DICOM

All developments were aligned with the Digital Imaging and Communications in Medicine (DICOM) standard, to maximize semantic and technical interoperability across workflow components. The DICOM standard is well established for the communication and the storage of medical imaging, clinical data and associated metadata. DICOM's standardized format ensures a robust and predictable structure, unlike more generic formats such as XML and JSON. DICOM is a strong foundation to build on, especially with FAIR data management principles in mind.

The DICOM standard provides more than 3600 data fields to store data and contextual information. For instance, a DICOM object could contain information such as the age of the patient, along with weight, date of birth and sex. DICOM data files can be seen as collections of standardized data fields related to a shared subject, with unique identifiers for sound data management. These files can then reference each other to better represent the complex relations between them, as expected in a medical imaging context. For example, a DICOM data file containing the actual image could reference other files pertaining to the patient or study such as segmentations, dose maps or dose reports.

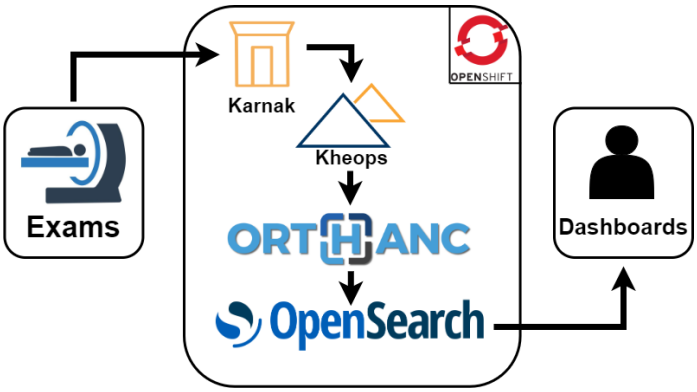

Figure 1: General flow within the PARADIM platform to expose data to OpenSearch.

2.2 Data flow

CT dose monitoring dashboards are fed by a data flow generated by routine clinical activities. Software components supporting this data flow are hosted at Université Laval within our custom-made PARADIM platform (*Plateforme d'annotation, de réutilisation et d'analyse d'images médicales* - Medical image annotation, reuse and analysis platform)[1]. PARADIM includes these components:

- Clinical data extraction and de-identification (`Karnak`)
- Data governance (auth/autz) (`Kheops`)
- Data storage (`Orthanc`)
- Data viz environment (`OpenSearch`)

`Karnak` - `Karnak` is an open-source DICOM gateway for data de-identification and DICOM attribute normalization. This software acts as a DICOM listener connected to the PACS (*Picture Archiving and Communication System*) and feeds de-identified data to Kheops through DICOMWeb. Data de-identification is supported field by field and includes: replacement by a dummy value, time-shift for dates or outright field removal. Various de-identification profiles can be managed within Karnak, including the DICOM basic privacy profile[4].
`Kheops` - `Kheops` is a DICOM-compliant image archive under MIT license offering data governance functionalities, including granular authentification/authorization (auth/autz) for data sharing for human an machine as well (through revokable API tokens). Images within `Kheops` are managed as data collections (called albums) accessible only with proper rights. Read and write permissions, as well as download and sharing rights are granted separately. A collection within Kheops was constituted for this particular project.
`Orthanc` - `Orthanc` is an open-source DICOM server used as the main DICOM database in PARADIM, with S3-compatible Ceph (RedHat) as an object storage backend. `Orthanc` provides a graphical web interface and RESTful API to request DICOM data. Moreover, `Orthanc` includes a Python (or lua) code interpreter to handle/transform DICOM data and ensure further data normalization through personalized scripts. For instance, one such script is used to collect DICOM date-time fields to guarantee conformance to DICOM standard's expected format. Another script extracts and normalizes dosimetric data from imaging exam data. Each data normalization script collects data stored within DICOM fields and reshapes it to ensure conformance to expected data format from the DICOM standard (commonly by data type conversion with the python standard library). Additionally, these scripts are automatically executed by `Orthanc` on every new DICOM study stored within its database, through a trigger mechanism.

`OpenSearch` - Following data ingestion, curated medical data stored within `Orthanc` are routed to `OpenSearch` in JSON format and in conformance with HTTP protocol (with the HTTP library for python called requests[2]). `OpenSearch`, a fork of Elasticsearch, is an open-source software under Apache 2.0 license offering data indexing, visualisation and exploration functionalities. Curated data elements are stored as documents (lists of data fields containing the relevant DICOM data), which are then clustered in indexes enabling `OpenSearch`'s powerful search engine. For the particular needs of this project, new indexes are generated daily to support expected continuous data ingestion. This index generation is supervised by a specific index pattern, ensuring structural cohesion between indexes.

2.3 Dashboards

Following data ingestion and indexation, dashboards are built within `OpenSearch` to offer flexible and user-friendly interfaces for data exploration, as shown for example in Figure 2. Dashboard offers metrics, graphs and monitoring tools tailored for specific needs. The dashboards can be accessed from any computer, assuming appropriate authentication. It is worth mentioning that dashboards do not report medical data, only aggregated metrics. Several data visualization options are available [3], as well as search and filter tools to drill down in data. Multiple dashboards can be hosted on a single `OpenSearch` instance, each with their distinct dataset. Dashboards are built according to Big Data visualization recommendations [5, 6]

2.4 Data Management

Data management best practices are integrated within PARADIM and throughout the workflow. Chief among them are the FAIR principles[4], as well as a general DataOps philosophy focusing on machine-actionability. These principles and guidelines offer guidance to data scientists and professionals on how data should be managed and integrated. For instance, in our data flows we enforce the preservation of all metadata and we rely on persistent unique identifiers, which is facilitated by the DICOM standard (which also handles the interoperability component of FAIR).

[4] https://www.go-fair.org/fair-principles/

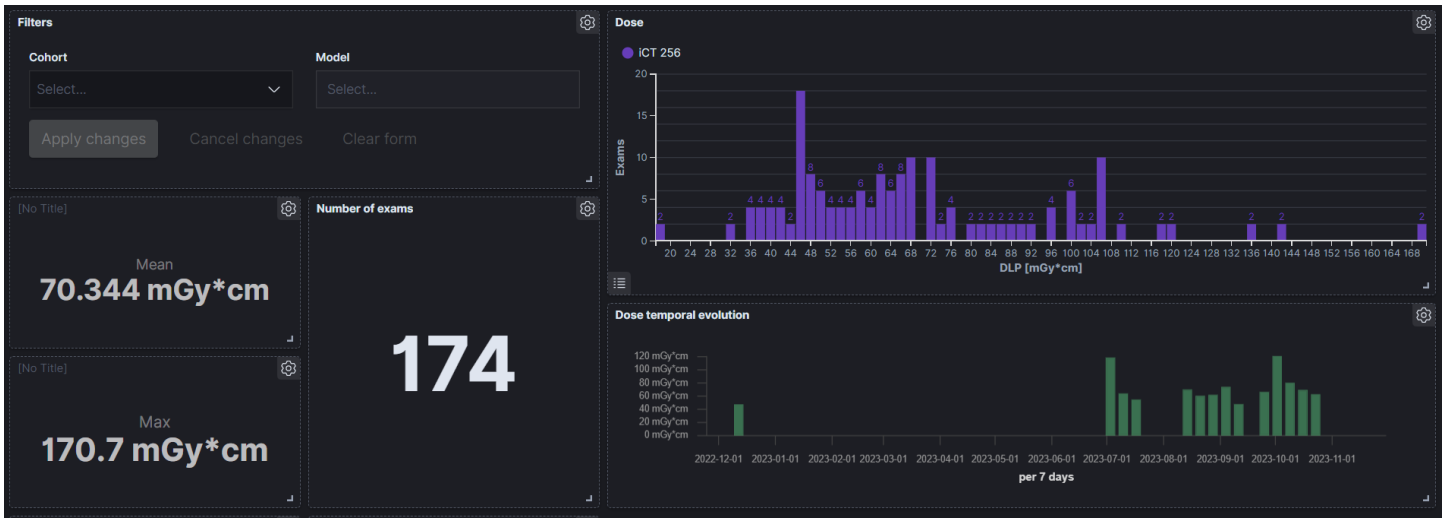

Figure 2: Dashboard example fed by the data pipeline.

3 Results

The robustness of the data pipeline was tested with the open access National Lung Screening Trial database[5]. The platform was able to ingest data at a rate of (5440 ± 145) image series per hour (from the `Karnak` gateway to visibility on dashboards), suggesting that real-time operations are possible for a large institution or even a regional/national setting.
The dashboard example presented in Figure 2 shows some available metrics, including mean and maximum dose, and stacked bar charts (for dose distribution and temporal evolution). Line graphs, pie charts, treemaps, gauge charts and tables can also be used. Additionally, dynamic filters can be integrated into the dashboard, such as the one at the upper left of the dashboard in Figure 2, which allows filtering on device model or clinical cohort. Multiple metrics, such as bar charts, can also be used to drill down to specific values with a single click.
Dashboards provide an overview of radiation usage in CT, leading to opportunities to study clinical practice trends and ease the identification of outliers to improve heath care.

4 Discussion

The proposed infrastructure is well suited to massive datasets and is designed with robustness in mind. PARADIM is deployed in a `kubernetes` environment, where applications are continuously monitored and can be restarted automatically upon failure [7].
The strict adherence to the DICOM standard enforces data normalization and preserves contextual information through rich metadata. Additionally, dosimetric data stored within DICOM radiation dose structured reports (RDSR), such as DLPs, was successfully extracted and ingested by dashboards. However, data kept within private tags is not normalized since their content is not controlled by the DICOM standard.
We have observed that access to rich dosimetric information often depends on the configuration of CT devices. By default, some do not send dosimetric data to the PACS or generate results that cannot be exploited easily (for example dosimetric reports added as images, requiring OCR to extract data, or dosimetry data in non-standard DICOM field). Furhtermore, manufacturers unfortunately offer distinct ways to store dosimetric data despite the availability of the Patient Radiation Dose Structured Report[8, 9]. This heterogeneity is a barrier to large scale dosimetric analyses.

5 Conclusion

A dashboard fed by secure data pipelines was developed to aggregate and visualize dosimetric data from clinical CT studies. The dashboard provides an overview of radiation usage in CT, give rise to opportunities to study clinical practice trends and ease the identification of outliers to improve heath care. Data ingestion is continuous and does not interfere with clinical workflow. Likewise, good data management practices are respected and integrated within the workflow. Moreover, the tool is compliant end-to-end to DICOM standard and uses only open-source, non-proprietary software. Next steps include the development of alerts for events (e.g. high dose, repeated exams) and the integration of data from other centers to generate a personalized report on cumulative dose from CT studies.
Additional work to promote sound data management within health institutions should be considered to maximize the tool's potential. Proper data management include data normalization, compliance to standards (such as DICOM) and richer metadata. Better compliance to the standard by vendors regarding dosimetry appears highly desirable.

Abstract A software system named AutoMRISimQA was developed to monitor the daily performance of a wide-bore 3T scanner (MRI) which was designed and dedicated to radiotherapy simulation. AutoMRISimQA can monitor the performance of the MRI simulator not only by using image quality indices such as signal-to-noise ratio (SNR), uniformity, ghosting, and contrast but also performing a quick check of geometric accuracy as well as the external lasers quantitatively. It was implemented into the daily clinical workflow in 2013 and has been used for more than 10 years. It was also seamlessly integrated with QATrack+, allowing continuous monitoring of the consistency of the MRI simulator's performance.

1 Introduction

MRI simulator (MRISim) is a magnetic resonant imaging (MRI) scanner designed and dedicated for radiotherapy planning, dose calculation and treatment response [1, 2]. The use of MRI in radiotherapy requires the scanner to be more stable and reproducible than the one used for diagnostic purposes. A recently published TG 284 report recommended a list of tests to be done daily, but how to perform these checks depends on the individual centre [3].
MRISim was commissioned and integrated into the routine workflow in 2013 in our centre [4, 5]. A fully automated daily quality control (QC) program was developed and has been running for more than 10 years. The purpose of this paper is to report how the system was designed, implemented and integrated into a radiation oncology workflow.

2 Materials and Methods

2.1 MRI Simulator and phantom

MRI simulator is a wide-bore 3T MRI scanner (Siemens 3T Skyra, Erlangen, Germany) equipped with an external simulation laser and a flat couch [5]. The phantom is the AQUARIUS phantom (MRI-0005, S/N 0010260016, LAP of America, Laser application, USA), which was originally designed for checking the alignment of simulation lasers [4]. The phantom is cylindrical, and inside the phantom, there are four long tubes filled with CuSO4 solution and the rest is filled with water. As shown in Figure 1, the phantom was set on the flat table aligned with external lasers and then scanned using a T1 weighted spin echo sequence (echo time(TE) =30ms and repetition time(TR)=3410ms) daily. The MRI images were transferred to a shared network location on a server. An in-house system, named AutoMRISimQA was developed to monitor the MRI simulator's daily performance using phantom images.

Figure 1: Siemens Skyra 3T MRI Simulator with a flat couch top. The AQUARIUS phantom was set up on the couch and aligned with external lasers.

2.2 Design of AutoMRISimQA system

The system was designed and divided into six modules. Figure 2 showes the overall structure of the system. The first module is used to detect if a new image series arrives. If the new images were found, the second module will be triggered to sort image series, according to the acquisition date and time. The image pixel data were also extracted. The second module uses these data to calculate image quality indices such as signal-to-noise ratio(SNR), which characterize the performance of the MRI scanner. The calculated QC parameters are passed to the third module, whose role is to make a logical judgement. The parameters are compared with their corresponding reference values and tolerance. If any of the QC parameters are out of tolerance, an alert e-mail will be automatically sent to the responsible physicists. A PDF report was also generated at the same time to assist physicists

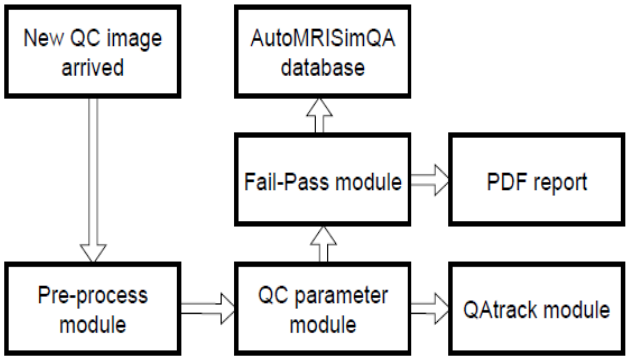

Figure 2: The modular structure of AutoMRISimQA

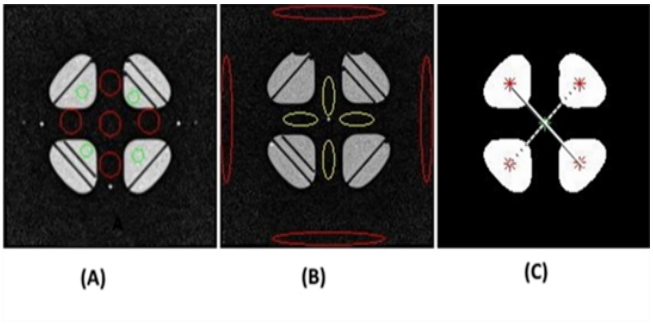

Figure 3: The centre slice of phantom images and ROIs used to calculate QC parameters.

in quickly diagnosing where the problem is. At our centre, all QC data for radiotherapy equipment were managed using QATrack+ [6], an open-source web-based system designed for radiotherapy quality control. The QATrack module is used to automatically update the database of QATrack+.

2.3 Implementation of the system

Matlab, Java and Python were used for system implementation. As QATrack+ was implemented in pure Python, the module for updating the QATrack+ database was written using Python. The access to the database was through the Python representational state transfer(REST)framework [7]. In this way, the risk of accidental damage to the database was minimized. Except for the report module, the rest of the system was implemented using Matlab. A rich of imaging process functions provided by Matlab's image processing toolbox is the major consideration of using Matlab as the main programming language. Matlab also can seamlessly integrate Java applications into the Matlab program. The report module was written in Java using the iText package [8]and integrated into Matlab.

The core component of the system is the one used for calculating the QC parameters from the phantom images. The image slice shown in Figure 3 (A) was used to calculate the uniformity and SNR using the four $1cm^2$ red circle regions. The percentage intensity uniformity (PIU) is defined as

$$PIU = 100 \times (1 - \frac{S_{max} - S_{min}}{S_{max} + S_{min}}) \quad (1)$$

Where S_{max} and S_{min} represent the maximum and minimum signal averaged over four red circles.

The SNR is calculated as the ratio of the mean signal averaged over four areas defined by the red circles to the standard deviation over the same ROI. Another parameter, termed output (MRI signal), is defined as the ratio of the standard deviation to the mean of the pixel values over the red circle ROI at the centre of the images.

The ghosting effect was calculated using the image slice and eight elliptical regions as indicated in Figure 3(B). The ghosting ratio (GR) was calculated as:

$$GR = \frac{|((S_{top} + S_{btm}) - (S_{top} + S_{btm}))|}{2S_{mean}} \quad (2)$$

Where S_{top} , S_{btm} , S_{left} and S_{right} are the signals averaged large eclipses at the top, bottom, right and left of the images, respectively. S_{mean} is the mean signal averaged over four small ellipsoids at the center of the image.

The contrast was calculated as the ratio of the mean signal value over areas defined by the four green circles in high contrast regions to the mean signal value determined over the four red circle regions. The image was segmented to isolate the four high signal regions and then the centroids of these regions were found. Two diagonal distances between these centers were calculated as shown in Figure 3(C). The forward and backward diagonal distance was recorded as d45 and d135 for reporting purposes. The laser coordinates Y is the slice position, where laser coordinates X and Z are the center of the central image slice, which were calculated using centroid coordinates of four high contrast regions.

3 Results

The system has been implemented into the MRI-based radiotherapy workflow since 2013. As a start of a daily routine, a radiographer or radiation therapist (RT) scans the laser phantom. Then the images are sent to a location sitting on a shared network drive. The system automatically processes the images and updates the QATrack+ database. The daily QC results can be viewed on any computer connected to the hospital's private network using the web-based interface of QATrack+ or the PDF report.

As an example, Figure 4 showed one QC result generated by autoMRISimQA results. The traffic lights were used to indicate the acceptability of the results along with the tolerance values.

The main setting for the system can also be configured via a text file as shown in Figure 5. The use of configuration files makes the system more flexible and maintainable.

The statistical analysis based on the data acquired over a certain period provided useful information regarding the MRI's performance and a tool for continuous monitoring of MRI scanner performance. As an example, Figure 6 shows the trend of SNR and MRI signals over a few months, which were generated by QATrack+.

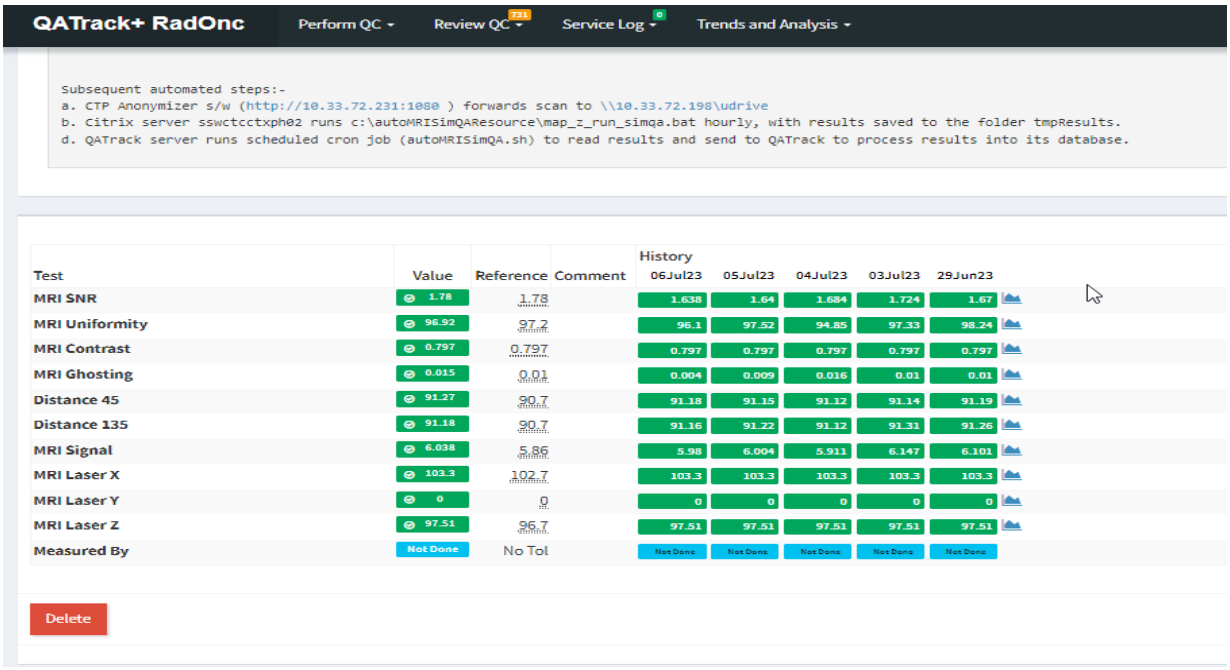

Figure 4: Updated daily QC results displayed through the QATrack+ web interface.

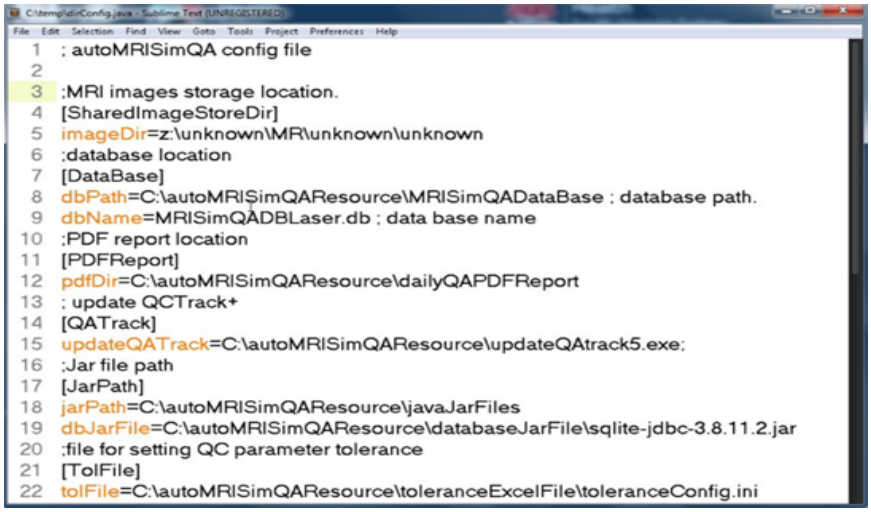

Figure 5: Configurability of the system using a simple text file.

4 Discussion

AutoMRISimQA achieved an automated constancy check of MRISim's performance by monitoring MRI imaging system in one go using multiple image quality indices, which are directly related to the use of MRI in radiotherapy planning and recommended by TG 284 [3], but also doing a quick check of geometric accuracy. In addition to the visual check of simulation laser alignment, the laser positions were also quantitatively monitored.

The work presented here demonstrates a feasible solution for developing an automated daily QC program for an MRI simulator, which can be used and implemented by other centres. The source code of the system is available on the request and will be on GitHub soon. Although the system implemented is based on the laser phantom, other commercial phantoms or custom-made phantoms can be used.

Several authors developed software tools for quality assurance of a diagnostic MRI scanner using ACR MRI phantom [9, 10]. An open-source image processing tool, IQWorks, was also used for MRI quality assurance purposes [11]. In comparison with these tools, autoMRISimQA has several unique features: (1) the system was fully automated once the phantom images were transferred to the network location from the MRI control console; (2) It was seamlessly integrated with an open-source QC data management system. The daily QA results and the trend of the system's performance can be viewed on any computer connected to the hospital network; (3) Automatic email notification allows physicists monitor the MRISim and take action only when it is required.

The clinical benefit of implementing the AutoMRISimQA system into the clinical workflow is efficiency, especially for a busy clinic with a large number of patients going through

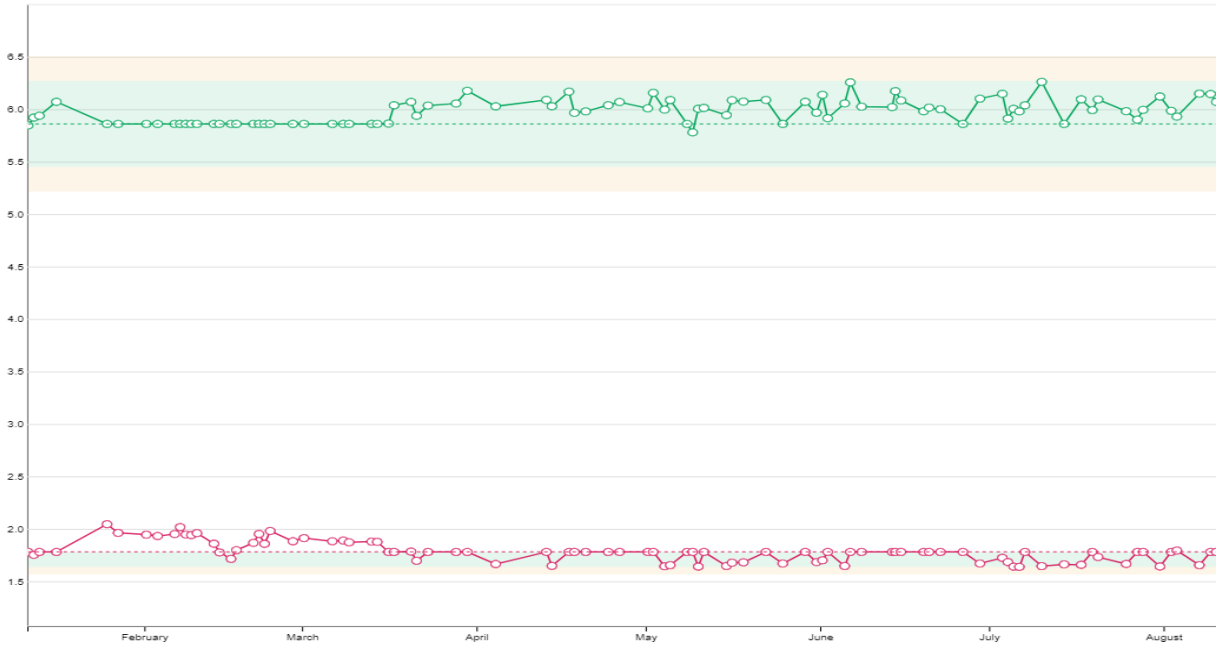

Figure 6: Continuous monitoring of MRI simulator using autoMRISimQA and QATrack+ web interface. SNR (green curve) and MRI signal (red curve) were generated by QATrack+.

the scanner. Before the use of this system, the RTs needed to do two QC tests daily: a customer QC using a uniform phantom and the check of the alignment of simulation lasers using the laser phantom. The average time spent on morning daily QC was half an hour. Now it was reduced to four minutes, the scanning time of laser phantom. Furthermore, the continuous monitoring of MRISim's performance ensures the short, medium and, especially, long-term follow-up of technical characteristics and their possible drift with time.

5 Conclusion

A software system was designed, and implemented for daily quality controls of an MRI simulator. As an open-source tool, the system provides a prototype solution for monitoring the performance of a dedicated MRI scanner used in a radiation oncology department.

Abstract

The Northern Plan Automation Services (NoPAUSE) project is a collection of in-house applications and scripts designed to improve efficiency and quality in radiotherapy treatment planning. The Treatment Planning Automation System (TPAS) is one of these services, and enables fully automatic VMAT plans to be produced within our Eclipse/ARIA environment. It supports a physician-initiated workflow that allows contouring, planning, and approval to occur in one encounter. This workflow is deployed at three centres within our institution for rapid-palliative VMAT. The purpose of this work is to investigate extending our system to curative protocols, beginning with prostate, rectum, and H&N. Retrospective clinical cases were used to tune the system. After tuning, a further five validation cases for each site were used to compare auto-plans to the manual clinical ones. For each site, TPAS produced clinically-acceptable plans that compared favorably to the matched retrospective control, and demonstrated comparable quality from a DVH perspective.

1 Introduction

Inverse treatment planning for IMRT or VMAT techniques is time-consuming, and significant contributor to the total delay between simulation and treatment. This is particularly the case when including delays associated with hand-offs between the physician who completes the contours and reviews the final plan, and the planning departments that are generally responsible for optimization. In busy clinics, many physicians opt to defer non patient-facing tasks like contouring and plan review until after hours, implying that at least a full business day may pass between those activities.

The Northern Planning Automation Services project is a collection of in-house applications and scripts designed to improve efficiency and quality in radiotherapy treatment planning. The core platform is the Treatment Planning Automation System (TPAS), which fully automates VMAT planning in Eclipse. There are many domains in which planning automation can be implemented[1]. In the present context the automation is inclusive of field-placement, planning structure creation, optimization, and dose constraint reporting. Physicians launch TPAS, submit a request, and receive an optimized plan for review and approval in a single encounter.

TPAS was originally deployed as an automation tool specific to rapid-palliative protocols, including two clinical trials. In these settings, it is considered sufficient for the plans to meet the constraints of those protocols for TPAS plans to be clinically acceptable. However, it is often possible to do much better than the hard constraint, so before expanding the system for curative treatments, it is desirable to ensure that the plans produced by the system are of comparable quality to those optimized manually. The purpose of this study was to assess the feasibility of extending TPAS using an RO-initiated workflow for curative protocols.

2 Materials and Methods

TPAS is implemented in C# for the Varian's Eclipse™ treatment planning system, using their ESAPI library. The system can be broadly divided into three components: The plan request submission interface, the distributor, and the planning servants. The specific approach to optimization for a given site or prescription is configured through a combination of user-editable (xml) protocol file and an associated Eclipse Clinical Protocol. TPAS also supports the use of Varian's RapidPlan™ product to determine appropriate optimization objectives, where such models exists. Protocol files can also specify logic to guide the automatic rescaling of priorities and re-optimization to address scenarios where clinical goals are not met.

Submission

The submission interface (Fig. 1) is a light-weight, single page form that begins the process. The user selects a protocol from a pull-down menu, which brings up the targets and organs-at-risk (OARs) relevant to the protocol. An aliasing system automatically maps detected patients contours to the protocol definitions when naming conventions (e.g. AAPM TG-263) are followed, but the interface allows this to be overridden if necessary. If the protocol allows variation in the prescription or fractionation, these adjustments can also be applied. Once this is complete, the request can be submitted and the interface closed. In uncomplicated cases, this typically takes a physician between 15-30s, after which they can close the form and continue other tasks.

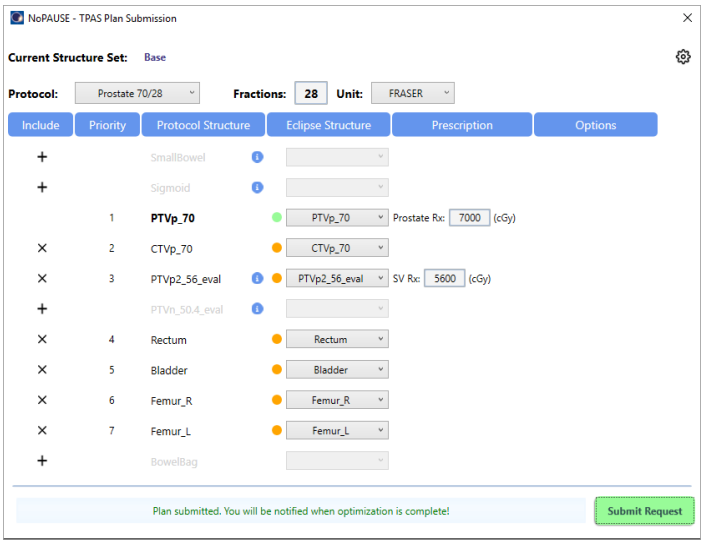

Figure 1: The submission interface, showing a request for a plan to be created according to the Prostate 70 Gy / 28# protocol. The only responsibility for the user-physician is to map the patient's contours to the protocol definitions, and adjust the prescription dose if necessary.

Distribution

The request is picked up by a central distributor, which sends an email to the user confirming the request, including the prescription and structure mapping. When the plan is completed by the planning servants, the distributor is also responsible for notifying the physician and staff subscribed to the protocol. The email includes a summary of the dosimetric clinical goals that were achieved or violated, as defined in the clinical protocol. The total planning time for a 2-arc TPAS plan is approximately 10-15 minutes from submission to completion.

Planning Servants

The planning servants are implemented as background ESAPI services. Each servant is capable of performing one plan per patient at a time. The distributor/servant model allows TPAS easily scales to larger departments with the installation of more planning servants, although this will eventually be limited by competition for optimization and dose calculation computation resources.

Plan Quality Validation

To assess plan quality against our clinical baseline, seventy-five plans across three sites (H&N, Prostate, Rectum) were retrospectively re-planned using TPAS. For the H&N site, our locally trained RapidPlan model was used. For each site, twenty plans were used to refine the configuration of the protocols, and the remaining five plans were used for validation. Plan quality was compared using the DVH quality metrics specific to each protocol.

3 Results

All plans in the validation-sets were considered clinically acceptable based on review of the 3D dosimetry and field/plan parameters by the principal author. There were minor variations in coverage between clinical and automatically planned cases. The average target coverage (V95%) for automated [manual] plans for each site was HN: 98.7% [99.1%], Prostate: 98.8% [98.9%], Rectum: 99.6% [99.1%]. High priority OAR doses were also comparable, although they trended lower for second-tier constraint doses where the TPAS protocol pushed harder than may have been deemed necessary in the clinical setting. For example, the average rectal D0.035% for prostate was 99.3% [99.5%], whereas the rectal V83% was 9% [13.4%]. In the H&N, minimizing salivary gland dose is usually a focus, and this was reflected by comparable results: Mean doses for combined parotids were 28.1 Gy [29.6 Gy]. Cord PRV D0.035cc doses were 41.5 Gy [47.1 Gy], and true cord D0.035cc was 35.7 Gy [42.0 Gy].

Figures 2-5 illustrate the relative dosimetric quality between TPAS and the retrospective clinical cases for the validation cases. Each column of the graph represents performance in one DVH metric, with the clinically acceptable constraint indicated by a horizontal bar. Upper constraints are indicated with a downward red arrow, and lower (target) constraints are indicated with an upward green arrow. Error bars on each column represent +/- one standard deviation.

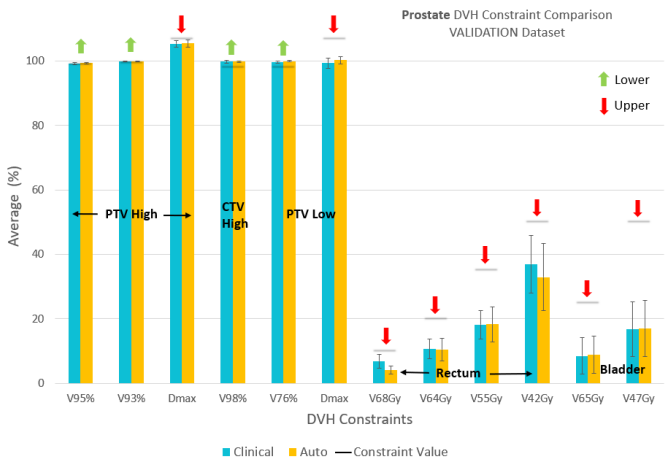

Figure 2 : Comparison of Prostate (70 Gy / 28 #) DVH quality metrics between automated and clinically optimized plans.

Figure 3 : Comparison of Rectum (50 Gy / 25 #) DVH quality metrics between automated and clinically optimized plans.

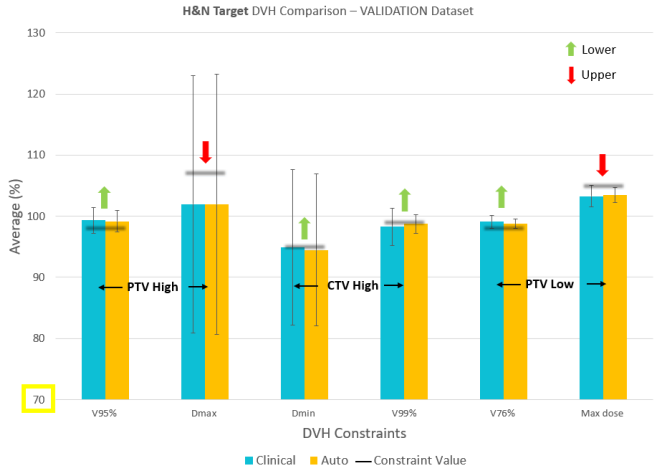

Figure 4 : Comparison of H&N (70 Gy / 35 #) DVH quality metrics for targets between automated and clinically optimized plans.

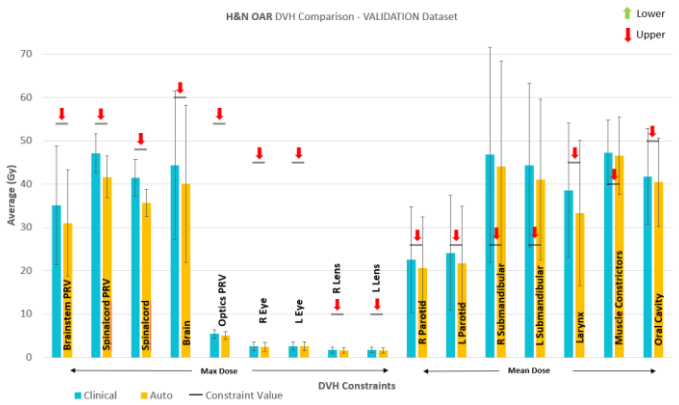

Figure 5 : Comparison of H&N (70 Gy / 35 #) DVH quality metrics for OARs between automated and clinically optimized plans.

4 Discussion

The quality of TPAS plans was broadly comparable to the clinical cases. For the prostate and rectum sites in particular, target coverage was very similar, with a slight trend toward higher (but clinically acceptable) maximum doses in the automated plans. This was attributed to greater sparing of adjacent OARs. TPAS protocols are highly configurable - in this study optimization objectives were used that initially prioritized OAR sparing, with rescaling of target priorities upward in subsequent iterations if coverage was not met. The patterns of heterogeneity in the targets were consistent with 'pushing' coverage later in the optimization process.

There was greater separation in average OAR sparing for the H&N protocols than for prostate and rectum. This is likely due to the way that TPAS segregates OARs into near-, mid- and distant (out-field-regions) and optimizes each region individually. Sparing in the mid- and distant- lower dose regions accounted for much of the average reduction. It is possible that manual planners did not focus on these regions once the overall OARs met clinical constraints.

This study was not powered to test for statistically significant differences between TPAS and manual planning. However, our results do suggest that such studies are worth pursuing with a larger sample size. The concept of clinical acceptability[2] is poorly defined and often institutionally specific and dose-volume metrics are incomplete characterization of plan quality. It is not clear whether the automated plans being produced using the protocols we developed would ultimately be preferrable to physicians, and DVH analysis can obscure features of the 3D distribution which may be important. It is likely that this will need to be further investigated in a prospective setting with physician preference as the endpoint.

5 Conclusion

This work suggests the TPAS system is a viable approach to RO-initiated automatic planning in a multi-site curative setting. Work is presently underway to assess the acceptability of TPAS plans for a variety of sites in a prospective setting.

Abstract This study aims to develop automated 3D conformal radiation therapy planning for the treatment of intact breast, considering individual patient factors and available resources.

In total, three automated treatment approaches were created. These comprise conventional tangents for whole breast treatment, and two options for additional regional lymph nodes treatment: wide tangents photon fields with supraclavicular nodes (SCLV) field, and a regular photon tangents field with a matched field to treat the internal mammary nodes, and a SCLV field. Each approach includes the choice of single or two isocenter setup (with couch rotation) to account for a full range of patient sizes.

All algorithms begin by generating automated contours for breast CTV, regional lymph nodes, and organs at risk using in-house nn-Unet deep learning models. Treatment fields are then automatically generated. Then gantry angles and field shapes are optimized, ensuring coverage of target contours while limiting dose to nearby organs. Algorithms were integrated into the Raystation treatment planning system, and then tested on 10 whole breast patients for clinical acceptability. Evaluation criteria included ensuring adequate coverage to targets and adherence to dose constraints for normal structures.

For the treatment of breast, the algorithms successfully replicated clinical plans, meeting dosage goals for all 10 cases. For breast and regional lymph nodes treatment, 5 out of the 10 plans met all preferred objectives. For the rest of the plans, axillary nodes coverage or lung or heart dose constraints were not met indicating that a different choice of treatment choice should be considered.

This study showcases the feasibility of a comprehensive automated treatment planning model for whole breast radiotherapy, accommodating diverse treatment paradigms.

1 Introduction

Radiation therapy is an integral part of breast cancer treatment, improving patients' outcomes and survival[1]. The incidence of breast cancer diagnoses is steadily increasing, with an anticipated 40% rise from the current rate by 2040. Despite this surge in demand, the radiation therapy workforce is projected to grow by only 25%, falling short of meeting the escalating requirements[2]. This imbalance is expected to be more pronounced in low- and middle-income countries, where the patient-to-oncologist ratio is already disproportionately high (1,000 patients for every 1 oncologist, compared to 150 patients for every 1 oncologist in developing countries)[3]. Treatment planning for radiotherapy is time-consuming and requires specific expertise. With the projected workforce shortage, planning will fall behind, and patients will have to wait longer to start their treatment. Even a four-week delay in adjuvant radiotherapy treatment for breast cancer has been associated with an increase in mortality rate[4]. Therefore, it is important to mitigate the consequences of the workforce shortage in treatment planning for breast radiotherapy. We propose the development of automated tools to facilitate the selection of the most suitable method for individual patient treatment, taking into account both clinical needs and available resources.

Various approaches exist for radiation therapy treatment for intact breast, the most common yet complex being 3D conformal radiation therapy (3DCRT). One comprehensive treatment with this approach consists of two wide opposing fields tangential to the breast, covering the internal mammary lymph nodes and an additional anterior field to cover the supraclavicular nodes. The extensive anatomical variation from patient to patient adds to the complexity of the individualized treatment and to the generalization of an automated approach.

One of the initial strides in automated planning was taken with a heuristic approach described by Purdie et al. [5]. This method necessitates the placement of BB markers at specific locations around the breast for functioning. Addressing this limitation, Sheng et al. introduced a more recent model utilizing a machine learning approach [6] . It is noteworthy, however, that their model is tailored to a standard breast tangent scenario and does not encompass considerations for lymph nodes. On the commercial front, Radformation's EZfluence provides a viable solution for automating breast treatment plans through fluence optimization. Nevertheless, it's important to acknowledge that, while effective, this solution may lean towards the higher end in terms of cost, which could pose a challenge for clinics with limited resources.

In this work, we propose an automated planning tool that provides a complete portfolio of treatment approaches, thus allowing the clinician to choose the approach based on the patient, their available resources and preferred clinical approach. This work is part of the Radiation Planning Assistant project, a web-based autocontouring and planning tool that is to be offered to clinics in low- and middle-income countries for minimal (likely zero) cost.

2 Materials and Methods

I-Algorithm Development:

All algorithms begin with automated contouring. The automated contours are generated using in house nn-Unet deep learning contouring models[7]. The generated target contours comprise of breast critical target volume (CTV),

supraclavicular lymph nodes CTV (SCLV), internal mammary nodes CTV (IMN) and axillary lymph nodes level I, II and III CTVs (AX1, AX2, AX3). The organs at risk (OARs) automated contours include heart, left ventricle, ipsilateral lung, trachea, esophagus, humerus head with acromioclavicular joint, cricoid cartilage, contralateral breast, and ipsilateral brachial plexus. All algorithms were implemented in the Raystation treatment planning system using scripting.

Three distinct automated treatment approaches were developed following clinical practice: Approach I; regular intact breast tangents, Approach II; wide tangents photon fields (breast + IMN) with SCLV field, Approach III: regular tangents with IMN electron matched field and SCLV field. For each approach, single and two isocenter solutions (with couch rotation) were developed to meet different clinical preferences, machine capabilities, and patient anatomy. An overview of the algorithm workflow is summarized in figure 1.

Isocenter Placement:

Single isocenter approach for breast and SCLV fields: The isocenter is placed on the caudal end of the SCLV auto-contour with a 7mm margin and centered between the breast structure's medial/lateral and anterior/posterior extent. If the distance between the isocenter and the inferior edge of the breast field is more than the jaw size limit of 20cm then the isocenter is moved inferiorly to meet this limit.

Two-isocenter approach for breast and SCLV fields: The isocenter of the SCLV field is placed as described above. The isocenter for the breast field is placed at the midpoint of the breast auto-contour. In this case, a couch rotation is applied to the tangents fields to achieve superior match with the SCLV field.

IMN field: The IMN isocenter is placed at the center of the IMN auto-contour then moved to 5cm away from the skin, in the beam's direction, for a treatment at an extended 105 cm SSD.

Aperture Generation:

For the SCLV field, the superior border is set to the inferior border of the cricoid cartilage. The inferior border is set on the isocenter. The medial border is closed on the SCLV contour with MLCs blocking the trachea. The lateral border is user defined with a default of 1.5cm from the AX1 contour. A humeral head and acromioclavicular joint block is created to protect the structure. An example of a SCLV aperture is shown in figure 2.

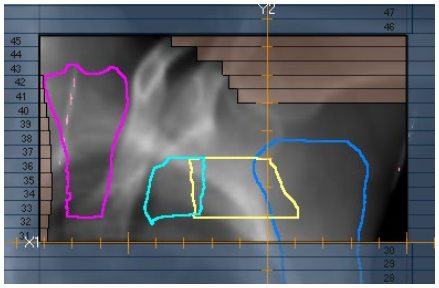

Figure 2. Beam's Eye View of a SCLV field aperture with a trachea and humeral head block. Automated contours are shown from left to right, SCLV, AX3, AX2, and AX.

For the breast field, the superior border is matched at the SCLV isocenter. The inferior border incudes a 2cm margin from the breast contour. A 2cm flash is created anteriorly to the breast contour. The posterior border is set to the target borders with a 7mm margin.

For the IMN field, the superior and inferior borders match the breast field. The medial border is placed 2 cm from the IMN contour. The lateral border is matched at the skin with the breast field.

Gantry Angle Selection:

For the SCLV field, the gantry angle is chosen within the range of 10 to 20 degrees (340-350 degrees for the left side). For each angle, the aperture is defined, and the minimum dose to the SCLV auto-contour, as well as the maximum dose to the esophagus, are calculated. The angle that optimizes coverage for the SCLV target while

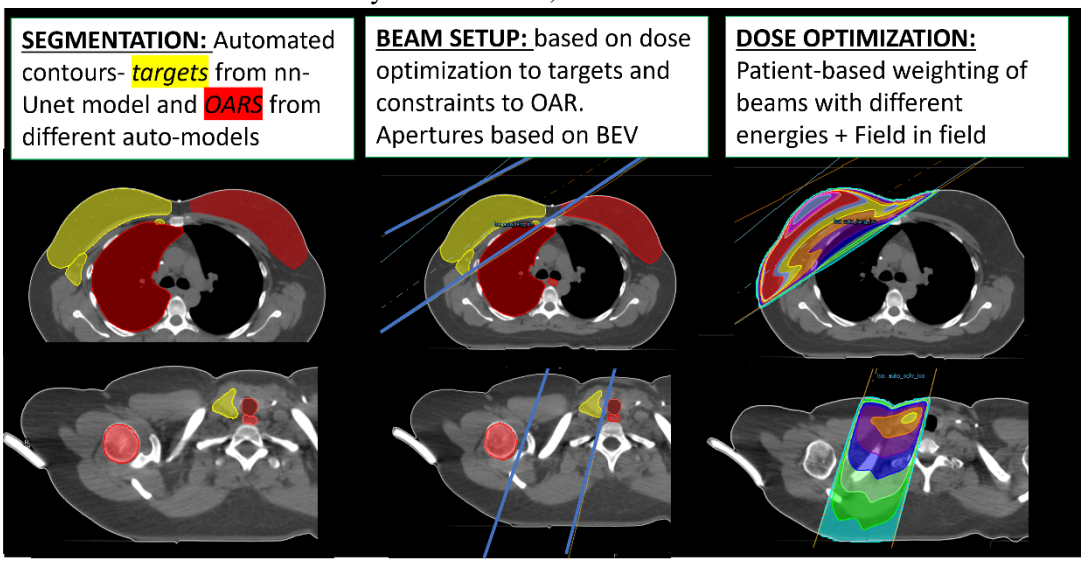

Figure 1. Design of the automated planning workflow for whole breast cancer radiotherapy treatment

ensuring that the maximum dose to the esophagus remains below 38 Gy is then selected.

For the breast field, the gantry angles for the medial and lateral fields are chosen from a range of 25 to 75 degrees (285-335 degrees for the left side). For each medial angle, a set of lateral angles is iterated over, and the volume of the ipsilateral lung receiving a 20 Gy dose, along with the dose to 5% of the volume of the contralateral breast, is calculated. The angles that minimize the volume of the ipsilateral lung receiving 20 Gy are selected. If the dose to 5% of the volume of the contralateral breast exceeds 5 Gy, angles that deviate from the direction of this structure are chosen. This process is repeated until the value of the dose to 5% of the volume is reduced to less than 5 Gy.

For the IMN field, the gantry angle is chosen within the range of 20-30 degrees. For each angle, the aperture is defined, and a contour based on the 20% isodose line is computed. The volume intersecting the isodose contour with the lung is then determined to reflect the shape of the dose at depth. The angle associated with the largest volume is selected, indicating the entrance of the beam through minimal skin curvature (assuming with curvature the isodose will be skewed, which decreases its volume). In this scenario, the medial gantry angle is designated as the IMN gantry angle plus 10 degrees (minus 10 degrees for the left side), and the corresponding lateral beam angle is determined to match the medial angle posteriorly.

Energy selection & Dose Optimization:

For the SCLV field: the energy and respective field weights are determined through iterative optimization, aiming to achieve the clinical objective of covering 90% of the SCLV volume with 90% of the prescribed dose.

For the breast field: field-in-field optimization is utilized to mitigate hot spots and enhance the coverage of the 100% isodose line. Concerning the IMN field, the energy selection is contingent on the depth of the IMN contour. If the depth is variable across the targeted area, an additional beam set is generated with a different energy to accommodate these variations.

II- Algorithm Testing:

Ten post-lumpectomy breast patients were selected retrospectively from our institutional database. Seven patients had right sided treatment while 3 were left sided. All the patients except for one had one of their arms above their head for their treatment setup.

In total, 50 plans were generated, encompassing three approaches for each patient. Each approach consisted of a version employing a single isocenter methodology, as well as another version utilizing a two isocenter methodology. Therefore, every patient had a total of 5 plans, each presenting a distinct perspective on the chosen methodology.

All automated plans were evaluated for clinical acceptability based on the 95% of the targets' volumes receiving more than 95% of the prescribed dose, in addition to meeting OAR constraints presented in table 1. Hot spots were evaluated for the SCLV and breast fields independently. The preferred criteria for the maximum dose was set at <115% of the prescription. The two isocenter approach was verified qualitatively by matching the superior border of the tangents field to a contour created from the external body contour at the SCLV isocenter.

OAR	*Constraint*
Heart	At most 5 Gy average dose
Left Ventricle	At most 25% volume at 5 Gy
Ipsilateral Lung	At most 35% at 20 Gy dose
Esophagus	At most 38 Gy at 0% volume
Ipsilateral Brachial Plexus	At most 53.5 Gy at 0% volume
Contralateral Breast	At most 5Gy average dose

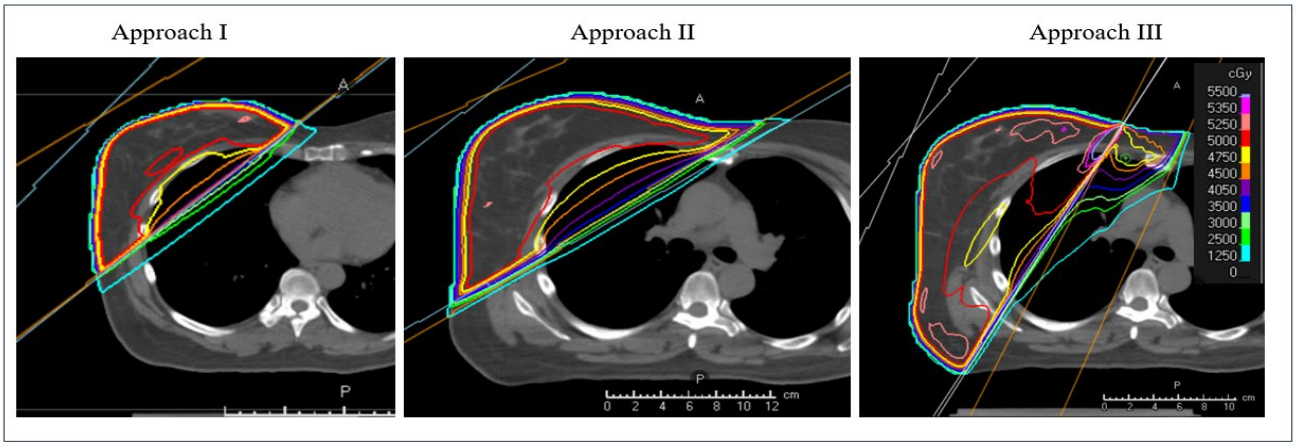

Figure 3. Example of axial slices with dose distribution of the 3 different approaches, approach I; regular tangent, approach III; wide tangents, approach III; tangents with electron IMN. Prescription was set to 50Gy for the breast and 45Gy for the lymph nodes

3 Results

For the regular tangents approach, all 10 automatically generated plans met the preferred objectives for targets coverage and OAR constraints as well as hotspot maximum. For the partial wide tangents approach, all targets and OARs have met their objectives for 50% of the plans. Three plans did not meet ipsilateral lung constraint (V20Gy= 40%, 43% and 42%). One plan with left sided treatment did not meet heart and left ventricle dose limit (mean heart dose= 5.8Gy and V5 left ventricle=28.3%). And one plan did not meet target coverage for AX1(D95%=38.4Gy) indicating the necessity for a posterior-anterior beam to encompass the deeper axillary nodes. Note, not meeting the lung or heart dose constraints may indicate that this approach is not appropriate for that patient.

For the third approach, with regular photon tangents field and a matched IMN electron field, 50% of the plans met all objectives and constraints. Four plans did not meet lung dose constraint, three of which were also flagged for the second approach. The plan that did not meet the heart dose limit in the second approach met the constraints following this method. The plan with low AX1 coverage was also flagged in this approach.

The two isocenters approach was successfully verified in all patients, correctly identifying the couch and collimator rotation angles to match the tangents and SCLV fields.
An example of all three approaches for a plan with a prescription of 50Gy to the breast and 45Gy to the lymph nodes is shown in figure 3.

4 Discussion

In this work, we have developed a portfolio of automated treatment plans for whole breast radiotherapy. This portfolio includes approaches for regular breast treatment without lymph nodes involvement and a comprehensive treatment option. Although in some cases, the automated plans did not meet the preferred objectives, this may be because of difficult patient anatomy. In all cases, it is likely that significant time savings could be realized through automation, followed by editing of the plans instead of starting anew. In addition, the clinical implementation of these automated models has the potential to mitigate the negative downfalls of radiation workforce shortage by improving workflows. Studies have shown that the integration of automated tools in clinical settings can effectively provide high-quality breast treatment plans, accompanied by potential time-saving benefits[8–10].

Effective screening and early diagnosis programs, combined with advanced radiation treatment planning tools, have the potential to contribute to shifting the standard of care for breast cancer in low-middle-income countries. This shift may involve a transition from mastectomy to lumpectomy care, emphasizing less invasive and more targeted treatment approaches. Our tools will hence have greater significance in helping resource constraint clinics where workforce expertise is lacking in transitioning their standard of care.

To our knowledge, this is the first work to automate electron treatment for IMN employing accurate energy selection and skin matching with the adjacent photon field. For clinics lacking machines with electron capabilities or having different clinical practice, a wide tangent approach was also developed for treatment of IMNs with photon beams. Along with breast and SCLV treatment, this therefore represents a first of its kind automation of all 3DCRT possible scenarios for comprehensive treatment of breast cancer.

Although no official physician review was performed for this study, informal feedback from MD Anderson's radiation oncologists sub-specialized in breast cancer, has guided the development of these tools. The next step in testing these tools will include a fully evaluation by radiation oncologists from multiple institutions.

5 Conclusion

The feasibility of an automated treatment planning model, encompassing different treatment paradigms and clinical preference for whole breast radiation therapy was proven. This work has the potential to improve the efficiency and outcome of whole breast radiotherapy globally.

[3]Department of Physics and Astronomy, Heidelberg University, Heidelberg, Germany

Abstract We present an implementation of a Pareto plan navigation framework in the open source treatment planning toolkit `matRad`. It expands on the existing weighted sum approach and allows for calculation and navigation of Pareto surfaces. Furthermore we introduce a lexicographic approach as an alternative to the weighted sum method.

1 Introduction

A central concern of the treatment planning problem in radiotherapy is the handling of different trade-offs like target coverage against organ at risk (OAR) sparing. Since the different objectives often contradict each other there is no single optimal plan, but rather an entire set of *Pareto optimal* plans that cannot improve on one objective without worsening at least another.

Methods to solve this multi-criteria optimization (MCO) problem evolved from an iterative tuning of weights in a weighted sum objective function to automated approaches using Pareto front approximation or lexicographic optimization. Pareto front approximation techniques automatically compute a set of Pareto optimal plans and allow navigation of the resulting Pareto front in an interactive user interface. Lexicographic approaches, on the other hand, require definition of a *wish list*, e. g., based on a clinical protocol prioritizing treatment goals, to automatically reach an acceptable plan. These approaches are now commonly implemented and used in commercial treatment planning systems. The open-source community is, however, lacking comprehensive implementation of such methods for research and education.

Within the open-source radiotherapy treatment planning toolkit `matRad`, which up to its latest release relies on the weighted sum approach for non-linear treatment plan optimization, we developed a MCO module to allow for Pareto front approximation and navigation as well as lexicographic optimization. The implementations are based on well-established methods published in literature.

For Pareto front approximation and navigation, we employ a so-called *sandwich* algorithm [1] that iteratively chooses weights automatically to generate a plan database approximating the Pareto front. Afterwards, a navigation algorithm finds convex combinations of the pre-calculated plans to allow near continuous and interactive exploration of the solutions.

For lexicographic optimization, `matRad` was extended with a priority and goal system to enable definition of a wish list. The $2p\varepsilon c$-method [2] was chosen to consecutively optimize individual objectives constrained by previous solutions and goals. In the end, this method results in a plan optimally fulfilling all the defined goals while prioritizing minimization of the objective functions according to their priority in the wish list.

In this work, we describe the implementation of said MCO framework in `matRad` and demonstrate both methods by application to a prostate case.[1]

2 Materials and Methods

2.1 Software framework

The basis for our MCO framework is `matRad` (version 2.10.1 *Blaise*) [3, 4]. It is written in `MATLAB` and allows for IMRT and IMPT dose calculation and plan optimization using a weighted sum approach with user chosen penalties. Photons, protons and carbon ions are available for planning including biological optimization for the latter. Optimization relies on `IPOPT` [5] or Matlab's `fmincon` using an L-BFGS approximation for Hessian matrices.

To implement Pareto front approximation, linear programs and convex hull calculations are required. These are solved using the `Matlab` functions *linprog* and *convhulln*, respectively.

2.2 The multi-criteria optimization problem in radiotherapy

The general multi-criteria RT treatment planning problem can be expressed through a set of functions $\mathbf{f}$ and hard constraints $\mathbf{c}$:

$$\begin{aligned} \underset{\mathbf{w}}{\text{minimize}} \quad & \mathbf{f}(\mathbf{d}) = [f_1(\mathbf{d}), f_2(\mathbf{d}), ..., f_n(\mathbf{d})] \\ \text{subject to} \quad & c_k^l \leq c_k(\mathbf{d}) \leq c_k^u \qquad \forall k, \\ & d_i = \sum_j D_{ij} w_j \qquad \forall i, \\ & w_i \geq 0 \qquad \forall i \end{aligned} \tag{1}$$

$\mathbf{d}$ is a discretized vector of dose values with elements d_i related to the beamlet weights $\mathbf{w}$ via the precomputed dose influence matrix $\mathbf{D}$ such that $\mathbf{d} = \mathbf{D}\mathbf{w}$. One approach minimizes the weighted sum, $\sum_i p_i f_i$, where p_i are weights/penalties applied to each objective.Varying the penalties allows to obtain different plan options.

[1]The implementation is available in the `matRad` repository on `Github` (Commit ID at submission: f19635f).

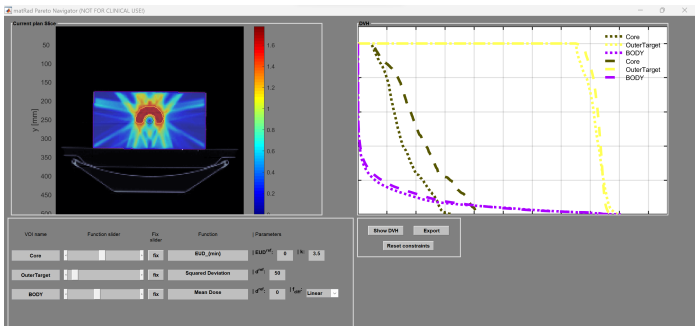

Figure 1: GUI for interactive plan navigation. Objective values can be adjusted by moving the sliders and limited through upper bounds. Additional buttons allow to show the current plan's DVH and to export it to the general `matRad` GUI.

2.3 Pareto front approximation

For Pareto front approximation, we rely on so-called *sandwich* algorithms that approximate the Pareto surface with polyhedral inner and outer approximations. Given an existing set of plans with corresponding objective function values $\mathbf{y}$ the inner approximation is formed by the corresponding convex hull while the outer approximation is bounded by the intersection of supporting hyperplanes. With the assistance of the maximum distance of inner and outer approximation a new weight vector is chosen to improve on the current approximation in the most improvable region.

The algorithm for our implementation was introduced by Rennen, Dam, and Hertog [1]. By optimizing each objective individually we calculate the anchor points of the Pareto front. The anchor point solutions are used to scale the objectives f_i to a range of 0 to 1, to better account for different dimensions of objective function values, using their highest values u_i and lowest value l_i. The scaled objectives f' are then given by $f'_i = \frac{f_i - l_i}{u_i - l_i}$. Afterwards the algorithm iterates over the bounding facets of the inner approximations and calculates new penalty vectors based on the normal vector of the facet with largest distance.

For optimization of individual weight computations found by the sandwich algorithm, we use `matRad`'s existing weighted sum optimization framework, allowing us to use any optimizer interfaced by `matRad`. The sandwich algorithm continues until the maximal distance between inner and outer approximation falls below a predetermined threshold or a certain number of iterations is passed.

Finally, all solutions are stored in form of the resulting beamlet intensity vectors for direct dose calculation or plan navigation.

2.4 Plan navigation on the Pareto front

For visualization of the different plans after database calculation, a dedicated widget is available for `matRad`'s graphical user interface (GUI). The widget is shown in Figure 1 with an example Pareto front approximation loaded.

Starting from an initial plan with objective function values $\hat{\mathbf{y}}$, a new plan can be investigated by moving across the Pareto surface using interactive sliders. Upon moving a slider, the corresponding objective function value is fixed and a new plan is found as a convex combination of pre-calculated plans using the algorithm introduced by Monz, Küfer, Bortfeld, et al. [6]. The core idea of the algorithm is to start from the point $\mathbf{y}^R$ obtained through the slider movement and then search along the line $\mathbf{y}^R + t\mathbf{1}$ for an intersection $\mathbf{y}'$ with the approximation of the Pareto surface, expressed as $\mathbf{y}' = \sum_k v_k \mathbf{y}^k$. $\mathbf{y}^k$ are the objective function values of the pre-calculated plans and v_k the corresponding convex coefficients, that are then used to calculate new weights $\mathbf{w}' = \sum_k v_k \mathbf{w}^k$ from the pre-calculated weights $\mathbf{w}^k$. While the new plans are not necessarily Pareto optimal,[2] they are still clinically relevant if the Pareto surface is sufficiently approximated.

To limit navigation to regions of interest, upper bounds may be added on specific objective functions. The range of the sliders is then adjusted to mimic the upper bound and since the change also limits the options for other objectives the respective slider ranges are changed as well.

2.5 Lexicographic optimization

Lexicographic optimization relies on a prioritized wish list formulating goals for each objective f_i. The chosen method for our implementation – the $2p\varepsilon c$-method [2, 7] – consists of two fully automated plan optimization phases of iterating to the wish list.

The first phase optimizes objectives individually one after the other (under the general constraints of Equation 1). In each step, moving to optimization of lower prioritized objectives adds additional constraints $f_j \leq \varepsilon_j$ to still respect higher priority objectives. ε_j is set to the corresponding aspired value g_j if it can be met and else to the achieved value f_j^* multiplied with a slack variable c (in our implementation chosen as $c = 1.03$).

The second phase then turns objectives that could not meet their goal value into hard constraints and they are not optimized again. For the remaining objectives it applies the ε-constraint method which can be formulated as

$$\begin{aligned} \underset{\mathbf{w}}{\text{minimize}} \quad & f_i(\mathbf{d}) \\ \text{subject to} \quad & c_k^l \leq c_k(\mathbf{d}) \leq c_k^u && \forall k, \\ & f_j(\mathbf{d}) \leq \varepsilon_j && \forall j \in \{1,..,n\} \backslash i, \\ & d_i = \sum_j D_{ij} w_j && \forall i, \\ & w_i \geq 0 && \forall i \end{aligned} \tag{2}$$

Initially the ε values are set as achieved in the first phase and after optimization are changed to cf_j^* for all following objectives.

This approach has the advantage that objectives that easily meet their goal value do not dominate the optimization in the second step, while ensuring that objectives which are not able to meet their goal value are still respected.

[2] for convex objectives it holds that $\mathbf{f}\left(\mathbf{D}\sum_k v_k \mathbf{w}^k\right) \leq \sum_k v_k \mathbf{y}^k$

	Objectives		Constraints	
Volume	Name	Parameters	Min[Gy]	Max[Gy]
Target	$f_{sq\ deviation}$	$\bar{d} = 50$	45	57
Core	f_{EUD}	$a = 3.5$	0	40
Body	f_{mean}	-	0	45

Table 1: Objectives and constraints used for the TG119 phantom.

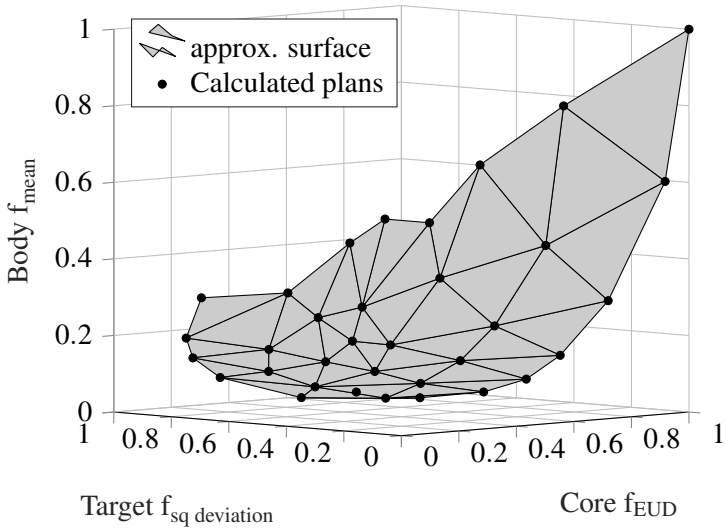

Figure 2: Example Pareto surface for the TG119 phantom. The (normalized) objective function values define the three axes. The plans obtained through optimizing the weight combinations found by the sandwich algorithm are shown as dots connected by the approximated Pareto surface.

3 Results

3.1 Pareto front approximation

The implementation of the Pareto front approximation algorithm was verified with the non-radiotherapy test case 1 from the original publication [1] in `MATLAB`.
It was then applied to two radiotherapy scenarios using the CORT dataset available within `matRad`. The first example uses the TG119 phantom shown in Figure 1. The three objectives set (see Table 1) allow to plot the Pareto surface approximation (see Figure 2).
The second example uses a prostate patient (shown in Table 2). In total, 105 plans were calculated for the database. In Figure 3, we show four plans: (1) anchor point plan focusing on the 68 Gy volume, (2) anchor point plan focusing on rectum, (3) a balanced plan from the precalculated database and (4) plan found with help of the navigation interface.

	Objectives		Constraints	
Volume	Name	Parameters	Min[Gy]	Max[Gy]
PTV 68	$f_{sq\ deviation}$	$\bar{d} = 68$	61.2	78.2
PTV 56	$f_{sq\ deviation}$	$\bar{d} = 56$	50.4	64.4
Bladder	f_{EUD}	$a = 3$	0	58
Rectum	f_{EUD}	$a = 8$	0	58
Body	f_{mean}	-	0	58

Table 2: Objectives and constraints used in the sandwich algorithm implementation for the prostate case.

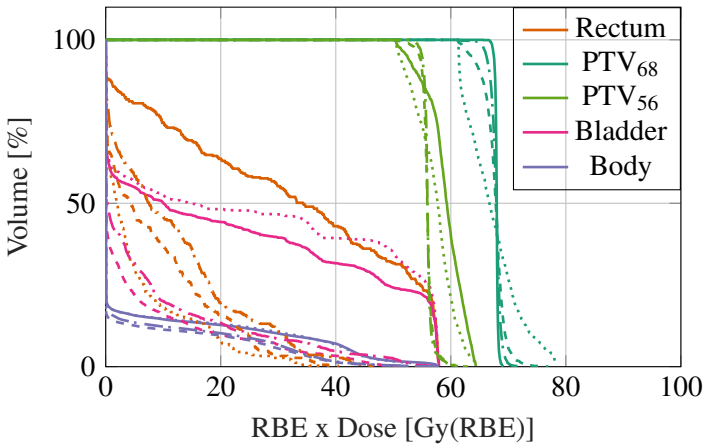

Figure 3: DVH for the four prostate plans. Anchor point plans (1) and (2) are shown as solid and dotted lines, respectively. The balanced database plans (3) and (4) are plotted dashed and dash-dotted.

3.2 Lexicographic optimization

To test the $2p\varepsilon c$-method a wish list on the prostate phantom presented in Table 3 was optimized.

Constraints				
Number	Volume	Name	Min[Gy]	Max[Gy]
1	Rectum	Min/Max Dose	0	58
2	Bladder	Min/Max Dose	0	58
3	Body	Min/Max Dose	0	58
Objectives				
Priority	Volume	Name	Param.	Goal
1	PTV 68	$f_{sq\ deviation}$	$\bar{d} = 68$	2
2	PTV 56	$f_{sq\ deviation}$	$\bar{d} = 56$	2
3	Rectum	EUD	$a = 8$	30
4	Bladder	EUD	$a = 3$	30
5	Body	Mean dose	-	10

Table 3: wish list for the prostate patient. Constraints for OAR are set as in the Pareto front approximation, while target constraints are omitted. The PTVs have highest priority and are are assigned a squared deviation objective each.

Table 4 shows achievable objective function values and chosen constraints in both phases of the $2p\varepsilon c$ approach. All objectives except for Rectum meet their aspired goal value in the first phase and are therefore optimized again. A DVH corresponding to the final plan can be found in Figure 4. The target coverage was achieved and while the Rectum goal is missed, the resulting plan was evaluated to be acceptable.

First step				
Priority	Volume	Goal	Achievable	New constraint
1	PTV 68	2	$5.9 \cdot 10^{-2}$	2
2	PTV 56	2	$2.6 \cdot 10^{-6}$	2
3	Rectum	20	22.6	23.3
4	Bladder	30	18.9	20
5	Body	10	5.1	10
Second step				
1	PTV 68	2	1.67	1.72
2	PTV 56	2	0.70	0.72
4	Bladder	30	23.8	24.5
5	Body	10	4.3	-

Table 4: Result table of the prostate patient. The goal on the rectum cannot be met in the first iteration and is therefore skipped in the second iteration.

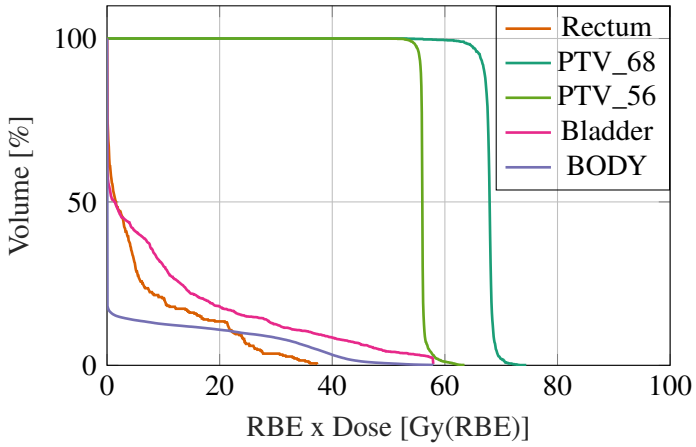

Figure 4: DVH for the prostate plan calculated with the $2p\varepsilon c$-method.

4 Discussion

Two established MCO treatment planning approaches were successfully implemented in the open-source treatment planning system `matRad`.

4.1 Pareto front approximation and navigation

The implemented sandwich algorithm was benchmarked against published results and the Pareto surface could be adequately approximated for two RT examples.
While navigation of the treatment plan is possible nearly in realtime, once the plan database is calculated using the sandwich algorithm, the computation time is limited by the constraint optimization method in `matRad`. Since `matRad` favors flexibility of computational performance optimization, the performance of the non-linear optimization approach is suboptimal for Pareto surface approximation. However, computational performance can be optimized in the future by users themselves or public community contributions.

Future improvements to the algorithm itself might include automatic clustering of correlated objectives to reduce the complexity of the calculation for high dimensional problems as well as the implementation of parallelizable sandwich algorithms.

4.2 Lexicographic optimization

Implementation of the $2p\varepsilon c$-method was demonstrated with a prostate plan and was shown to work as expected. It allows for a more automated and clinically oriented steering of the treatment plan than the weighted sum approach, however design of a suitable wish list depends on the planner's experience. Similar computational limits as in the Pareto front approximation approach apply, as the approach is limited in performance by `matRad's` underlying optimization algorithm.

5 Conclusion

We present our MCO framework in the open source treatment planning software `matRad` which includes: (1) A sandwich algorithm implementation to calculate Pareto optimal plans and a navigation interface to allow their exploration afterwards. (2) also introduced a lexicographic method for automated treatment plan generation. This package facilitates future research into advanced treatment plan optimization strategies.

[2]Inpictura Ltd, Oxford, United Kingdom

Abstract Automation of segmentation and treatment planning is an important development in radiotherapy. While this automation can save time, the auxiliary workflow steps are still time consuming, and typically involve multiple hand-overs between personnel, hampering an efficient process. To create a fully automated workflow, segmentation and planning need to be embedded within an automation framework. In this work we describe a fully automated workflow of the complete treatment preparation chain from CT to RTPlan export. All key components of this workflow are currently in clinical use. Starting from the CT, auto-segmentation is performed by Mirada WorkflowBox. The CT and resulting structure set are sent to Pinnacle, which in combination with our automation framework FAST creates and exports RTPlan and Dose. We discuss the implications of full automation of all auxiliary steps on the architecture of the workflow.

1 Introduction

Automation of treatment preparation for radiotherapy is an ongoing and crucial development. Main steps in the process include image segmentation and treatment planning. A wide range of solutions, both commercially available and home-built, is used to perform these tasks[1-4]. However, for a full automation of the workflow, data flow, protocol selection and auxiliary steps also need to be performed automatically[5].

In clinical practice automatically generated structures and plans often still require manual verification. The auxiliary workflow steps (which include data transfer, data import, creation of help-structures, choice of isocenter, selection of CT reference point beam setup, choice of prescription, selecting isodose color scheme, etc.) are therefore often not automated as they can simply be performed by the user that is already present for the verification. This, however, does limit the potential time saving and hampers the development of full automation of the preparation workflow.

Automated treatment preparation executes a substantial part of the radiotherapy treatment chain. It saves time, boosts staff productivity and can result in consistent and high plan quality. The only requirements are a planning scan and a clinical protocol as input and an evaluation of the final output by a clinician. Due to its speed and efficiency, automated treatment preparation can also be highly beneficial for online adaptive radiotherapy[6] or the development of a one-stop-shop.

In this work we describe a fully automated workflow of the complete treatment preparation chain. This workflow is based on our clinically used automated segmentation and planning methods and designed such that it can be integrated into our clinical practice. The focus of this work is on building the automation framework. Further improvements in segmentation and plan quality can be achieved by implementing future state-of-the-art segmentation and planning methods. The workflow was submitted to the AUTO-RTP challenge, presented at the 2023 ESTRO Physics Workshop on automation.

This challenge asked participants to generate treatment plans as-automated-as-possible, based only on the planning CT and a description of the treatment protocol[7].

2 Materials and Methods

In the proposed fully automated workflow, the segmentation is done in Mirada WorkflowBox 2.6.2. (Mirada Medical, Oxford, UK) and plan optimization is done in Pinnacle 16.2 (Philips Radiation Oncology, Madison, WI), using our automation framework FAST[8].

2.1 Challenge data, protocol and scoring

Planning CT scans of ten prostate cancer patients were made available via the AUTO-RTP challenge website. The cases were a mix of prostate only, prostate with nodes, and prostate bed with nodes cancer patients. Organs at risk (bowel bag, bladder, rectum, and femoral heads) and CTVs (prostate(bed), seminal vesicles and lymph node regions) were all to be auto-segmented according to published guidelines. Dose prescription, DVH constraints and PTV expansions were also provided, broadly based on the PIVOTAL trial[9].

After submission to the AUTO-RTP challenge, submissions were scored on a single plan quality measure (range 0 – 100%). This measure was calculated based on DVH parameters of the submitted RTdose when evaluated using consensus contours from three experts. The consensus contour was not available for participants. For details, see the AUTO-RTP grand challenge website[7].

2.2 Image acquisition, DICOM routing and segmentation

The workflow starts with a planning CT that is sent to the general DICOM server. The DICOM series description contains the clinical protocol name. The DICOM server forwards all planning scans to the Mirada WorkflowBox (WFB), a server that performs automated processing. The Mirada WFB contains routing rules that configure how to process incoming DICOM objects that meet certain criteria. In this workflow, the WFB responds to the clinical protocol name, which is read from the DICOM series description of the planning CT.

As the protocol name was not available in the DICOM objects of the ESTRO challenge, a data-preprocessing step

was added where we entered the protocol name in the series description of the CT.

The Mirada WFB is configured to segment the images using Mirada DLCExpert[10]. As two separate DLC modules had to be run to obtain all required structures, a step was added to the Mirada WFB to combine the two resulting structure sets (RTSS). Next, the CTV-PTV expansions are performed as configured in the WFB, and the CT and complete RTSS are automatically sent to Pinnacle.

A FAST listener was built that triggers on DICOM files arriving in the Pinnacle DICOM pool. Based on the plan protocol in the series description, automatic planning is started using the corresponding FAST protocol. An existing clinical protocol was modified to adjust to the treatment prescriptions as described in the challenge. After performing the planning FAST automatically exports the RTPlan and RTDose DICOM objects. Automated protocol-based DVH analysis and plan evaluation documentation is generated and sent as pdf to the record and verify system for verification. More details on FAST planning will be given in the next section.

The entire workflow is fully automatic. It responds to a CT scan arriving on the DICOM server and concludes with an export of RTSS, RTPlan and RTDose and evaluation pdf. A summary of the automated workflow, compared to the current clinical workflow, is shown in Figure 1.

2.2 FAST Planning

The treatment plans are generated using Pinnacle, including the Auto-Planning module, and our in-house developed automation framework FAST.

FAST was designed to automate the entire planning process. In a typical clinical workflow, FAST is started manually from Mirada RTx and it performs planning headless in the background. If needed the planning process can be monitored on a dashboard. Once planning is done, the RTT and physician can evaluate the treatment plan in Pinnacle. Alternatively, all FAST functionality is also available from a user menu within the TPS. FAST was clinically released in February 2015. Since then, it has been clinically used to create over 20.000 plans.

The core of FAST consists of 1) planning protocols, 2) modules that interact with Pinnacle and 3) a workflow engine.

The protocols are xml-based and contain all information that is required to generate a plan. This includes the definition of auxiliary structures, beam configurations, dose calculation settings, planning optimization objectives and planning constraints for evaluation. An important advantage of the protocols is that they separate the configuration from the planning functionality.

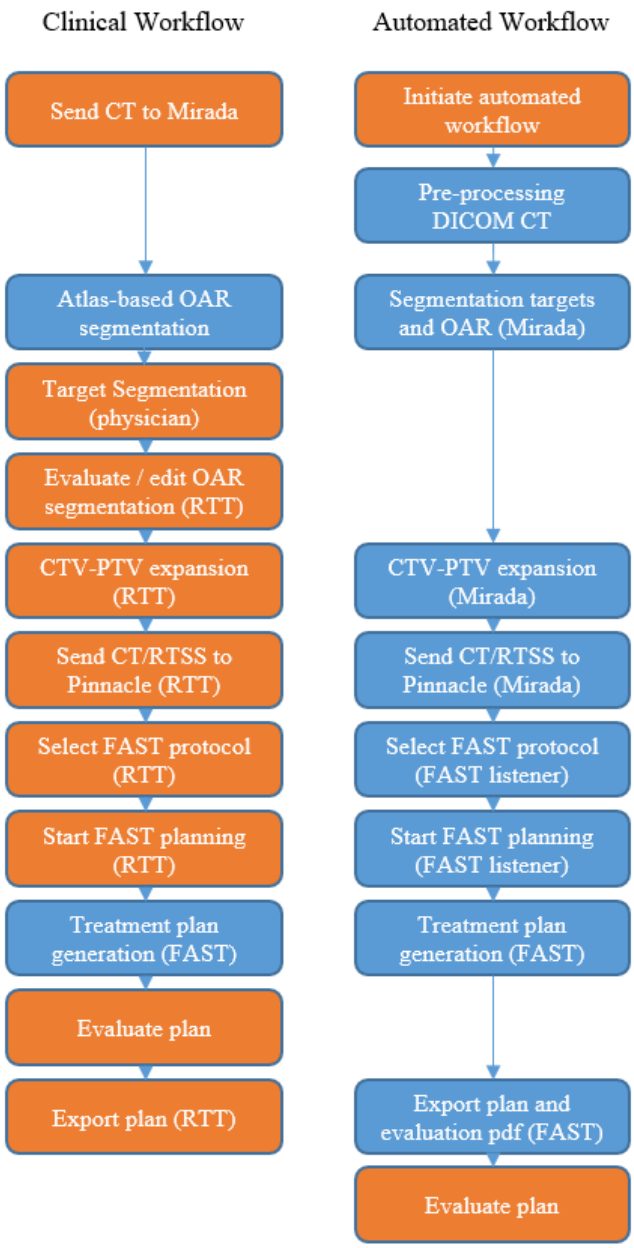

Figure 1: A comparison of the current clinical (left) and fully automated workflow (right). The orange blocks are manual, the blue blocks are automated.

Modules were built for each step in plan generation. A module executes its tasks based on the assigned protocol and current status in the TPS. Modules communicate with Pinnacle using an in-house developed Pinnacle API that enables direct use of Pinnacle scripting from Python.

The workflow engine consecutively starts all the modules. For the standard planning workflow, the order of the modules is determined by the natural order of the steps in the planning process.

The modules were designed to be robust and multi-purpose. In case something has to be changed in an early step of the planning, all modules following that step can simply be re-executed. FAST continuously monitors the

status of the TPS and therefore can trigger on unexpected events or a module which is not executed properly.
The workflows are started by sending an URL to the FAST webservice. This URL crucially contains the DICOM UIDs of the CT and RTSS to be used for the plan, and the protocol name. FAST will create a patient record in Pinnacle, add the DICOM files and the workflow engine will start the planning.
Once the plan is done, a DVH report is generated and saved as pdf. A DICOM export module is available to export any DICOM objects. In the clinical workflow, this is not used as the planners always evaluate the plan before export.
To generate optimal dose distributions, the plan optimization is done using Pinnacle Auto-Planning. For each treatment protocol, an automation template was developed that contains the required target dose as well as the priorities in OAR sparing and dose conformity[11]. The Pinnacle Auto-Planning template was encoded in the FAST protocol and Auto-Planning is started by a FAST module.
In the clinic, the acceptance rate of the automatically generated prostate plans is 75%[9].

3 Results

The fully automatic workflow ran successfully for all 10 patients in the challenge. The total runtime was approximately 30 minutes (5 minutes for segmentation, 25 minutes for planning) per prostate cases and took about 60 minutes for cases involving nodes (10 for segmentation, 50 for planning).
The primary aim of the challenge was to gauge the state of automation in the field. Our submission was fully automated (‘zero click’) and from all participants, the closest to clinical practice as all key components are currently in clinical use.
In the challenge we achieved a 70% score based on DVH evaluation. This resulted in 7th place out of 13 participants.
In one out the ten plans all clinical constraints were met. In the remaining nine, most constraints were met except for the D95% target coverage. The reason was that the autosegmentation missed a small part of the target compared to the consensus contour, immediately resulting in insufficient target coverage when evaluated on the consensus contour. The objectives were met on our own auto-segmentations.
For prostate cases we scored average plan quality measures of 76%, for prostate plus nodes 71% and for prostate bed plus nodes 58%. The low score for prostate bed cases is mostly due by the fact that we did not have an auto segmentation method available for the prostate bed and used our available prostate model instead.

4 Discussion

In this work we showed that a fully automatic radiotherapy planning workflow is feasible using clinically available auto-segmentation and auto-planning methods.
While a lot of automation literature focusses on the specific task of segmentation and treatment plan optimization, a fully automated workflow is considerably more than that, since all auxilliary steps taken by a user in clinical practice also need to be automated.
Automation of the segmentation part of plan preparation was achieved by adding extra rules for DICOM routing and Boolean operations on auto-segmented structures in WFB. The dose optimization part of planning was performed by our existing automation framework FAST. WFB and FAST were connected by a newly developed FAST listener. Possible alternatives include either starting FAST explicitly from WFB or WFB from FAST, or adding an overarching workflow manager that first starts the segmentation and then the planning.
Even though plans could be prepared fully automatically, they were not always of acceptable quality when evaluated on the challenge golden standard segmentation. This was mostly due to deviations in the target segmentation, which was strongly penalized in the scoring. However, the autosegmentaion models used were not optimized on this guideline and inter-observer variation in segmentation is always present. Still, this shows that in a fully automated workflow, high quality target segmentation is a crucial bottleneck. As long as this is not near flawless, it is sensible to at least evaluate target segmentations before starting an automated plan preparation. With improved segmentation methods, however, it becomes feasible to automate the entire planning and check the segmentation only once the plan is done.
A major factor in the implementation of automated treatment preparation is trust. The acceptance rate of the resulting plans should be high enough to make it perceived as useful to skip intermediate evaluations. In case an aspect of a plan has to be improved, all steps of the workflow depending on the improved factor also have to be re-executed. This requires extra time as well as flexibility of the involved software. This factor becomes of less importance as the execution time of segmentation and planning methods decrease. Whereas our current implementation is still relatively slow, speed increase is expect e.g. due to GPU-based dose computation[12]. The applied software should be designed such that plans can easily be rerun and the overview of data and plans remains clear.
In this work, we showed automation from CT to plan. However, after RTplan export additional steps are often required. These could include import of the rtplan in the Record and Verify system and pre-treatment planQA. Automation of these steps might also be (partially)

possible, but were outside the scope of the challenge and therefore also not taken into account in this work.

5 Conclusion

Full automation of the treatment preparation workflow is possible and requires embedding auto segmentation and auto treatment planning into an automation framework. Crucial aspects regarding this workflow are that all required input and information should be present when the preparation starts, all data transfer and starting of applications or modules should be automated, and a framework is required in which the next component in the workflow starts or is started at the right moment. Arguably, the most crucial aspect of creating the appropriate trust in the automated workflow is the auto-segmentation of the targets to be near flawless.

Development of Bolus Optimization System for Electron Conformal Therapy

Sang-Won Kang[1], Woong Cho[2], Dongsan Kang[3], Moo-Jae Han[1], and Jin-Beom Chung[1]

[1]Department of Radiation Oncology, Seoul National University Bundang Hospital, Seongnam, Korea
[2]Department of Radiation Oncology, Seoul National University Borame Medical Center, Seoul, Korea
[3]Department of Biomedical Engineering and of Biomedicine & Health Sciences, The Catholic University of Korea, Seoul, South Korea

Abstract Aim of this study is to develop a bolus optimization system for electron conformal therapy (ECT). To develop the optimization system, the electron dose calculation engine and an optimization algorithm should be built. Thus, Hogstrom's dose calulation algorithm and backtracking line search were implemented and applied in the optimization system. Accuracy of the developed dose calculation algorithm was verified by a 94.97% passing-rate in a gamma evaluation with a commercially available program. With evaluating the dose of the target-line by applying the optimzed bolus, the average dose and root mean square error were 95.23% and 15.17, respectively. In this study, we evaluated the developed bolus optimization system for ECT. Although some limitations are presented, it has shown feasibility of the opimization system to apply in clinical practice. In future study, we will imporve the performance of the system and incorporate 3D printing technology into the optimization system.

1 Introduction

Electron radiotherapy is commonly used for the skin cancer or malignant tumors within 7.5 cm of the patient's surface.[1-3] However, when the patient's surface is not flat or the tumor has a complex morphology, it is not an effective treatment due to it's physical limitations. To overcome these limitations, the concept of electron conformal therapy (ECT) using a bolus compensator [4-7] or an electron-collimator [8-11] has been proposed, but practical clinical utilization has not been achieved due to the failure to control the electron scattering effect and the cost of manufacturing.

Recently, the clinical application of ECT with bolus has been facilitated by the availability of 3D printing technology. However, there is no commercially optimization technique for bolus shape as the target, so this study aims to develop the bolus optimization system for ECT.

2 Materials and Methods

At first, to develop a bolus optimization system, the electron dose calculation algorithm refered by Hogstrom's was builted in this study. [12] Secondly, an optimization algorithm was also built. In general, multi-criteria optimization method is usually used for optimization in radiotherapy, but the bolus optimization system applied the backtracking line search method to the prescribeed dose-line (target-line) for dose optimization.

The electron dose calcualtion algorithm assumes that overall calculation was performed in the infinitesimal area and the electron beam are parallel beams. Thus, the percentage depth dose (PDD) of a pencil beam falling on a plane is the same shape in the calculation. In addition, when an electron reacts in a medium and transfers energy to a distant location, the direction of transfer is assumed to be perpendicular to the incident direction.

S(x', y', z') is the relative amount of electron fluence when an electron of initial mono-energy arrives at position (x', y', z'). An electron arriving at (x', y', z') will undergo multiple scattering processes and transfer energy to point (x, y, z) as a kernel. Define the rate of this transfer as K(x' →x, y'→y, z'→z). To summarize the above concept, the dose arriving at (x, y, z) is expressed as the sum of energy contributions from electrons falling everywhere.

$$D(x,y,z) = \iint S(x',y') \cdot K(x' \to x,\ \ y' \to y, z' \to z)\ \ dx'dy'$$

S(x', y') is a kind of off-axis electron fluence ratio, and it is preferentially set to 1 for simplicity of calculation in this study. To solve for K(x' →x, y'→y, z'→z), it is assumed that the vertically incident pencil beam has a Gaussian distribution in the horizontal direction and a spread function similar to that of a water droplet. Assuming that the vertical function is G(z) and the horizontal function is F(x,y,z), and that the horizontal function takes the form of a Gaussian distribution, it can be expressed as follows.

$$\mathrm{dose}_{\mathrm{Pencil}}(x,y,z) = F(x,y,z) \cdot G(z)$$

F(x,y,z) is presented for multiple Coulomb scattering (MCS) function according to the Fermi-Eyges theroy, and it indicates that σ_{MCS}^2 becomes more diffuse in the lateral direction as it grows.

$$F(x,y,z) = \frac{1}{2\pi\sigma_{MCS}^2} \exp\left(-\frac{x^2+y^2}{2\pi\sigma_{MCS}^2}\right)$$

G(z) is a function of the depth direction within a single pencil beam, represented by the following equation.

$$G(z) = G_{water}(Z_{eff}) \cdot \left(\frac{SSD + Z_{eff}}{SSD + z}\right)^2$$

Using the above electron dose calculation engine, the bolus optimization system that can match the desired target-line was built using backtracking line search algorithm. The objective function is the mean square error (mse) of the dose within the target-line according to the change of the

thickness of bolus, and the parameters α and β were set as 0.5 and 0.9, respectively.

3 Results

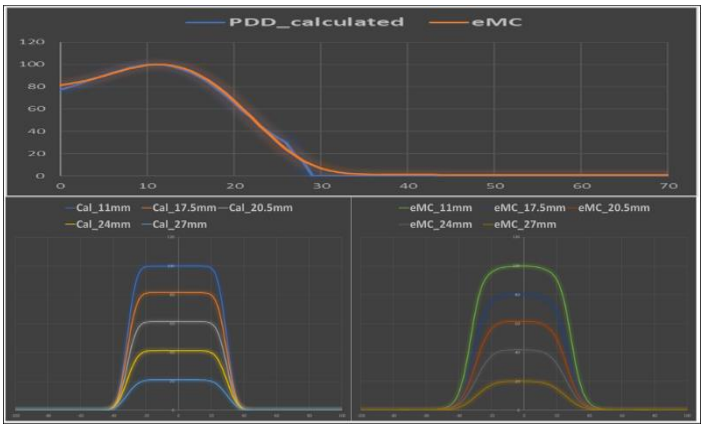

Figure 1: Comparison of percentage depth dose and profile calculated with the our electron beam dose calculation program and the commercialized dose calculation algorithm (eMC).

Figure 1 shows the comparison of PDD and profile calculated by eMC, which is a Monte-Carlo simulation-based electron dose calculation algorithm within Eclipse, and the our developed electron dose calculation engine. For PDD, the root mean square error (RMSE) analysis showed an error rate of 2.07. For profile, the RMSE was calculated to be 3.10, 3.89, 3.34, 2.30, and 1.54 at depths of 11, 17.5, 20.5, 24, and 27 mm, respectively.

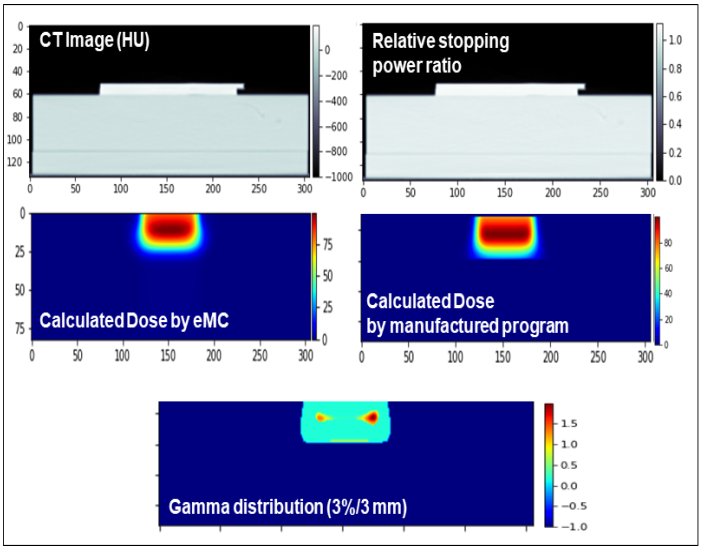

Figure 2. Dose and gamma distribution calculated with the developed dose calculation system and commercialized dose calculation algorithm (eMC) at the center axial within the phantom.

A result of the gamma evaluation between the dose distribution calculated by eMC and our dose calculation engine is 94.97% within 3%/3 mm criterion.

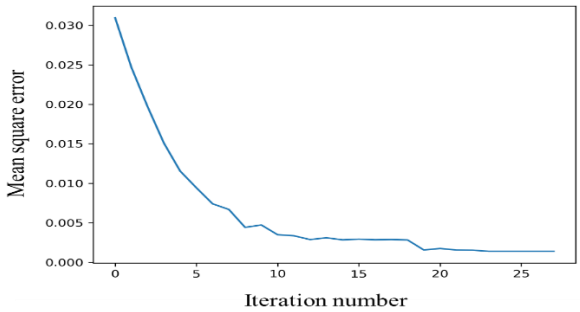

Figure 3. Mean square error variation as the number of iterations.

As shown in figure 3, after more than 25 iterations, the MSE converged to about 0.0014.

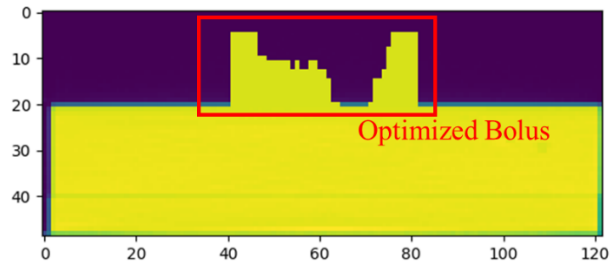

Figure 4. Optimized bolus shape

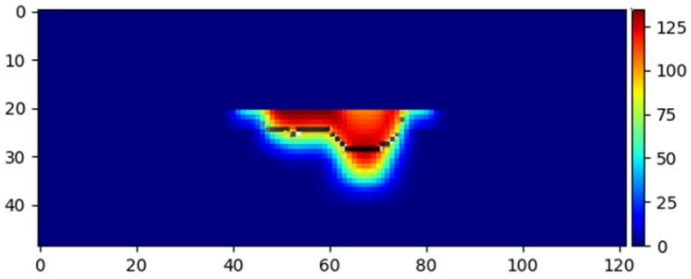

Figure 5. Dose distribution inside the body. The black dot represents the target line, which is the 95% dose fraction.

When the target line is normalized to the 95% prescribed dose, the Dmax is 135% within the target, and the mean value and the root mean square error of the dose on the target line is 95.23% and 15.17, respectively.

4 Discussion

Based on the results, it is shown that our developed electron radiation dose calculation engine can be utilized in optimization and is somewhat consistent with commercially available algorithms. However, there is a difference with the eMC result due to the calculation assuming S(x', y') = 1 and ignoring the beam divergence. Although the computational algorithm is less accurate than commercially available algorithms, the calculation algorithm was enough to be used as a dose calculation algorithm for bolus optimization.

The current optimization algorithm has limited simulation of scatter effects in the lateral direction to improve optimization speed. This causes a difference between the actual final calculation and the optimization stage. If a secondary optimization with more precise calculations is added after the first optimization, the accuracy of the optimization algorithm can be improved. Therefore, we will try to improve the dose calculation algorithm and optimization algorithm as future research.

The above studies have not yet been validated using measurements. Therefore, as a future study, we would like to manufacture the optimized bolus using a 3D printer and verify its clinical use through measurement.

5 Conclusion

In this study, we developed the electron dose calculation engine and optimization system to build a bolus optimization system for ECT and evaluated its feasibility.

A Python Script to Analyse Treatment Planning Throughput

Ezhilalan Ramalingam

Department of Radiotherapy Physics, Cork University Hospital, Cork, Ireland

Abstract: The aim of this study is to estimate radiotherapy treatment planning throughput from the data extracted from our Oncology Information System (Mosaiq, OIS). We have developed an in-house Python script[1] to analyse the data exported from the OIS. The Quality Check List (QCL) data captured between April 2021 and March 2022 and from April 2022 to March 2023 by our treatment planning team has been used in the data analysis. The QCL data includes but not limited to planning categories such as radical, palliative, and re-planning. The OIS data has been exported in an Excel file format, preprocessed to eliminate extraneous information and saved as a Comma Separated Value (CSV) file. Tasks like image fusion, contouring, and the reconstructions of previous treatments are inherent components of the planning process and have been excluded from the data analysis. Measure of central tendency and dispersion such as mean, median, mode, and standard deviation have been documented for the daily, weekly, and monthly treatment planning throughput.

While the throughput distributions of individual planners deviate from normality, the collective probability distributions of all planners in the study display nearly normal (symmetrical) distributions. The selection of the specific time period (April to March) for analysis aligns with our center's leave calendar, ensuring the inclusion of annual leave taken by the planners involved in the study.
From April 2022 to March 2023, an average of 3.9 planners generated a mean of 9.5 treatment plans per day. Similarly, the mean number of treatment plans produced per week by an average of 6.8 planners is 45.6, and the mean number produced per month by an average of 7.9 planners is 197.7. With a total of 249 working days, averaging 4.8 days per week, the daily throughput can be approximately scaled to weekly ($9.5 \times 4.8 = 45.6$), and the weekly figure can be approximately scaled to monthly ($45.6 \times 4.33 = 197.5$). From April 2021 to March 2022, an average of 3.9 planners generated a mean of 7.7 treatment plans per day. Similarly, the mean number of treatment plans produced per week by an average of 7.3 planners is 35.9, and the mean number produced per month by an average of 8.8 planners is 146.8. With a total of 230 working days (with approximately 3 weeks lost due to a cyber-attack), averaging 4.7 days per week, the daily throughput can be approximately scaled to weekly, and the weekly figure can be approximately scaled to monthly, as outlined earlier. Due to variations in individual planner's work patterns, their throughput also needs to be analysed independently.

1 Introduction

Due to recent advancements in radiotherapy treatment techniques, treatment planning process in general has become more complicated and time-consuming. As a result, managing the treatment planning workload coming into the department is crucial for efficiency and smooth functioning. A well-organised planning department, equipped with efficient workflows and adequate staffing, minimises bottlenecks in day-to-day operations. However, in situations where the workload significantly increases or when there is a shortage of staff, managing the planning workload can be challenging, especially if it’s uncertain how many plans the currently available staff can safely handle. Nonetheless, with knowledge of treatment planning throughput, extreme fluctuations in workload can be efficiently managed by implementing proper control measures such as assurance of adequate staffing levels and means to monitor workload periodically. In this study, we aim to estimate our treatment planning throughput through the analysis of data recorded in the Mosaiq OIS.

2 Materials and Methods

For fast data extraction and analysis, an Excel spreadsheet can be used. However, handling large amounts of data in Excel becomes impractical without the use of extensive Visual Basic (VB) codes running in the background or resorting to laborious manual data manipulation to derive meaningful insights from the collected data. To overcome this hurdle, a Python script (version 3.8) was written to read and process the Excel data extracted from the OIS. For the data analysis, a Python package called pandas (version 1.2.3) was used. The package Pandas is a versatile, powerful, and efficient open-source Python library that can be used to read, manipulate, and analyse data from a CSV file. Our Python script includes the pandas and matplotlib packages for data analysis and plotting, respectively. The script reads the data from a CSV file (created from an Excel file), forms a Data Frame (DF), and manipulates the data depending on the user input. The Excel file exported from the OIS was

preprocessed to include only relevant data columns such as the date of task capture, patient identification (ID), task captured, and planner initials. The filtered data was then saved as a CSV file. The Python script utilises the pandas library to read data from the ‘date’, 'task' and 'planner’s initial (Dosimetrist-dos) columns, storing them as a Data Frame (DF) for further manipulation. The DF is then processed to a specific set of tasks in the 'task' column (e.g., '1B Planning' & '2B Planning') for a given number of planners in the 'dos' column. The script then calculates various parameters, including the total number of days, weeks and months during which the specified tasks were captured. In addition, the total number of tasks (plans) per unique planner is also reported. Metrics such as the total number of unique planners present per day, per week, and per month are also reported. The script is capable of generating bar charts to visualise the number of tasks captured per day, per week, and per month. Three separate scripts were developed for daily, weekly, and monthly data analysis. Descriptive statistical metrics such as minimum, maximum, mean, mode, standard deviation, skewness, and kurtosis have been calculated. To validate the script, it was initially tested on a small data file collected for a month from the OIS. The results were then compared against manually calculated figures directly in an Excel file.

3 Results

The table below (Table 1) presents the central tendency statistics calculated for the data collected over the two-year period mentioned earlier. Planning throughput for daily, weekly, and monthly periods is depicted, aggregating contributions from all planners in the study. However, it's important to note that, due to varied work patterns, the throughput for individual planners can only be accurately calculated from the specific data collected for each planner. Table 1 provides a basis for estimating the combined throughput from the entire dataset.

Central tendency and dispersion statistics	April 2022 to March 2023			April 2021 to March 2022		
	daily	weekly	monthly	daily	weekly	monthly
Mean number of plans	9.5	45.6	197.7	7.7	35.9	146.8
Median number of plans	9.0	44.0	187.5	7.0	35.0	163.5
Mode number of plans	10.0	33.0	(n/a)	5.0	46.0	(n/a)
Std. deviation	4.3	13.4	43.9	3.7	11.1	46.1
Minimum number of plans	1.0	16.0	149.0	1.0	8.0	47.0
Maximum number of plans	21.0	79.0	294.0	20.0	59.0	216.0
Skew	0.6	0.2	1.1	0.6	-0.2	-1.1
Kurtosis	0.1	0.1	0.6	0.4	-0.3	1.1
Mean number of planners	3.9	6.8	7.9	3.9	7.3	8.8
Total number of plans	2372.0	2372.0	2372.0	1761.0	1761.0	1761.0
Total time (days, weeks, months)	249.0	52.0	12.0	230.0	49.0	12.0

Table-1, the central tendency and dispersion of the throughput data calculated for the two consecutive years.

The figures (Figure 1 and Figure 2) display the histogram and the Quantile-Quantile (QQ) plot of the weekly planning throughput for the period April 2022 to March 2023 respectively.

Figure-2, weekly throughput QQ plot

4 Discussion

The throughput of radiotherapy treatment planning can be influenced by numerous factors, including planner experience, plan complexity, the efficiency of the planning system used, and the collaborative influence of other Multi-Disciplinary Team (MDT) members involved in the process. The rate of treatment plan production is likely to be affected by all of these aforementioned factors. By analysing the data captured in the Oncology Information System (OIS), treatment planning throughput can be reasonably estimated. In our study, the estimated planning throughput was particularly influenced by factors such as planner work patterns and experience. To mitigate this impact, we exclusively included experienced planners in the study, examining both combined and independent throughput for all planners involved. While individual planner statistics are not presented in this overview, such data can be easily obtained by applying appropriate filters within the Python code.

5 Conclusion

From our study, it can be concluded that treatment planning throughput can be consistently estimated from the data collected from an OIS using an independent computer programming language such as Python. The time required to develop such a system is a one-time effort, and an appropriately validated script can be applied repeatedly for any length of data. Additionally, this method can be employed periodically to monitor workload, allowing for proactive measures to be taken as needed.

Development of dynamic collimator mixed beam radiotherapy to explore the dosimetric benefits of non-coplanar and mixed photon-electron beam setups

Abstract Dynamic collimator mixed beam radiotherapy (colli-DYMBER) is a novel treatment technique that uses non-coplanar table angles, dynamic gantry and collimator rotation, mixed photon-electron beams/arcs, and intensity modulation.
The aim of this work is to solve the beam angle optimization (BAO) problem dosimetrically using a direct aperture optimization (DAO)-based pathfinding strategy that iteratively adds promising apertures to form paths. We show how the developed dosimetrically motivated pathfinding strategy can be used to investigate the dosimetric benefit of using non-coplanar beam setups and/or mixed photon-electron modality by comparing colli-DYMBER plans with non-coplanar photon-only plans (dynamic collimator trajectory radiotherapy, colli-DTRT), coplanar mixed beam plans (coplanar-DYMBER), and coplanar photon-only plans (coplanar-VMAT) for three clinically motivated cases. The dosimetric benefit observed by incorporating non-coplanar/mixed beam setups varied for the considered cases.

1 Introduction

Ongoing research in radiotherapy aims to improve treatment quality by developing novel techniques that maximize organ-at-risk (OAR) sparing while maintaining treatment efficacy. Current clinic practices include intensity modulated radiation therapy (IMRT), where intensity modulation is performed using a photon multileaf collimator (pMLC) [1], and volumetric modulated arc therapy (VMAT) where the dynamic gantry rotation during beam on improves delivery efficiency without compromising the dosimetric plan quality from IMRT [2]. In recent years, non-coplanar radiotherapy and mixed beam photon-electron beam radiotherapy have been explored to further improve the dosimetric plan quality [3-7]. Bertholet et al. explored dynamic collimator trajectory radiotherapy (colli-DTRT), where non-coplanar photon-only paths were determined using dosimetrically motivated pathfinding based on iterative fluence map optimization (FMO) and beam elimination [4]. In the work of Guyer et al., coplanar mixed photon-electron arcs (Arc-MBRT) were manually set for breast cases to improve delivery efficiency without compromising the dosimetric plan quality compared to Static-MBRT (with static electron fields) [5]. However, the benefit from non-coplanarity or mixed photon-electron treatments varies for different treatment sites and differences in the pathfinding strategy or beam setup raise difficulties in discerning the origin of the outcomes.

A novel treatment technique called dynamic collimator mixed beam radiotherapy (colli-DYMBER) exploits different degrees of freedom (DoFs) offered by the clinical machines: dynamic gantry rotation, multiple different table angles, dynamic collimator rotation, and mixed photon and electron beams, both intensity-modulated with pMLC. The beam angle optimization (BAO) problem for colli-DYMBER is solved with a dosimetrically motivated pathfinding approach that simultaneously optimizes photon and electron contributions based on hybrid-direct aperture optimization (H-DAO) [6].

In this work, we show how the pathfinding approach for colli-DYMBER can be used to investigate the dosimetric benefit of non-coplanarity/mixed beam modality on the treatment plan. The dosimetric plan quality was compared to variations of colli-DYMBER by enabling/disenabling the non-coplanarity or mixed beam feature using the same pathfinding strategy for three clinically motivated cases.

2 Materials and Methods

The dosimetrically motivated pathfinding approach for colli-DYMBER is illustrated in Fig. 1.

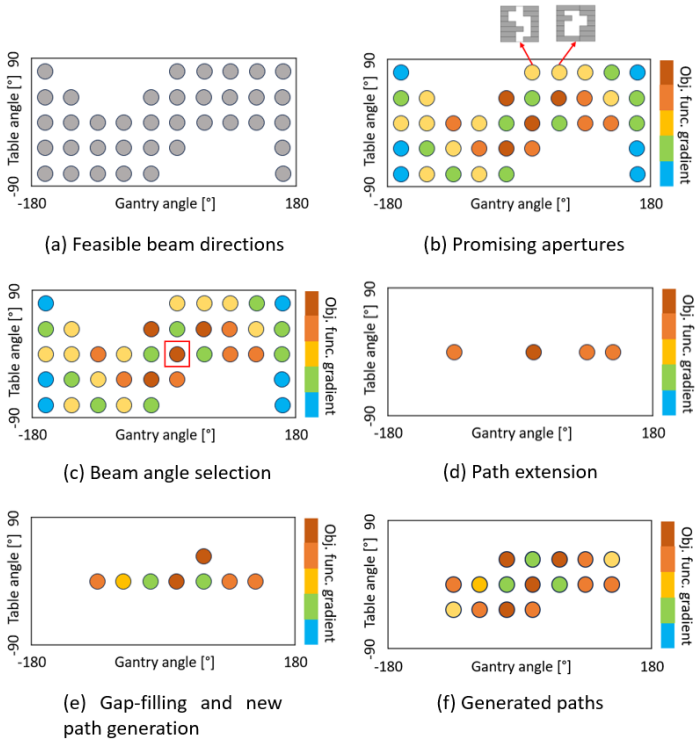

Fig. 1 Pathfinding approach for colli-DYMBER. Favorable beam directions have steeper objective function gradients (red) while unfavorable beam directions have shallower gradients (blue).

First, the user defines the resolution (10° used in this work) along the gantry and table axes, setting up a grid of map points of different gantry-table angle combinations for different beam qualities: 6 MV (photon), 6, 9, 12, 15, 18, and 22 MeV (electron). The collimator angle is aligned with the superior-inferior axis of the patient (constant for 0° table angle). A fixed source-to-surface distance (SSD) of 80 cm is used for electron beams/arcs to limit electron in-air scattering resulting in non-isocentric electron arcs. Beam directions leading to collisions are excluded by a collision prediction tool [7], as well as beams coming through the end of the CT stack. Electron beams with insufficient range to reach the target or impinging on the table before reaching the patient are eliminated from the set of feasible beam directions (Fig. 1a). Each beam is discretized into beamlets of 5 x 5 mm^2 and the beamlet dose calculation is performed using voxel grids of 5 x 5 x 5 mm^3. A column generation algorithm is used to iteratively generate promising apertures for all feasible beams and select the beam direction with the most promising aperture (Fig. 1b, 1c) based on the gradient of the objective function, defined as a weighted sum of dose-volume and generalized equivalent uniform dose objectives. The selected beam directions are formed into paths and the maximum number of paths allowed is defined by the user. In this path formation process, non-adjacent beams can also be selected (Fig. 1d) and the gap between them is subsequently filled with intermediate beam directions to form connected paths (Fig. 1e). The path formation terminates when a user-defined total gantry angle range is achieved, or no more promising apertures are available (Fig. 1f).

The colli-DYMBER paths are resampled to increase the gantry angle resolution to 5° and a second beamlet dose calculation (with finer voxel grids of 2.5 x 2.5 x 2.5 mm^3) is performed. A second H-DAO is performed to determine the intensity modulation along the resulting colli-DYMBER paths, optimizing the aperture weights and shapes [6]. A final dose calculation considering the exact MLC model is then performed with subsequent monitor unit (MU) weight re-optimization using a limited-memory Broyden-Fletcher-Goldfarb-Shanno algorithm.

Both beamlet and final dose calculations are performed using the Swiss Monte Carlo Plan (SMCP) integrated beam models and dose calculation algorithms VMC++ [8] and macro Monte Carlo [11-13] for photon and electron beams, respectively.

The treatment planning process is used to create plans for a TrueBeam system (Varian, a Siemens Healthineers Company, Germany) and three clinically motivated cases have been considered in this study: one brain (30 x 2 Gy), one breast (16 x 2.65 Gy), and one pelvis (28 x 1.8 Gy) case. All prescriptions referred to the median dose to the planning target volume (PTV). For each case, four plans were created to investigate the potential benefit of using non-coplanar beam setups or mixed photon-electron beams in improving OAR sparing while maintaining similar target coverage:

- colli-DYMBER plan (non-coplanar, mixed beam)
- colli-DTRT plan (non-coplanar, photon beams only)
- coplanar-DYMBER plan (coplanar, mixed beam)
- VMAT plan (coplanar, photon beams only) as reference

For colli-DYMBER and its variations, a maximum of 7 arcs and a total gantry angle range of 720° were used for the brain and pelvis cases. For the breast case, a maximum of 10 arcs for a 1080° total gantry angle range were used. VMAT plans with the same total gantry angle range as the corresponding colli-DYMBER plans were created for the brain (2 arcs), breast (4 arcs), and pelvis (4 arcs) cases. Dose distributions and differences in dosimetric endpoints were evaluated and compared. Paddick conformity index (CI) and homogeneity index (HI = $(D_{2\%} - D_{98\%})/D_{50\%}$) were calculated for all plans.

3 Results

For the mixed photon-electron plans, the photon and electron contributions to the mean PTV dose are reported in Table 1. The electron contribution increases when restricting to use only coplanar beam setups. The highest electron contribution observed is 39.2% in the coplanar-DYMBER plan for the pelvis case.

		colli-DYMBER	coplanar-DYMBER
Brain case	X	97.6%	75.6%
	E	2.4%	24.4%
Breast case	X	94.5%	88.9%
	E	5.5%	11.1%
Pelvis case	X	61.0%	60.8%
	E	39.0%	39.2%

X = photon contribution to mean PTV dose; E = electron contribution to mean PTV dose.

Table 1 Photon and electron contributions to mean PTV dose for colli-DYMBER and coplanar-DYMBER for the considered cases.

Similar target conformity and homogeneity are reported for all cases as shown in Table 2.

		colli-DYMBER	colli-DTRT	coplanar-DYMBER	VMAT
Brain case	CI	**0.499**	0.496	0.497	**0.499**
	HI	**0.088**	0.089	0.100	0.100
Breast case	CI	**0.498**	**0.498**	0.497	**0.498**
	HI	**0.074**	0.079	0.079	0.079
Pelvis case	CI	0.493	0.495	**0.496**	0.486
	HI	**0.059**	0.073	**0.059**	0.078

Table 2 Conformity and homogeneity indexes for the considered cases. The best values for each row are highlighted in bold.

Fig. 2 illustrates the difference in dosimetric end-points for the considered cases relative to VMAT for colli-DYMBER, colli-DTRT, and coplanar-DYMBER.

Substantial dose reductions to OARs were observed for the non-coplanar techniques compared to VMAT for the brain case (Fig. 2, top). Mean doses to the OARs were reduced by 1.2-4.7 Gy for colli-DYMBER and colli-DTRT compared

to VMAT. $D_{2\%}$ were reduced by 1.1-14.6 Gy for serial organs. coplanar-DYMBER also reduced D_{mean} and $D_{2\%}$ for the considered organs by 0.4-3.0 Gy and 1.1-9.8 Gy, respectively, compared to VMAT, except for the ipsilateral optic nerve where $D_{2\%}$ was increased by 7.1 Gy.

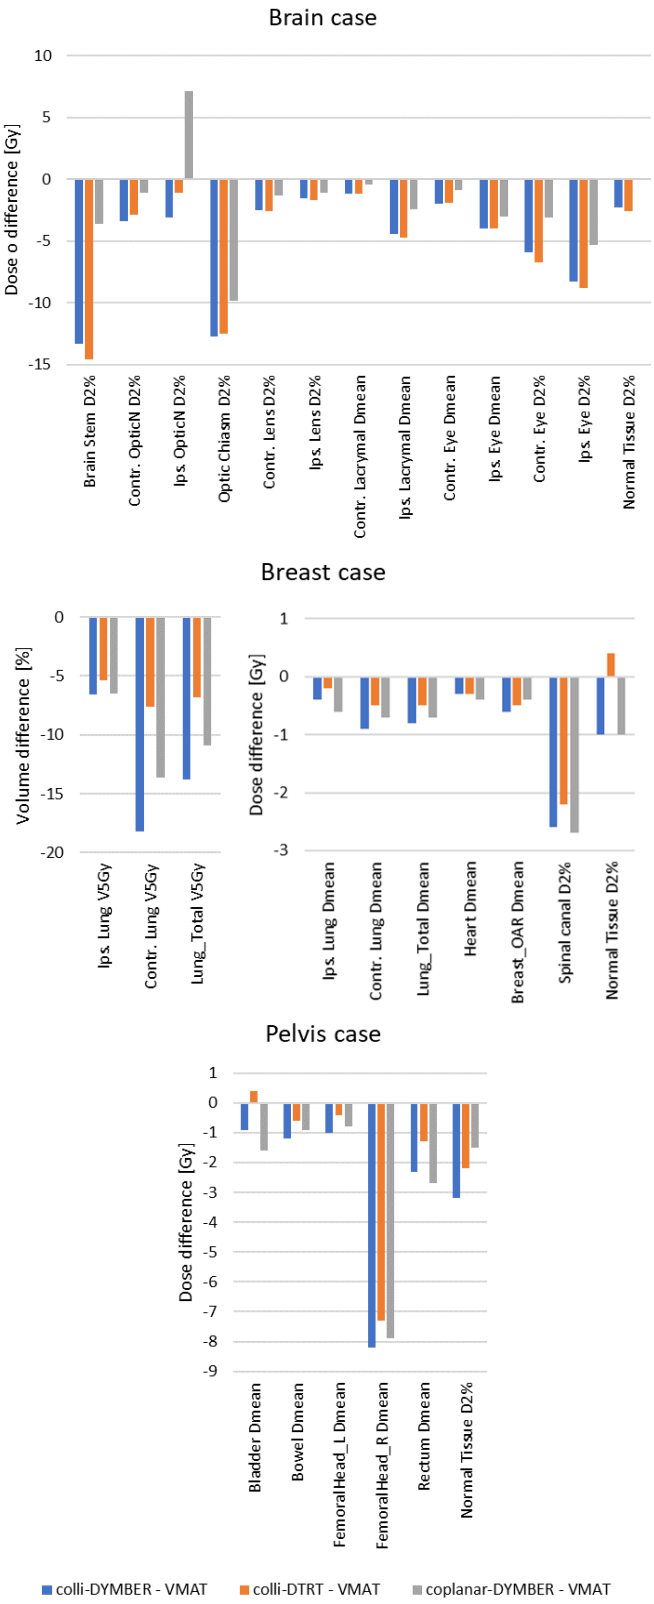

Fig. 2 Differences in dosimetric end-points for colli-DYMBER (blue), colli-DTRT (orange), and coplanar-DYMBER (gray), compared to the VMAT plan for the brain (top), breast (middle), and pelvis (bottom) case. Negative values indicate a reduction in OAR dose compared to VMAT.

For the breast case (Fig. 2, middle), a larger reduction in V_{5Gy} to both lungs is observed for coplanar-DYMBER compared to colli-DTRT, while colli-DYMBER obtained slightly lower doses to the contralateral lung compared to coplanar-DYMBER. Reductions in mean doses to the OARs are below 1.0 Gy for the non-coplanar/mixed beam techniques compared to VMAT.

Greater reductions in mean doses to OARs were also achieved by coplanar-DYMBER compared to colli-DTRT for the pelvis case (Fig. 2, bottom), except for the near maximum dose to the normal tissue, which is lower when non-coplanar beams were used. Further dose reductions to the bowel and femoral heads were achieved by the colli-DYMBER plan compared to coplanar-DYMBER, albeit at the cost of increased mean doses to the bladder and rectum. Fig. 3 illustrates the axial dose distributions for the pelvis case.

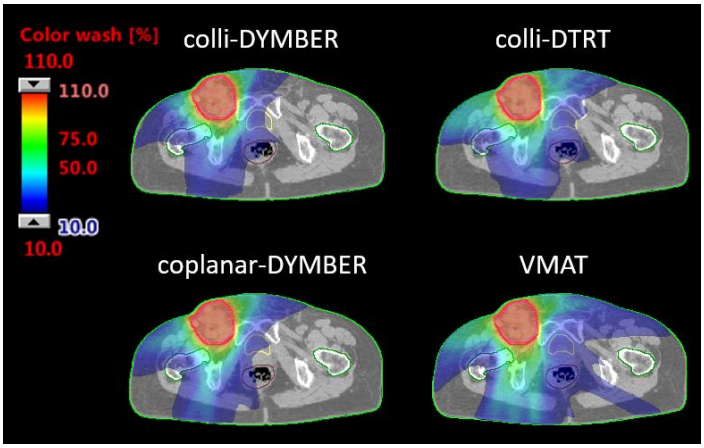

Fig. 3 Dose distributions on an axial plane for the pelvis case.

4 Discussion

In this work we explored the dosimetric benefits of non-coplanar photon/electron fields/arcs with a novel treatment technique called colli-DYMBER, combining non-coplanarity, mixed beam, and dosimetrically motivated BAO. The increased DoF was expected to improve the dosimetric plan quality owing to the increased solution space. Bertholet et al. investigated colli-DTRT using an FMO-based dosimetrically motivated pathfinding strategy. However, mechanical constraints for the delivery were not taken into account during the path determination process and this could lead to degradation in the dosimetric plan quality for the final plan. Mueller et al. investigated DYMBER which combined dynamic photon trajectories with static electron fields [6]. The addition of electrons to dynamic photon trajectories brought dosimetric benefits in OAR sparing, but only static electron fields were considered which were manually set up. Mixed photon/electron arcs have also been investigated by Guyer et al. in a technique called Arc-MBRT, where the use of manually defined

coplanar photon and electron arcs outperformed the photon-only plans dosimetrically [7].

In these studies, the differences in the pathfinding strategy used or in the planner's experience to set up beams manually pose difficulties in comparing the different techniques and identifying the origin of the benefit observed (non-coplanarity or combination of photons and electrons). With colli-DYMBER, we can "enable/disable" the non-coplanarity or mixed beam feature using the same optimization algorithm and dosimetrically motivated BAO. The benefit of non-coplanarity and mixed beam modality can be identified conclusively from the comparison between variations of colli-DYMBER enabling the comparison between the different techniques.

For the cases analyzed in this study, the increased DoF improved the dose distributions compared to coplanar photon treatments overall. For the brain case, non-coplanarity brought a larger benefit in improving the dose distribution compared to the inclusion of electrons, suggesting that the use of electrons might not be needed if favorable non-coplanar beam directions can be found. On the other hand, for the breast case, the mixed beam modalities brought the largest improvement compared to VMAT. The additional benefit of non-coplanarity was not substantial. For the pelvis case, mixed beam was also revealed to be beneficial in improving the dosimetric plan quality. This might be explained by the fact that electrons become more important to spare critical organs for cases where the collision-free space is limited (Fig. 2, Table 1). A study with a larger cohort is needed to generalize the findings of this work, as well as the assessment of delivery times for the different techniques.

5 Conclusion

We developed a dosimetrically motivated BAO for colli-DYMBER which enabled equitable comparisons with its variants by selectively disabling one of the features. By combining both non-coplanarity and mixed beam qualities, the dosimetric plan quality can be improved compared to coplanar photon-only treatments. For the considered cases, a reduction of doses in critical organs has been generally observed for the proposed method, suggesting that colli-DYMBER is a promising treatment technique for future radiation therapy treatments.

Abstract Adaptive radiotherapy shows potential in enhancing patient outcomes through the acquisition of longitudinal images during treatment, facilitating the management of anatomical changes that happen during treatment. Given the resource and time cost of adaptive treatment, careful consideration is put to the selection of patients who might benefit from it. The goal of this work is twofold. First, it investigates the sensitivity of proton therapy adaptation rate to various residual setup errors in patients with esophageal cancer. Second, four different fully automatic strategies for online adaptive planning are implemented and compared. These strategies combine deformable registration and deep learning based methods, both for contouring and planning. Our preliminary results serve as a proof of concept for the feasibility of the presented planning strategies, which are compared to a fully manual approach in terms of timing and target coverage (D98%). We show that, on the single patient used for this preliminary study, the four strategies achieve similar D98% as the manual approach while being much faster. The clinical significance of these results still needs to be confirmed on a larger cohort of patients.

1. Introduction

Adaptive radiotherapy (ART) aims at ensuring an optimal treatment for the patient despite anatomical changes, by acquiring longitudinal images (e.g., weekly or daily) and adjusting the treatment plan to the new anatomy (1). ART has shown potential for improving patient outcomes (2) although its implementation is known to be resource intensive. When performed offline, clinicians spend some time (i.e., a few hours) to prepare the new treatment. In contrast, online ART requires highly optimized workflows that ideally generate plans in a few minutes, since the patient is waiting on the treatment couch. Commercial solutions for streamlined online adaptive intensity-modulated radiotherapy (IMRT) are becoming available, achieving adapted plans within 15 min up to an hour (3). These solutions typically integrate artificial intelligence (AI) (4,5) and deformable registration (5) for automatic contouring, as well as fast plan optimization algorithms through template-based approaches (6).

In the case of protons (PT), online adaptive solutions are lagging behind (4,7). Indeed, treatment planning is typically slower and more challenging in PT, since it entails robust optimization to be safe against range uncertainties in addition to setup uncertainties, delineation errors, etc. already addressed in conventional radiotherapy (XT). Therefore, clinical goals are first often evaluated on the initial plan recomputed on the new anatomy, here referred as the NA dose, and if these goals are not met, only then the patient should be considered for adaptation. After the patient gets selected for adaption, the adaptation process should be streamlined for the sake of fast clinical workflow and high patient throughput, while still minimizing the intra-fractional motion. Consequently, in this work, we present a comparison of online adaptive strategies for proton therapy (OAPT), all relying on fully automated methods. Since AI-guided treatment planning and contouring has recently gained popularity, the proposed methods partly rely on such techniques.

Esophageal cancer (EC) is the 8th most common cancer type worldwide and is associated with a severe reduction in the patients quality of life. Locally advanced EC is typically treated with neoadjuvant chemoradiotherapy followed by surgery (8). PT has shown to improve toxicity by better sparing organs-at-risk (OARs) like lungs and heart.

This study aims at investigating online adaptive strategies for PT from the perspective of treatment plan optimization and evaluation. First the adaptation rate for several EC patients will be evaluated, in agreement with the PROTECT clinical trial guidelines (9). The benefits of using adaptation for this cohort of patients are also reported. Secondly, the first results obtained by comparing automated strategies, including AI-models for OARs contouring and dose prediction, will be presented.

2 Materials and Methods

Patient cohort and planning strategies

Between 2016 and 2018, a cohort of 40 patients diagnosed with locally advanced EC underwent neoadjuvant chemoradiation therapy followed by surgery at the University Hospital of Leuven (UZLeuven). We received planning CT scans (pCT) and corresponding manually generated contours for these 40 patients. To ensure database consistency and quality, all patients were systematically planned for proton beam scanning (PBS), adhering to the treatment planning guidelines outlined in PROTECT (5). The prescribed treatment regimen involved a total dose of 50.4Gy delivered over 28 fractions.

Among the patient cohort, 18 out of 40 individuals underwent a repeated CT scan (rCT) after approximately 3 weeks

of treatment, corresponding to about 15 treatment fractions. New contours were delineated on these rCT scans.

Adaptation rate

NA doses were generated by recomputing the initial plan on the rCT scans. When evaluating this NA dose on the new anatomy, it is also important to address its robustness against treatment delivery errors. Different setup error strategies have been investigated with residual setup uncertainties of 2, 4, and 5 mm, respectively. We may justify the use of these different strategies by assuming that the new image realizes a greater or lesser part of the intra-fraction residual setup error, which is added to an isocenter positioning error or contouring errors. Corresponding adaptation rates are reported.

Benefits of adaptation for EC

Additionally, the no-adaptation strategy (NA dose) was compared with a fully manual approach (MA dose) in terms of dose volume histograms (DVH) that are important in the PROTECT protocol. Robustness evaluation was also conducted with a 7mm setup error for the manual strategy and 2, 4 and 5 mm of residual setup error for the no-adaptation strategy.

OAPT strategies

Four different OAPT strategies were compared with the fully manual approach. These different strategies were implemented on the rCT scans from our 18 patients and are represented in Figure 1.

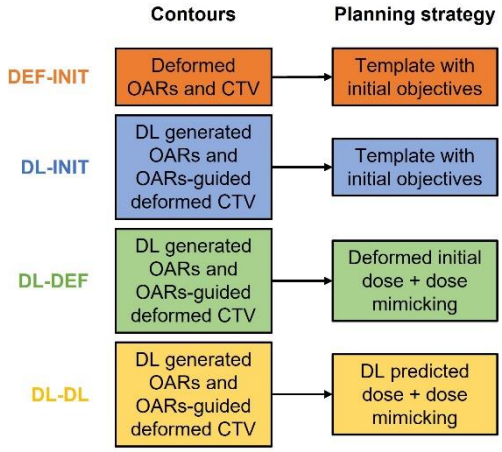

Figure 1: Workflow illustrating the four OAPT strategies.

The strategies were implemented on a Raystation 2023B Software by using scripted actions, apart from deep learning (DL) models, which have been trained and used for inference on GPUs hosted by the *Consortium des Equipements de Calculs Intensifs (CECI).*

a. Contour delineation

In DEF-INIT, contours of OARs and CTV were mapped from the pCT scan to the rCT scan using deformable image registration (DIR).

In DL-INIT, DL-DEF and DL-DL a nnUNet model *(10)* is used for automated OARs contouring. The nnUnet model was trained on our database of 40 EC patients with pCT

scans, using a k-fold cross-validation strategy. Careful selection of models used for inference on the 18 rCTs was conducted, to avoid selecting a model already trained on corresponding patient's pCT. The model predicts contours of 9 OARs per patient in XX seconds on a TeslaA100_80 GPU. Subsequently, DL generated OARs, identified as structures influencing the shape of the iCTV, are used to guide a DIR which later serve for iCTV mapping from the pCT scan to the rCT scan.

b. Planning strategies

In DEF-INIT and DL-INIT, initial optimization objectives, originally specified in the pCT scan, are copied in a newly generated plan in the rCT scan, prior to running an optimization for 200 iterations. These objectives are defined on the deformed and nnUNet-generated contours, respectively.

In DL-DEF, the initial dose, originally defined in the pCT scan, is mapped to the rCT scan using DIR. A dose mimicking strategy is then applied to this deformed dose. It uses isodoses-based and voxelwise least square error optimization. Additionally, conventional weighted objectives on the CTV are added to the optimization problem, before running the optimization process for 60 iterations.

In DL-DL, a HD-Unet *(11)* is cascaded with the previously described nnUnet. This second model is used for inference of dose distribution on the rCTs and corresponding contours previously generated by the nnUnet. The HD-UNet was trained with a k-fold cross-validation on the 40 pCTs and corresponding contours. Again, we performed a careful selection of the model used for inference on the rCTs. More information about the model training can be found in *(11)*. Our HD-UNet predicts a dose distribution for a patient in 3.76 seconds on a TeslaA100_80 GPU. The dose mimicking strategy is applied on the HD-UNet generated dose distribution.

3 Results

Adaptation rate

Figure 2 provides the adaptation rate for each patient and shows the PROTECT criteria for adaptation after 3 weeks of treatment in the nominal and worst-case scenarios. As observed in Figure 2, three patients (17%) require adaptation based on the nominal criteria only. When considering worst-case scenario criteria (V95% iCTV > 95%), two more patients require adaptation with a 5mm residual setup error (28% in total) and only one additional patient for 4mm and 2mm residual setup errors (22%). The

PROTECT criteria on OARs are not shown in this Figure since they did not trigger any adaptations.

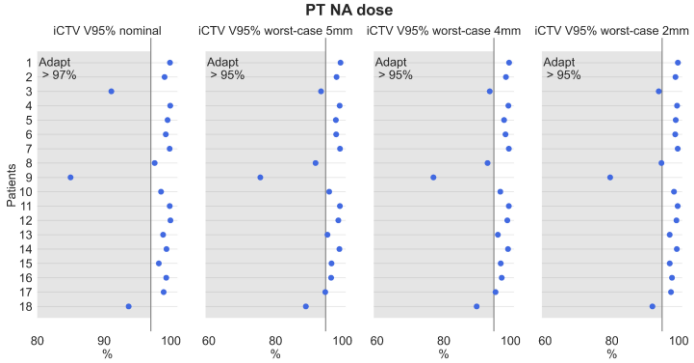

Figure 2: Criteria for adaptation on the CTV in the nominal case and worst-case scenario computed with a 2, 4 or 5mm residual setup errors. The range uncertainty for plan evaluation is 2.6%.

Benefits of adaptation for EC

The second experiment emphasizes how patients would benefit from adaptation. This is depicted in Figure 2. In the nominal scenario, the MA dose tends to have a higher target coverage than the NA dose, both in XT and PT, with an average difference between V95% to iCTV of more than 2%.

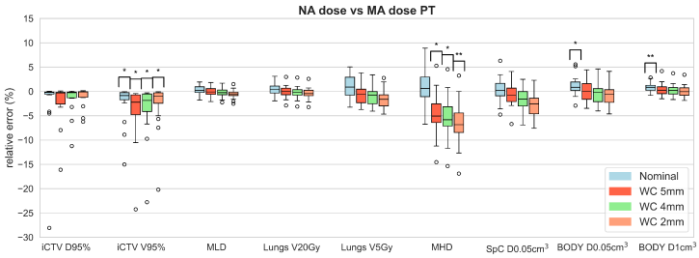

*Figure 3: Comparison between NA dose and MA dose. Boxplots show the error (NA dose - MA dose) relative to the prescription (50.4Gy) or to the structure's volume. Worst-case (WC) scenarios are computed with residual setup errors of 2, 4 or 5mm for the NA dose and a setup error of 7mm for the MA dose. * indicates a statistically significant difference (p = 0.05) between NA dose and MA dose, ** indicates a highly statistically significant difference (p = 0.001) between NA dose and MA dose.*

Moreover, the nominal dose to most organs at risk is on average higher in the NA dose than in the MA dose. However, we can observe a general trend while diminishing the residual setup error with a NA dose having a decreasingly lower dose to OARs in the worst-case scenario. Sometimes, this dose to OARs becomes even lower than the MA dose. For the mean heart dose (MHD), the different worst-case scenarios present a NA dose which is significantly lower than the MA dose (p = 0.05).

Comparison of OAPT Strategies

The different OAPT strategies were compared to the manual approach in terms of D98% to the iCTV. Additionally, timings for contours and plan dose generation are also reported in Table 1. These results were observed on a single patient and are preliminary results of a bigger study integrating our 18 patients with a rCT scan.

In the nominal scenario, all 4 OAPT strategies achieve a D98% which is comparable to the manual approach. It should be noted that the strategy involving dose deformation (DL-DEF) does not reach a D98% of 95% of the prescription (47.88 Gy). Regarding timings, the bottleneck step remains the planning strategy, and the associated time depends on the chosen number of iterations.

	D98%		Timing		
	Nom. (Gy)	*WC (Gy)*	*Contours*	*Planning strategy*	*Total*
Manual	49.07	48.98	Hours	Hours	Hours
DEF-INIT	48.95	47.94	80 s	1055 s	1135 s ~ 19 min
DL-INIT	49.09	48.23	60 s + 70 s	1055 s	1185 s ~ 20 min
DL-DEF	49.04	47.86	60 s + 70 s	360 s	490 s ~ 8 min
DL-DL	49.36	48.43	60 s + 70 s	3.8 x 5 folds + 455 s	585 s ~ 10 min

Table 1: Comparison of the manual adaptation strategy with the proposed OAPT strategies. In DL-INIT, DL-DEF and DL-DL, the time needed for DL OARs segmentation is summed with the time needed for OARs-guided iCTV mapping. In DL-DL, 5 folds are used for dose prediction. The corresponding prediction time is thus summed with the time needed for dose mimicking.

4 Discussion

Adapting a plan during treatment requires significant computational and time resources. Therefore, assessing the need for adaptation is important. This study reports the adaptation rate for different robust evaluation scenarios, with different residual setup errors. The choice of the residual setup error for evaluation must be conducted carefully as this will influence the number of patients requiring adaptation. However, the rationale behind the different options for residual setup uncertainties lies in the fact that intra-fractional motion (other than breathing) is not or at least not totally realized and observed in the newly acquired image. Moreover, unpredicted isocenter shifts and delineation errors need to be accounted for. Our results suggest that robustly optimized PT plans for EC patients may lead to treatments that are often robust to anatomical changes. Indeed, we observe that few patients require adaptation while treated with PT and also that the sensitivity of PT dose to the choice of the residual setup error is relatively low, with only one extra patient being selected for adaptation while varying the residual setup error. However, these results were obtained on a small cohort of 18 patients. Different conclusions could be drawn from a larger batch of patients.

Additionally, results of the second experiment demonstrate that in the nominal scenario, adaptation may lead to a safer target coverage and to lower dose to OARs for EC patients. However, only a few of these improvements reach statistical significance and results for worst-case scenarios are sometimes worse for the MA dose. This might be caused by the fixed margins used for optimization and evaluation of adapted dose in this work. Existing research suggests that ART with reduced margins may enhance organ sparing without compromising target coverage (12), leading to a potential reduction in normal tissue complication probability (NTCP) (13). These findings indicate that, despite evidence for dose distribution improvements, ART with fixed margins may not provide significant clinical benefits and clinical resources might be put to better use.

Preliminary results for OAPT strategies comparison suggest that close to manually optimized D98% can be obtained with all four strategies. However, DL-generated contours associated with initial objectives optimization (DL-INIT) or with DL dose prediction and dose mimicking (DL-DL) exhibits a larger robustness to treatment uncertainties than the other two strategies. It is however necessary to validate this intuition on a larger cohort of patients. This work complements the work of (14) and a broader comparison with other OAPT strategies from the literature could be of interest.

The advantage of the proposed OAPT methods is that they require no manual intervention. All actions were scripted and could be obtained with a single click. In methods integrating a dose mimicking step on a reference dose, fewer iterations were used for optimization, shortening the time needed for the whole process. However, it should be noted that timings for data transfer and conversion between the CECI GPU and RayStation software were not included. It was considered that with a thoughtful end-to-end workflow and collaboration to integrate DL-models in RaySearch software, these steps would not be necessary.

5 Conclusion

To conclude, this work is a step towards fast and automated online plan adaptation and gives us insight about adaptation rates for EC patients. Our results show that the choice of the residual setup error will slightly affect the number of patients requiring adaptation in PT. It serves also as a proof-of-concept for the implementation of 4 fully automated online adaptive proton therapy strategies.

[4]Department of Radiation Oncology, Johns Hopkins University, Baltimore, MD, USA

Abstract. Dose volume histogram predictions from a custom random forest ensemble model were integrated into an automated heuristic planning engine for unattended plan generation. Optimization objectives are derived from the prediction of the 5% quantile doses at given volumes. Two optimization iterations were performed separated by an intermediate dose calculation. IMRT and VMAT plans were generated in batch mode for fifty previously treated prostate cancer patients and compared to the clinically approved and treated plans. Doses covering large portions of bladder and rectum were substantially lower compared to reference, with 9 Gy and 7 Gy reductions in D80%, respectively. Prescription dose coverage of target volumes was not compromised, and homogeneity was comparable. Combining personalized dose predictions with an automated planning engine has the potential to efficiently generate clinically acceptable patient-specific treatment plans in a standardized way. This would decrease planning staff workloads and have the potential to increase radiotherapy access in low- and middle-income countries, and underserved areas.

1 Introduction

Therapeutic radiology and radiation oncology are technology-driven medical sub-specialties and over the last two decades have become increasingly and pervasively computerized. Advanced radiation therapy (RT) planning and delivery would be infeasible without the use of advanced software for image processing and treatment planning.

Artificial intelligence (AI) driven models for automatic plan generation and dose prediction provide excellent opportunities to increase efficiency and standardization of the treatment planning workflow while increasing the use of individualized medicine [1]. Of those, substantial progress has been made in knowledge-based planning by researchers and vendors alike [2–9]. AI predictions of individual dose/volume metrics [10], dose volume histograms (DVH) [5,7], and entire 3D dose distributions [11] can provide both clinicians and planning staff with varying levels of information on achievable plan metrics. DVH prediction methods, perhaps counterintuitively, provide the most robust results, as they only predict the statistical description of dose distributions given the input data, allowing to capture clinical tradeoffs in the dataset.

Here, we utilized a custom random forest ensemble model (Oncospace Inc., Baltimore, MD) to predict the best achievable individual patient's organ-at-risk (OAR) DVHs as an initialization to a heuristic automated planning engine built using the Varian Eclipse (Varian, Palo Alto, CA) Scripting API (ESAPI). The results were evaluated for both Volumetric Modulated Arc Therapy (VMAT) and static field Intensity Modulated Therapy (IMRT) geometries on two different delivery platforms, a conventional C-arm linac (TDS) and a ring-gantry based linac (RDS).

2 Materials and Methods

Unattended planning (UPG) using predicted best achievable OAR DVHs was performed for fifty patients who previously underwent conventionally fractionated radiotherapy for prostate cancer. The clinically approved and treated plans served as reference for evaluation.

The initialization of plan optimization began with the DVH predictions of best achievable doses. The random forest ensemble prediction model was trained with 1336 patient treatment plans and was constructed to support the full range of treatment protocols for prostate cancer. For this study, the focus was on the initial plan of the whole pelvis PTV given its complexity.

The prediction model utilizes a multi-target to OAR geometry categorization. Input features include 2D and 3D overlap volume histograms between each OAR and target; shape features to characterize target size, complexity, and concavity; and prescriptions to identify the intended targets

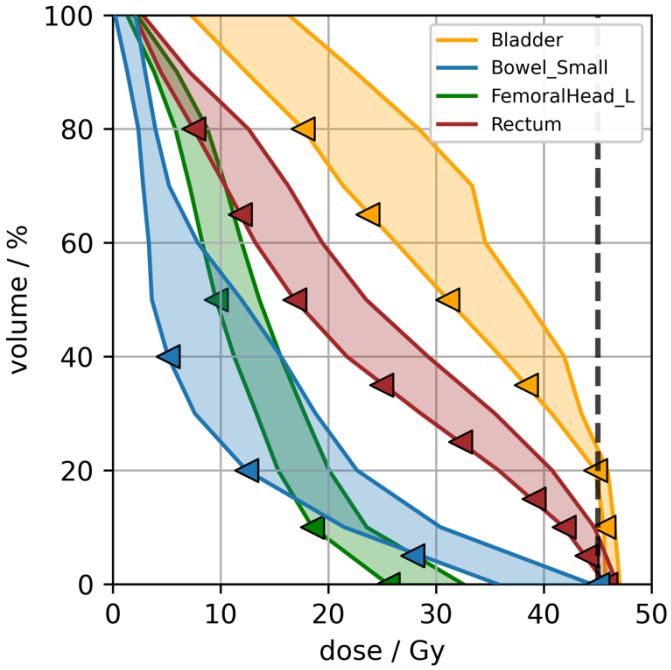

Figure 1. Example model predictions (q5% to mean) of OAR DVHs with associated optimization objectives derived from q5% dose values at a given volume. Structures are (left-to-right): small bowel (blue), femoral head (green), rectum (brown), bladder (yellow).

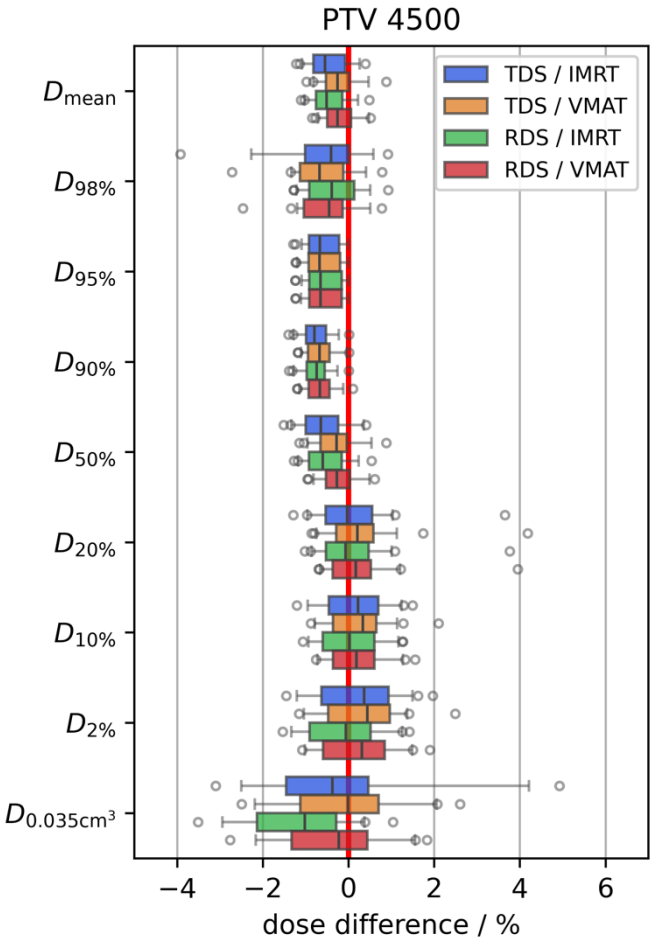

Figure 2. 45 Gy planning target volume relative differences for mean dose, doses covering 0.035 cm^3, and 98% to 2% of the volume. UPG plans were normalized to the clinical minimum goal of $V_{100\%}$=95%, whereas clinical plans often achieved ≥ 95%, leading to a systematic difference of < 1 Gy for $D_{95\%}$. Boxes indicate the interquartile range, while whiskers include 95% of the data points.

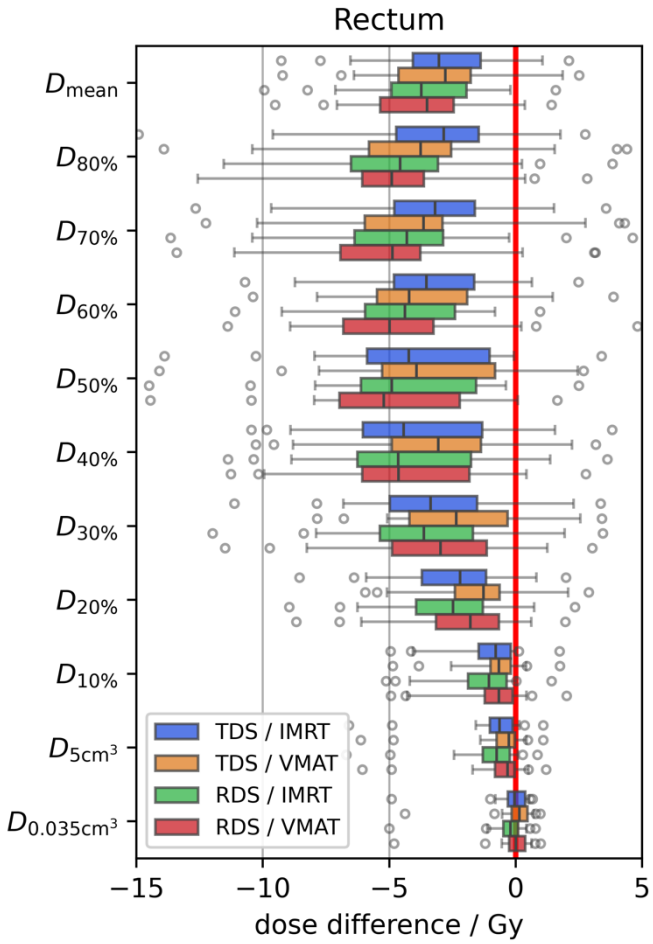

Figure 3. Rectum organ-at-risk differences for mean dose, doses covering 5 cm^3, 0.035 cm^3, and 80% to 10% of the structure.

and relative dosimetry for the plan. The model is trained to predict both the mean and 5% quantile dose-volume metrics to generate a range representing an above average quality plan. Optimization objectives are derived from the prediction of the 5% quantile dose at a given volume value of the OAR's DVH distribution to push the solution towards this best achievable result. Plan doses within the mean to 5% quartile range are identified as meeting the expected doses for a given patient and, thus are considered better than average.

Planning procedures were generalized and implemented in C# using the Varian Eclipse Scripting API (ESAPI) to generate binary plug-ins and standalone executables for batch execution. Plan generation was preceded by structure set duplication and generation of generalized planning structures. Beam arrangements were fifteen equidistant static IMRT fields and two to three full VMAT arcs. IMRT collimator angles were optimized using ESAPI methods, while for VMAT 0º and 90º collimator angles were used with the latter split into overlapping superior/inferior arcs when otherwise exceeding an aperture of 17 cm. The isocenter was defined by the target volume's geometric center.

Optimization and dose calculation were performed using version 16.1 of the Photon Optimizer and AAA algorithm. For VMAT, continuing optimization was restarted at MR level 3 and for RDS VMAT plans convergence mode was enabled (*on*). All plans utilized the normal tissue objectives (NTO) with customized parameters (priority 100, distance from target 0.5 cm, initial dose level 105%, final dose level 40%, fall-off 0.05). Ring objectives were added for each target to avoid high dose spillage for areas of concave target volumes where NTO can struggle to achieve conformality.

To improve dose homogeneity within the target volume, areas exceeding 105% of the prescription dose were outlined after initial optimization and additionally restricted in the second (continued) optimization. Finally, the dose at 6.5 cm (∥)and 1.5 cm (⊥) distance perpendicular from the largest (by volume) target was limited to 50% of the highest prescription dose. All UPG plans were normalized to cover 95% of the target volume with the 45 Gy prescription dose. Batch UPG was executed on a Varian Eclipse TPS v16.1 system in research mode with two distributed calculation servers without GPU. DVH data were subsequently extracted for both reference and UPG plans. Evaluated plan metrics included mean dose and doses covering relative and absolute volumes for both OARs and targets.

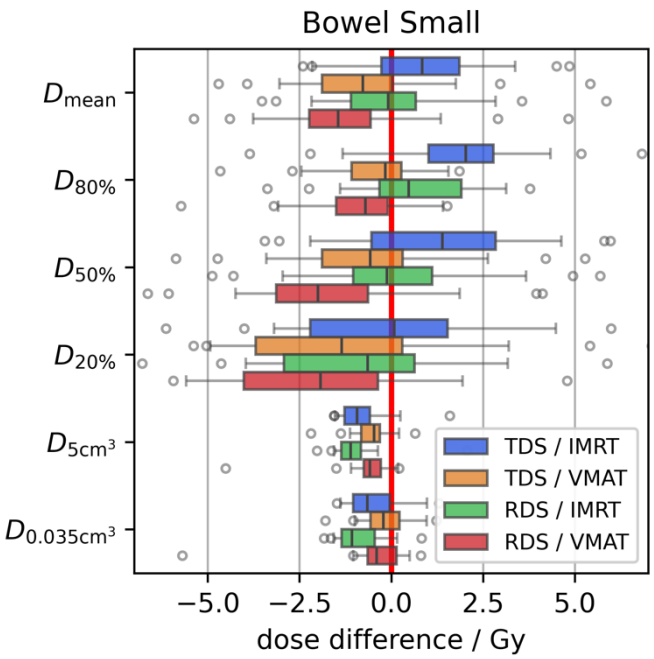

Figure 4. Small bowel organ-at-risk differences for mean dose and doses covering 5 cm^3, 0.035 cm^3, 20%, 50%, and 80% of the structure.

3 Results

Doses covering the 90% to 98% of the 45 Gy target volume (PTV 4500) as well as mean doses were up to 1% lower in most cases (fig. 2). Doses covering smaller volumes (0 to 20%) of the target, often called *hot spots*, were comparable on average deviating less than ±1%, except for $D_{0.035cm^3}$, chosen to be a clinically relevant surrogate for maximum point dose. Subtle differences between the two techniques (IMRT vs. VMAT) were observed for most metrics with IMRT scoring better (negative values) with respect to target mean dose and low volume (≤ 50%) doses. Differences between the two machines (TDS vs. RDS) at the same technique were generally unobservable, except for $D_{2\%}$ and $D_{0.035cm^3}$, with RDS scoring better.

Rectum OAR maximum point doses (fig. 3) were comparable to reference plans with negligible differences, while mean doses were 2.5 Gy to over 5 Gy lower. With increasing volume UPG plans achieved increasingly lower doses covering the OAR. For example, D_{5cm^3} and $D_{10\%}$ had median reductions less than 1 Gy, while median reductions in $D_{20\%}$ were around 2.5 Gy increasing to about 5 Gy for $D_{50\%}$ to $D_{80\%}$. The interquartile ranges for mean dose and D20% to D80% were about 2.5 Gy to 5 Gy and less than 2 Gy for volumes ≤ 10%. Similar results were observed for the bladder and sigmoid colon.

For the small bowel (delineated as bowel bag / potential space) UPG achieved lower doses to small volumes (0.035 cm^3 and 5 cm^3), while doses to larger volumes as well as mean dose varied with respect to treatment machine and technique (fig. 4). UPG VMAT plans yielded overall higher doses, most notably for D_{mean}, $D_{80\%}$, and $D_{50\%}$. Using the same techniques, UPG TDS doses also yielded higher doses.

4 Discussion

This study developed an unattended plan generation workflow utilizing ESAPI and Oncospace DVH predictions for optimization objective generation and applied the workflow to fifty prostate cancer datasets. The results show that plans were both clinically acceptable and comparable to the reference plans. Differences in PTV coverage metrics ($D_{90\%}$ to $D_{98\%}$) are due to most clinical plans achieved prescription dose coverage fractions exceeding 95%, which was the setting for this study. It is important to note that even at a higher UPG coverage goal, it is unlikely to see $D_{20\%}$ to $D_{2\%}$ and $D_{0.035cm^3}$ increase substantially. This is because the optimization setup is built to attempt to compensate for higher doses at these smaller volumes in the second step. A coverage goal of 97% or 98% may thus be feasible for plans like these. For OARs, UPG results were overall more favorable achieving at times significant reductions in doses covering large portions of the OARs: reducing the dose covering 80% of the rectum and bladder by up to 7 Gy (fig. 3) and 9 Gy, respectively. These reductions may help reduce the incidence and/or severity of proctitis and cystitis further [12–14].

While it is possible for dosimetrists and physicists to achieve similar improvements through manual iterative optimization and by utilizing assistive tools, it would require substantially more resources. For example, we found that setting up an individual patient's treatment protocol for prediction required at most 5 minutes, often less. DVH predictions subsequently take less than 5 minutes. Finally, unattended plan generation took 2.5 min to 40 min (without GPU acceleration) depending on the technique used and the number of concurrent calculations. However, since UPG does not require user interaction its actuarial time requirement may be negligible. In the author's experience, manual generation of clinically acceptable plans without AI-guided optimization objectives requires no less than 60 min of undivided attention by the planning staff.

5 Conclusion

Personalized dose-volume objectives were predicted and integrated into an automated heuristic planning solution. Unattended plan generation successfully created plans that were comparable and often superior to clinical plans with respect to OAR sparing. Deployment of this workflow could substantially reduce planning staff workload or allow staff to focus on quality assurance of data and plans. Finally, an automated and unattended workflow as presented here has the potential to increase access to radiotherapy care in low- to middle-income countries and underserved areas.

Abstract: The objective of this prospective study was to evaluate the impact of commercially available solution (SubtleMR®), which halve the acquisition time on the detectability of brain lesions in radiology and radiotherapy in a clinical routine way.
Methods: T1-MRI of 33 patients with brain metastases were analyzed. Images acquired quickly have a matrix divided by two which halve the acquisition time. The visual quality and lesion detectability of the AI images were evaluated by radiologists and radiation oncologist as well as pixel intensity and lesions size.
Results: Analysis of the lesion detectability shows a specificity of 1 and a sensitivity of 0.92 and 0.77 for radiology and radiotherapy respectively. Undetected-lesions on IA image were with a diameter <4mm and statistically low Gadolinium-enhancement-contrast.
Conclusions: It is possible to half MRI acquisition times by using the commercial algorithm and obtain good specificity and sensitivity for lesions with a diameter greater than 4 mm.

1 Introduction

Magnetic resonance imaging (MRI) is an important medical imaging tool for the diagnosis and treatment of cancer. Despite the presence of more than 800 MRIs on French territory, the average time to obtain an appointment for this type of examination is about 32 days, higher than the waiting time target of 20 days set by the 2014-2019 Cancer Plan. Reducing the acquisition time would increase the availability of MRIs and reduce the time to obtain an appointment. There is therefore a real need to reduce this acquisition time to improve patient care. However, reducing acquisition time is only possible by reducing the acquisition matrix or by image averaging, which reduces image quality [1]. Therefore, solutions are needed to restore image quality after acquisition time reduction.
Artificial intelligence (AI), and in particular deep learning, a subfield of AI, has seen tremendous progress and application in medicine in recent years [2]. NYU Langone and Facebook AI Research collaborated on a research project called "fastMRI", which consists of open datasets and benchmarks for accelerating MRI sequence acquisition. They have focused on brain and knee [3-5], and more recently on prostate data [6]. Other applications of these algorithms exist, ranging from image denoising to improving the rendering of examination images [7] to super-resolution [8]. One super-resolution algorithm, Subtle MR™, has been validated by the Food and Drug Administration for routine clinical use. This solution has reduced acquisition time by 40% in spinal MRI [9] and by 60% in brain MRI in multi-centre and multi-MRI studies [10]. To our knowledge, only one study has evaluated the use of the AI solution in the assessment of brain lesions, using a cohort of 25 patients and achieving a 45% reduction in acquisition time with half the number of phase-encode lines [11]. Despite these findings, no studies have addressed how the associated decrease in resolution due to the shorter acquisition time could potentially affect tumour delineation. In addition, there is no information on the lesion size threshold for detectability when using the AI solution. As this is a resampling problem for the algorithm, there may be a problem with removing or creating some lesions, especially the smaller ones. Therefore, in this prospective study, we evaluated the impact of the AI solution, which halves the acquisition time, on the therapeutic management of small lesions such as brain metastases.

2 Materials and Methods

For this prospective study thirty-three patients with brain metastases (BM) and meningioma (MG) referred to our oncology centre between August 2022 and March 2023 were included. MRI was performed for initial diagnosis or treatment efficacy follow-up. MR-004, a French national institution (INDS) that sets guidelines for the conduct of health research, was used for this study.

MRI was performed on an AREA SIEMENS 1.5 Tesla magnet. Tumour gadolinium enhancement was detected with a post-Gd T1 brain sequence. T2 FLAIR sequences were also used to assess oedema. Each sequence was acquired clinically (reference, longer) and then accelerated (half the time, with two times lower spatial resolution). Images from the accelerated sequences were then processed using the commercial AI solution.

The commercially available deep learning model SubtleMR™, was used for resampling. SubtleMR™ is based on a U-Net deep convolutional neural network backbone that was previously trained on a large number of paired low- and high-resolution images acquired from a variety of vendors, field strengths, and institutions. A new series with the same nominal resolution as the standard of care sequence was generated after applying the AI-enhanced algorithm. This model is used for inference, without any local fine-tuning or adaptation.

Visual analysis: Reference and AI reconstructed images were reviewed by one experienced radiologist and three experienced radiation oncologist who have attributed a global, whole-image quality (IQ) score to each MRI series: 1=poor; 2, 3=moderate; 4=good and 5=very good.

Semi-quantitative analysis:
Radiology: As part of routine image review, one radiologist evaluated the maximum length of each lesion and comparison was made between reference and AI reconstructed images.
Radiotherapy: Following a routine workflow in radiotherapy department, radiation oncologist delimited in 3D volume of interest (VOI) the volume of each lesion. Structural similarity index measure (SSIM) and Jaccard index were used to compare the VOI delimited by the radiation oncologist on reference and AI reconstructed images.

Global analysis: First order intensity evaluation was performed using mean, standard deviation, min, max, skewness, kurtosis, signal to noise ratio and absolute contrast. Specificity and sensitivity were evaluated to control potential radiologist and radiation oncologist failure to detect lesions after AI reconstruction.

Student's t-test was used to compare the different quantitative metrics between reference and AI reconstructed images. All statistical analyses were performed using Python [12] and the SciPy library. All python codes used in the analysis are available at https://github.com/AurelienCD/Impact-of-AI-MRI-solution-on-clinical-routine.

3 Results

Visual analysis:
As presented in Figure 1, AI reconstruction improves some details in the image, with the large lesion (white arrow) easily distinguishable, but the smaller lesion (black arrow) suffering from loss of detail.

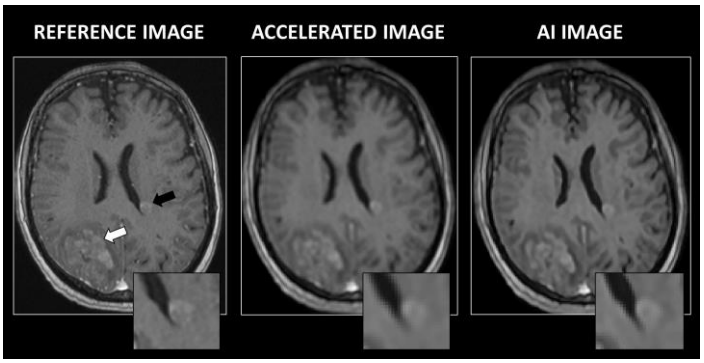

Figure 1: Representative MRI of reference image, accelerated image and AI reconstructed image in brain presenting brain metastases

Radiologist IQ scores are lower for AI images compared to reference images (mean score 4.79 ± 0.43 vs. 1.86 ± 0.77, ***p<0.001 for reference and AI images, respectively). Radiation oncologist IQ were similar.

Semi-quantitative analysis:
First order signal intensity analysis of the whole image was performed and showed a decrease in mean pixel value in accelerated and AI reconstructed images compared to reference images (p<0.001). No difference was found for minimum, maximum and skewness values. In order to assess the ability of the AI solution to restore details lost in the accelerated images, difference maps between accelerated and reference and AI and reference were computed. The subtraction map between the reference and accelerated images shows a 60% difference in pixel values in the contrast-enhanced area. Interestingly, the AI solution was able to restore the shape of the lesion with pixel value differences of less than 30%.
SSIM was then evaluated to compare the similarity of the accelerated and AI images to the reference. SSIM was significantly higher in the AI images compared to the accelerated images (SSIM 0.5921 ± 0.0577 vs. 0.5878 ± 0.0588, **p<0.01 for AI and accelerated images, respectively).
Impact of AI solution on radiology department:
Lesion max diameters delimited by the radiologist were similarly drawn in the reference and in the AI images. No statistical difference were observed in lesion max diameter. However, two lesions were not detected by the radiologist in the AI images. This result leads to a specificity of 1 and a sensitivity of 0.92 in comparison to reference images. However, if we analyse the lesions missed by the radiologist in the AI images, it appeared that these lesions are the smaller in dimension with max lengths of three and four millimetres respectively.

Impact of AI solution on radiotherapy department:
No significant differences were observed between volumes of interest drawn by the radiation oncologist on the reference and the AI images. However, five lesions were missed by the radiation oncologist in the AI images in comparison to the reference images. Specificity and

sensitivity were respectively 1 and 0.77. As for the radiology part, lesions missed were smaller in dimension, with volumes below 0.12 cm^3. It can also be noted that these lesions have a significant lower contrast enhancement in comparison to the other lesions (absolute contrast 0.007 ± 0.0028 vs 0.0154 ± 0.0074 for AI and reference images respectively, $p<0.05$).

4 Discussion

Excessive delays in MRI acquisition result in long waiting times for patients who urgently need medical intervention. Many research groups, MRI manufacturers or even start-ups are developing solutions to enable faster acquisition without losing the diagnostic quality of the images. In our study, we analysed one of these solutions, SubtleMR™. Specifically, we evaluated whether this solution is able to reconstruct an image acquired two times faster than clinical routine acquisition time, without significant loss of image quality, as required for routine clinical management of these patients.

Regarding visual analysis, Bash and colleagues [9] showed similar image quality for reference and AI reconstructed images. In our study, radiologists and radiation oncologists found lower image quality for AI images. This difference with the literature may be due to the fact that the matrix is only divided by two on the phase encoding axis, whereas we chose to divide it on the x and y axes to achieve a significant reduction in acquisition time. However, with respect to the cited study, we show that the AI solution is able to recover image details lost during the accelerated acquisition process.

Regarding the semi-quantitative analysis, in literature studies [7], the signal intensity values collected on the AI image are generally closer to those of the reference image than to those of the accelerated image. This phenomenon is also present in our study. This observation was also true for standard deviation, kurtosis and signal-to-noise ratio. As for the study by Jin and colleagues [8], our results show that SSIM with reference images is higher in AI images compared to accelerated images.

Regarding the effect of the AI solution on lesion detectability and delineation, the maximum diameters and three-dimensional delineations by the radiologist and radiation oncologist, respectively, were not significantly different using reference or AI images. This conclusion is in line with the literature showing that AI solutions need to be improved but are sufficient for safe use in clinical routine [2]. As we have shown in a previous study using an AI solution with PET imaging [13]), missed lesions correspond only to small lesions with low radiotracer uptake, which will have a limited impact on clinical therapeutic care and patient outcome.

Finally, it is important to compare the performance of an AI solution applied to final MRI images with an AI algorithm developed using a raw MRI signal as K-space. In the literature, several articles use K-space images as input with better results because more information can be found in this image than in the final MRI image [14]. However, in a clinical situation, it is often not possible to routinely access k-space, except for directly embedded AI solutions from the manufacturer.

5 Conclusion

In a busy clinical MRI department, the AI solution was used to increase patient throughput without strong significant loss of resolution. This was demonstrated in the comparable assessment of brain lesions > 4 mm in diameter by both oncologists and radiologists. Future multicentre studies including other MRI sequences and tumour sites are warranted.

[3]Department of Surgery, Christie Hospital NHS Foundation Trust, Manchester, M20 4BX. UK

Abstract Body composition, muscle mass in particular, is an established prognostic factor in oncology as it provides complementary information to performance status about patient fitness. Manual assessment is time-consuming so current practice does not use information about body composition, even though it could be extracted from routine CT or MRI scans. Instead, clinical practice still relies on broad and subjective criteria, like performance status and BMI, for patient stratification and monitoring. To facilitate large-scale research and promote (eventual) integration into routine clinical care we have developed the Automatic Body Composition (ABC) Toolkit. ABC was designed with flexibility in mind; it provides a browser-based front end for use by those without programming experience and exposes a set of APIs for simple integration into research and clinical workflows. It includes AI-based segmentation and efficient quality assurance. ABC is currently available for collaborative projects upon request.

1 Introduction

Skeletal muscle plays a key role in regulating several physiological systems and is therefore vital for responding to stressors (e.g., cancer and its treatments) [1]. Sarcopenia, the loss of muscle mass and function due to ageing, is a central component of frailty, and can be compounded by cancer driven muscle loss through cachexia. Sarcopenic cancer patients are known to have poorer outcomes. Across disease sites and treatment modalities, low muscle mass is associated with both decreased survival and increased toxicities [2]. This effect is not just limited to cancer patients: burn victims and patients in intensive care presenting with low muscle mass also experience worse survival and increased recovery times [3]. However, as imaging biomarkers of muscle health are time-consuming to measure, this information is not yet used in clinical practice. Instead, clinicians rely on broad and subjective criteria, like BMI and performance status, to inform treatment decisions.

A common approach to muscle mass estimation involves segmentation of the muscle compartment on a CT scan. Typically, this is performed on a single slice at the L3 vertebral level as this region has been shown to be highly correlated with total body muscle mass [4]. However, even finding and delineating a single slice is a time-consuming process and reliance on L3 excludes all scans where this level is not imaged. Radiotherapy planning and image-guided radiotherapy offers a wealth of imaging data that could be used to measure, monitor, and intervene based on body composition and its dynamic behaviour. However, current approaches to measuring body composition make this unfeasible.

Automatic muscle segmentation is common in literature, but few methods are publicly available. Comp2Comp from Stanford's Machine Intelligence in Medical Imaging lab is an open-source toolkit for measuring body composition from CT imaging [5]. It enables measurements of aortic calcifications, vertebral body density estimation (between T12-L5), muscle and fat quantification, as well as estimates of liver, spleen and pancreas volume and density. Similarly, the Opportunistic Screening Consortium in Abdominal Radiology (OSCAR) developed a toolkit to extract the same features with the omission of the pancreas and the addition of the kidneys [6]. Although, both Comp2Comp and OSCAR provide detailed insights into body composition, they are restricted to CT scans of the abdomen, which limits their use in radiotherapy where imaging is generally only available around the target volume. Although relatively simple to use, both lack a graphical interface and are aimed at researchers with some programming experience.

A commercial alternative is the Data Analysis Facilitation Suite (DAFS) by Voronoi Health Analytics. It provides a wide range of models for full-body tissue and organ segmentation and can be applied to scans with varying fields of view. DAFS is a powerful tool aimed at facilitating large-scale retrospective analyses. It can provide detailed insight into patient anatomy and can be applied to a wider range of scans than Comp2Comp or the OSCAR toolkit. However, it has its limitations. DAFS does not save model predictions, so segmentations cannot be corrected, and further (e.g. radiomic) analyses cannot be performed. Reliance on volumetric segmentation of tissues and organs increases execution time and computational and data transfer requirements. In terms of body composition, there is no evidence to suggest a benefit from using volumetric measurements compared to single-slice measurements [7]. DAFS can only be operated via its graphical interface and data must be organised in a specific manner, which limits integration with research and clinical workflows. Finally, its cost, which includes a per-scan fee, hinders analyses of large-scale, longitudinal data - one of the remaining gaps in the field.

We present the Automatic Body Composition (ABC) toolkit, a tool for fast and accurate measurement of skeletal muscle and fat from routinely collected CT imaging (including cone-beam CTs of the head and neck). The toolkit can be applied

to scans of varying fields of view, with segmentation models extending from neck to thigh. It provides a user-friendly interface for those without programming experience, as well as an API for simple integration with scripting languages. Built-in DICOM communication also enables integration with research databases and clinical picture archiving and communication systems (PACS).

2 Materials and Methods

2.1 System Architecture

A schematic of the ABC Toolkit is shown in Figure 1. The toolkit itself is composed of several Docker (v24.0.7) containers managed by Docker Compose (v2.21.0). The task controller exposes a set of APIs for executing specific pipelines. Processing is performed by separate worker nodes such that the task controller can handle asynchronous requests. This feature is especially useful when performing large-scale batch analyses, as it does not block incoming requests. Deep-learning inference is composed of two main tasks: spine labelling, which consists of automatically labelling all vertebrae in the CT scan; and tissue segmentation, which automatically segments the muscle and fat compartments at the desired level(s) as identified by spine labelling. Estimates of muscle/fat area and density are then calculated and pushed to the database.

The web server communicates with the task controller to display web pages for simplified processing. Importantly, it exposes a quality assurance (QA) page to quickly check model predictions. The user identifies failed segmentations and can leave a note explaining their decision. These notes can then be used to highlight consistent errors that need to be addressed.

A core design choice was to make the toolkit flexible and amenable to different use cases, some of which are shown in Figure 1. By exposing a set of APIs, standardised HTTP methods can be used to make requests and incorporate different elements of the toolkit into other workflows (scripting mode). For example, the spine labelling pipeline can be executed alone, and the results used to initialise a separate registration pipeline. For large-scale analyses, we have built-in communication with XNAT, an open-source imaging platform that is widely used for hosting, organising and sharing imaging data. The ABC toolkit can display available XNAT projects and batch process all the CT scans in a selected project (batch mode). Finally, communication with clinical DICOM interfaces (e.g. Conquest [REF]) enables real-time inference when the interface posts a trigger to the toolkit (real-time mode). The trigger could be the result of an incoming C-STORE, from the clinical PACS for example, with the resulting report pushed back into the PACS.

2.2 Deep-learning

We have chosen to omit many of the technical details for conciseness but thought it important to describe the implementation of the deep-learning pipelines. Spine labelling is based on the method first developed by Payer et al. for the VerSe Challenge at MICCAI 2020 [8]. This is a multi-stage approach in which a 3D convolutional neural network first locates the spine on the full CT scan. The prediction is then used to crop the image around the spine and a second model labels the vertebrae. These steps are computationally expensive since the 3D CT volume is processed, as a result a GPU is needed for inference. We aim to decrease computational complexity in future to facilitate deployment and improve inference speed.

The segmentation pipeline consists of several 2D convolutional networks optimised for different anatomical locations. Currently, these include models for C3, T4, T9, T12, L3, L5 and the thigh. U-Net architectures with MixNet encoders are used as they are lightweight and accurate [9, 10]. Following training, the models are compiled using the Open Neural Network Exchange (ONNX) to reduce memory footprint and improve inference speed . As a result, fast inference can be performed on CPU alone [11]. In addition, reducing the parameter count allows models to be trained with fewer training examples, which accelerates development of new models. We have previously shown that there are minimal benefits to training on more than 25 examples, and in practice models were trained on approximately 40 cases [12]. We would like to extend our models to additional anatomical sites, but data collection is time-consuming.

3 Results

3.1 Benchmarking

The following tests were performed with an AMD Ryzen Threadripper 2950X 16-Core processor running Ubuntu 22.04. An NVIDIA GeForce RTX 2080 Ti with 12 Gb of VRAM was available but only used for spine labelling. Table 1 shows the timings of each step in the processing pipeline. This was performed on a single CT thorax, abdomen and pelvis (large field of view). Total processing time was 58.07 seconds. A formal analysis has not yet been performed to measure average QA time but, from experience analysing thousands of predictions, we estimate this to be between 1-5 seconds per scan. There remain improvements to be made, notably in terms of vertebral labelling, but these results show feasibility of use in large-scale analyses as well as time-sensitive settings.

3.2 Validation

The ABC toolkit was then validated against both Comp2Comp and the OSCAR toolkit, as they are the openly

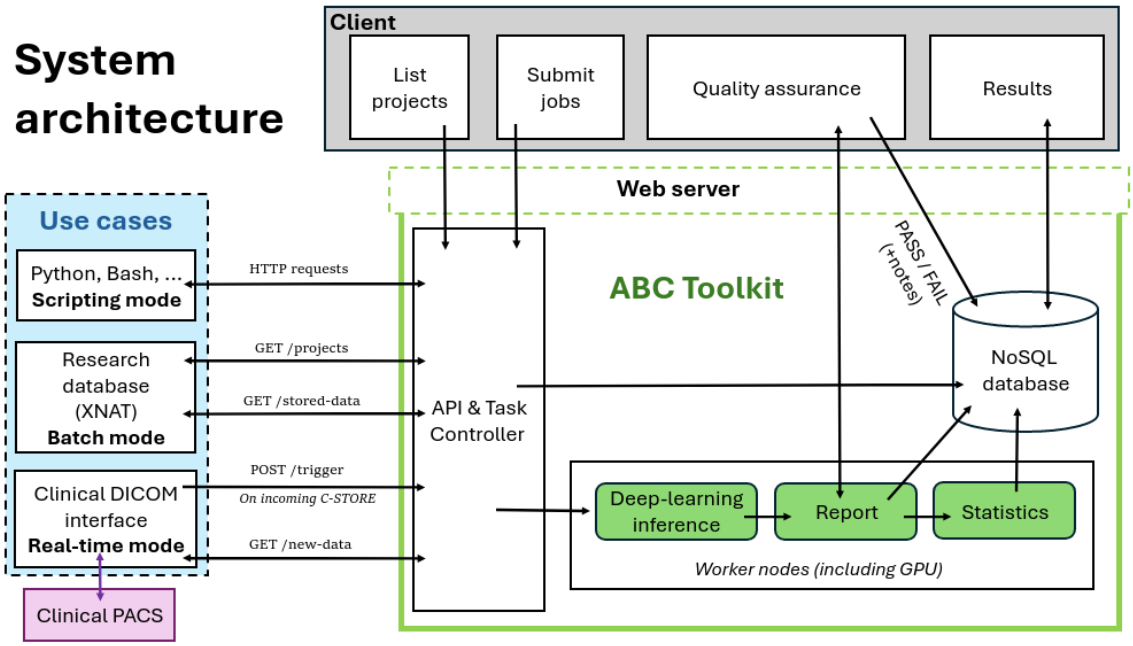

Figure 1: Schematic overview of the ABC Toolkit. The task controller exposes a set of APIs which makes the tool amenable to a variety of use cases. A web server enables use without programming experience and presents a QA page to quickly check model predictions.

Table 1: Table showing model size and processing times for each step in the pipeline. In total, the pipeline takes 58.07 seconds per example. The example used was a CT thorax, abdomen and pelvis of a man treated for prostate cancer. Note post-processing time includes writing segmentation outputs, which is the most time-consuming element of the segmentation pipeline.

	Model Size (Mb)	**Pre-processing** (s)	**Inference** (s)	**Post-processing** (s)	**Total** (s)
Spine locating	72	9.36	3.18	0.02	12.56
Vertebrae labelling	72	0.45	22.58	13.71	36.74
Muscle/fat segmentation	20	1.80	0.37	6.6	8.77

available alternatives. Note that this comparison was performed at the L3 vertebral level since this is the reference site used throughout the literature, and both Comp2Comp and OSCAR focus on analysing abdominal CTs.

First, segmentation accuracy was evaluated against manual delineations of the muscle compartment at the L3 vertebral level. Contouring was performed at two timepoints on 21 cases by a single trained annotator (CJ) with 11 years of experience. Note that CJ was not involved in model development, models were not re-trained following this comparison. Contouring was performed across three slices spanning the L3 vertebra. The 95% Haussdorf distance and mean distance-to-agreement were used to assess accuracy. Importantly, both Comp2Comp and the ABC toolkit separate skeletal muscle from intramuscular adipose tissue, whereas the human annotator did not make this distinction. For clarity, here, we compared total skeletal muscle area or, the union of the skeletal muscle mask and the intramuscular adipose tissue mask. Results are shown in Figure 3. ABC consistently outperforms both Comp2Comp and OSCAR when compared to manual delineations.

4 Discussion

We present the Automatic Body Composition (ABC) toolkit: a flexible, accurate and easy-to-use tool for the estimation of muscle and fat mass from routinely collected CT imaging. Importantly, ABC was designed with radiotherapy in mind and is therefore applicable to scans of varying fields of view including cone-beam CTs. However, we have only trained a head and neck CBCT model so far. A browser-based frontend supports fast QA and allows users with no programming experience to run analyses, while a set of APIs enable simple integration with other research and clinical workflows.
Comp2Comp and the OSCAR toolkit are comparable tools, but both are restricted to analysing abdominal CTs and are therefore unsuited to many applications in radiotherapy. Figure 3 shows that the ABC toolkit outperforms both Comp2Comp and OSCAR in terms of segmentation accuracy. Regardless, these tools extract additional measures of body composition including bone mineral density and estimates of aortic calcifications that are not yet implemented in ABC. A commercial alternative is DAFS by Voronoi Health Analytics. DAFS is aimed at facilitating large-scale retrospective analyses by enabling full-body tissue and organ segmentation. As a result, it is not easily integrable into other pipelines. Moreover, model predictions are not saved so external validation

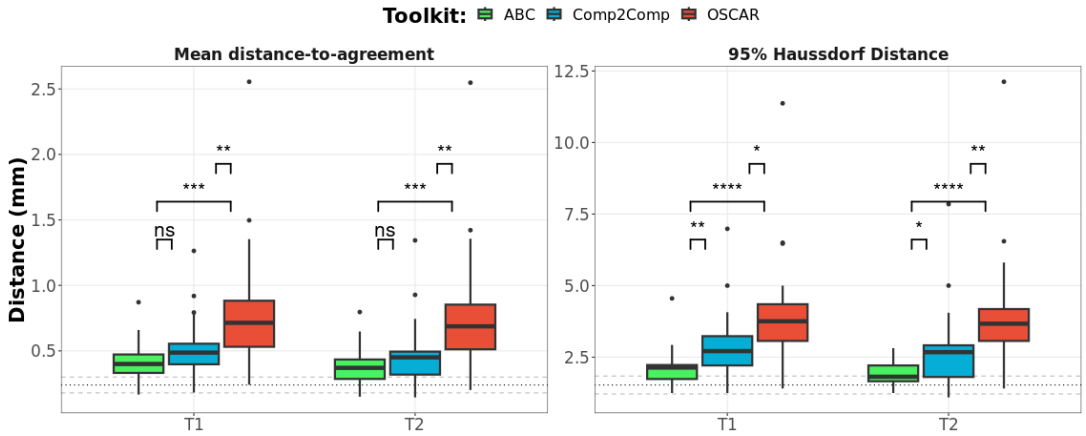

Figure 2: Validation of the ABC Toolkit against openly available toolkits. Models were compared to manual annotations performed at two time-points (T1 & T2). Dotted lines represent mean and standard deviations of the intra-observer agreement. ABC consistently outperformed both Comp2Comp and OSCAR.

cannot be performed.

The ABC toolkit is currently limited in that it only segments fat compartments in the abdomen. At all levels, the muscle compartment is segmented alongside a body mask that provides an estimate of total body size. In future, we aim to integrate more models with the capacity to segment both fat and muscle. Moreover, an aim of the ABC toolkit was to be lightweight and fast. The vertebral labelling module lacks in this aspect as it is still relatively slow (Table 1) and still requires a GPU for inference. Future work will seek to optimise this aspect to ensure the toolkit can be easily deployed on a range of hardware.

The ABC toolkit presents a step towards implementing muscle mass assessment in radiotherapy clinics. By developing a tool that is amenable to both large-scale research and on-demand requests from clinical PACS we hope to promote further research in the field and facilitate the use of body composition in patient stratification, patient monitoring and the development of targeted interventions.

5 Conclusion

We developed a toolkit for automatically measuring body composition from routinely collected CT scans. The ABC toolkit's unique selling point is flexibility. It is set up as a service whereby it listens for incoming processing requests and returns the results to the requester. ABC is suited to both large-scale analyses and real-time processing, which facilitates integration into both research and clinical workflows. This proof-of-concept presents a potential road towards clinical implementation.

Abstract

Purpose
Radiation oncology is a highly specialized field requiring an accurate and clinically relevant treatment summary. There is a clear need for standardization of radiation therapy data to facilitate care coordination.

Methods
For a year, the OSIRIS (Interoperability and data sharing of clinical and biological data in oncology) group based in France has worked on structuring radiotherapy data and identifying technical solutions for collecting and sharing them. The group used a multidisciplinary approach that included weekly scientific and technical meetings to foster a national consensus on a minimal data set.

Results
The resulting set and event-based data model, which is able to capture radiation therapy treatments, was built with 32 clinical and 60 imaging items. The group made it compatible with the HL7 Fast Healthcare Interoperability Resources (FHIR) format to maximize interoperability. The OSIRIS set was reviewed, approved by a National Plan Strategic Committee, and freely released to the community. A proof-of-concept study is underway in France to put the OSIRIS set and Common Data Model into practice using a national and multi-centric cohort of 10.000 patients.

Conclusion
Using a national and bottom-up approach, the OSIRIS group has defined a model including a minimal set of radiation therapy data that can be used to accelerate data sharing. The model relies on clear and formally defined terminologies and, as such, may also benefit the larger radiotherapy community.

1 Introduction

The lack of cohesion, coordination, and structured data sharing between Radiation Oncology Information Systems (ROIS) and other health information systems is due to the lack of standardized data in the radiation oncology domain and absence of Fast Healthcare Interoperability Resources (FHIR) standards to support data transmission.

Recent national[1] and international[2,3] (e.g. American Society for Radiation Oncology) initiatives to standardize radiotherapy data testify to a growing interest in collecting consistent and comparable data in this field. Identifying a minimum set of data for radiotherapy will help to improve care coordination, reduce data entry and provide a more comprehensive view of the holistic approach required for cancer treatment.

The definition of a minimum data elements for radiation oncology is currently underway with the CodeX project[4] with the participation of the American Association of Physicists in Medicine (AAPM) and major software publishers.

The OSIRIS group has taken over part of the work of the CodeX project to integrate an imaging and radiotherapy module into its data model, which already includes clinical and genomic data.[5]

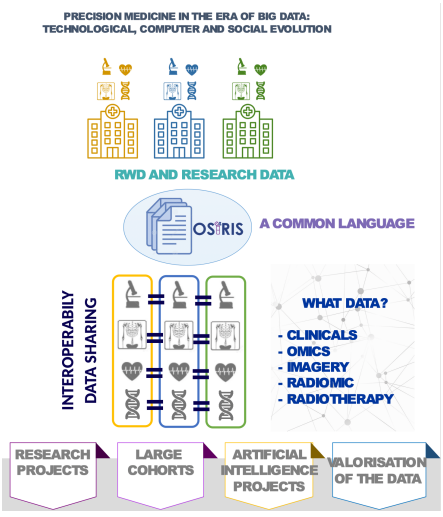

Figure 1 : OSIRIS : French National Initiative on interoperability and data sharing of health data

2 Materials and Methods

The OSIRIS group has proposed to break down the extension of the OSIRIS set into three stages :
1. Determine the important concepts in radiotherapy and how to relate them to the OSIRIS clinical data model,

2. Determine a minimum set of attributes (CDEs, Common Data Elements) by comparing national and international initiatives in the field,
3. Associate a list of possible values (CLs, Code Lists) for each CDE using international terminologies. For example, we could use web portals reflecting biomedical ontologies (such as BIOPORTAL[6] from NCBO-National Center for Biomedical Ontology or UMLS-Unified Medical Language System - NIH National Library of Medicine).

To define a minimum set at national level, our approach will be based on the following steps: (i) identification of the most relevant CDEs based on local partner initiatives; (ii) standardization of the list of possible CDE values using appropriate international terminologies where possible.
The RadioTransNet network (Réseau National de Recherche Préclinique en Radiothérapie)[7] and the Unitrad group[8] (Groupe de recherche en radiothérapie oncologique) have joined the OSIRIS group to define a minimum set of standardized data for radiotherapy.

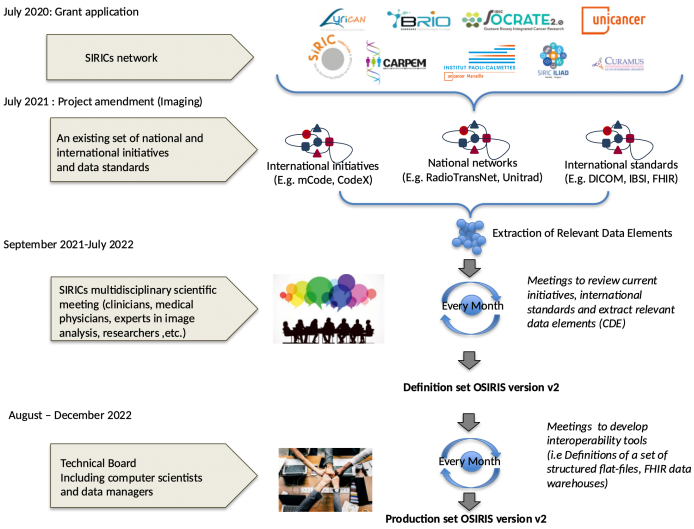

Figure 2 : Overall methodology used between July 2021 and December 2022 to deliver a minimum Common Data Elements (CDEs) for radiation oncology.

3 Results

OSIRIS RT-CDM

A first version of the RT-CDM (v1) was published in december 2022 and freely available to the community on GitHub[9]. This version formed the basis for discussion between the integrated cancer research sites in France (SIRICs), the Unitrad and RadioTransNet groups, and, later, for technical council meetings. Several institutions tested the model (i.e. level of completeness and inconsistency rate), and the group proposed and implemented substantial revisions through functional analysis and data integration feedback. The result is a reliable, robust and comprehensive model for describing radiotherapy treatments.

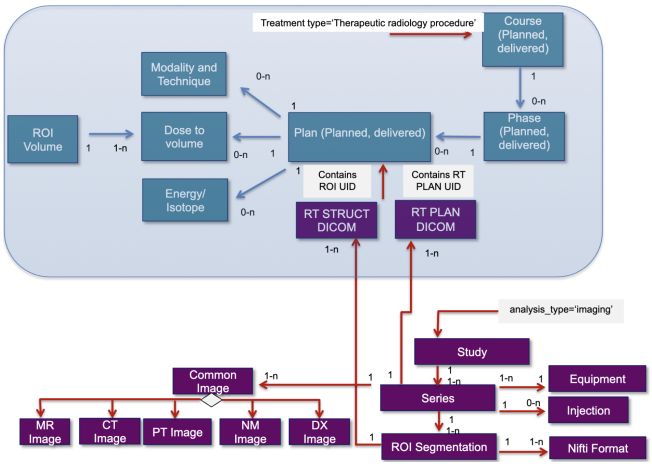

Figure 3 : OSIRIS RT-Common Data Model (CDM)

The *figure 3 (in blue)* shows the radiotherapy data model with the CDEs and the relationships between them. The RT-CDM is connected to the DICOM-Imaging CDM *(in purple)* and is an extension of the OSIRIS clinical CDM when the "Treatment_Type" DE value is "Therapeutic radiology procedure". The RT-CDM facilitates the development and management of the course, phases and treatment plans after care has been provided.

Given that health data change over time, the OSIRIS group focused its efforts on modeling an event-based temporal data model. Each DE of the OSIRIS RT-CDM is linked to a particular treatment plan (ie, planned or delivered).

OSIRIS RT set

Once the OSIRIS set reached a steady state in terms of its semantic content, a first version was released in december 2022. This current release, built on an event-based data model, describes a minimum data set that allows capture of the RT course. This release, freely available to the community on GitHub consists of a minimal data set of 32 clinical and 60 imaging items required and validated by the national scientific board[10]. CLs are based on international terminologies.

OSIRIS-RT FHIR Implementation Guides (IG)

To ensure the sustainability, expandability, and interoperability of the OSIRIS RT set with other systems, the first release was made compatible with the growing health information exchange standard HL7 FHIR in 2023. The OSIRIS-FHIR implementation guide is documented on the GitHub[11]. This guide summarizes a set of rules on how to implement OSIRIS with the HL7 FHIR standard. You can install this implementation guide to facilitate its maintenance and evolution.

HYPO-RT Prostate[12] : a national RT project as a proof-of-concept

A national, multi-centric proof-of-concept is underway to validate the OSIRIS RT set and the CDM. The evaluation will be based in real-life situations on 10.000 patients treated for prostate cancer. The aim is to assess the efficacy and safety of moderately hypofractionated and extremely hypofractionated radiotherapy regimens, in terms of recurrence-free survival, metastasis-free survival, overall survival, severe toxicity (digestive or urinary), compared with normofractionated regimens.

4 Discussion

The OSIRIS group has carried out a substantial amount of work, with the support of INCa (French Institut National du Cancer) but also thanks to the desire and effort of a collective mobilized around these issues of data sharing in radiotherapy. The deliverables of the project will be promoted through national use cases in 2024 (e.g. ODH, OncoDS projects[13]) or working discussions at European level (e.g. UNCAN.eu[14]).

5 Conclusion

OSIRIS use cases for collecting and sharing patient data for clinical trials/studies with Real World Data (OSIRIS-RWD) demonstrate the potential for improving research and care. This is being demonstrated by international standards such as FHIR, and by new national projects planned for 2024 all driven in the field by stakeholders.

With these new projects, the use of OSIRIS RT at national level will expand rapidly, and the project leader will face a number of challenges. It will be necessary to establish a transparent and participative governance (steering committee, operational) but also to establish a community of practice in Radiotherapy. The aim of this community would be to set up an open forum to listen to and share requirements and experiences around OSIRIS RT.

The development of technical solutions for data collection in OSIRIS format from ROIS (e.g. MOSAIQ©,ARIA©), documentation (e.g. OSIRIS-FHIR IG, documented use cases, maintenance and evolution of RT-CDM and minimal set) will be necessary for the completion of projects in 2024.

*these authors contributed equally

Abstract Cachexia is a devastating condition, often occurring during cancer, diminishing cancer treatment effects and increasing mortality. Currently, there are no methods to accurately monitor cachexia during cancer treatment. Therefore, we present a proof-of-concept for monitoring cachexia based on cone beam computed tomography (CBCT) images acquired during radiotherapy treatment.

Data from 140 stage III non-small cell lung cancer patients was used. Two deep learning models, CycleGAN and CUT, were used for unpaired training of CBCT-to-CT conversion. U-Net was used for automatic pectoralis muscle segmentation.

Both CycleGAN and CUT restored the Hounsfield Unit fidelity and reduced artifacts in CBCT, with CUT displaying the best performance. The U-Net model achieved a DSC of 0.88 on a hold-out test set.

This study shows a proof-of-concept for automatic monitoring of the pectoralis muscle area during radiotherapy treatment based on CBCT, which can serve as a surrogate for cachexia progression.

1 Introduction

Lung cancer is the second most prevalent cancer type worldwide and is the leading cause of cancer-related deaths [1]. More than half of lung cancer patients suffer from cachexia: a devastating syndrome characterized by loss of skeletal muscle mass, with or without loss of fat tissue. It is a sign of poor prognosis and is suggested to account for 20% of all cancer-related deaths. Cachexia is associated with diminished effects of chemotherapy, functional impairment and increased mortality [2]. Consequently, it is important to gain insights into the dynamics of cachexia and monitor muscle wasting over time.

Assessment of skeletal muscle mass at the third lumbar vertebrae (L3 level) on computed tomography (CT) imaging is considered the gold standard for evaluating body composition, due to its high accuracy and specificity [2]. However, manual fat and muscle tissue delineation is a tedious process, limiting the widespread use of body composition analysis in clinical decision-making. For this purpose, deep learning (DL) segmentation models have been developed for the segmentation of skeletal muscle tissue, as well as subcutaneous and visceral adipose tissue, in 2D slices of CT images at the L3 level [3][4].

During the course of radiotherapy treatment, part of standard treatment for stage III non-small cell lung cancer (NSCLC) patients, cone beam CT (CBCT) images are acquired before each fraction, to verify patient positioning and check for anatomical changes. As CBCT images are acquired sequentially over time, commonly for up to 30 fractions, they contain valuable information to investigate the dynamics of cachexia during the course of treatment. However, the L3 level is often not visible in CBCT and CT images of lung cancer patients. As an alternative, skeletal muscle mass at the level of the fourth thoracic vertebrae (T4) has been shown to correlate with muscle mass at L3 and is suited as a surrogate for body composition analysis [5]. Furthermore, low pectoralis muscle area (PMA), approximately at T4 level, at the time of diagnosis is associated with worse overall survival of patients with NSCLC [6].

Using CBCT images to monitor muscle mass is challenging, as CBCT images are lower in quality than conventional CT, due to more scattered radiation reaching the detector and more artifacts resulting from breathing motion. This results in suboptimal Hounsfield Unit (HU) fidelity, and thus suboptimal segmentation of fat and muscle tissue. However, DL models are able to translate low-quality CBCT images to their high-quality CT counterparts [7][8], so-called image-to-image translation (I2I).

The purpose of this study is two-fold. First, I2I of CBCT images to high-quality synthetic CT images (sCT) will be performed, on a dataset of images from stage III NSCLC patients. Secondly, a DL segmentation model will be developed to segment the pectoralis major and minor muscles at the first axial slices above the aortic arch in both the synthetic and original CT images. Ultimately, this study seeks to develop an automatic framework to monitor muscle wasting during the course of radiotherapy treatment and gain insights into the dynamics of lung cancer cachexia.

2 Materials and Methods

2.1 CBCT-to-CT conversion

2.1.1 Dataset & preprocessing

The dataset consisted of the planning CT and, on average, 30 CBCT images of 140 patients treated for stage III NSCLC. First, both the CT and CBCT images were

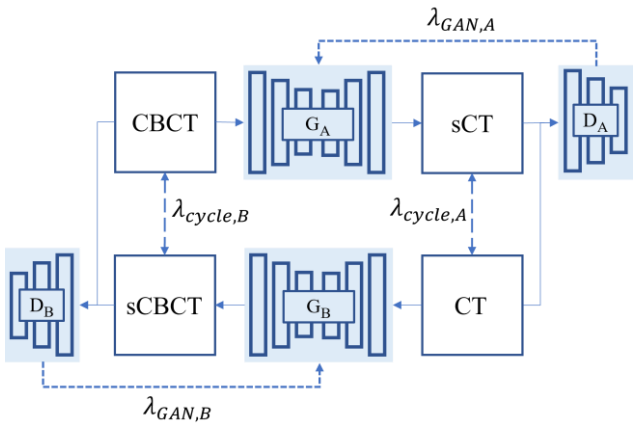

***Figure 1**: Schematic representation of the architecture of the CycleGAN model. G_A and G_B are the generators, and D_A and D_B are the discriminators. λ_{cycle} and λ_{GAN} are the loss functions used. (s)CT and (s)CBCT are the (synthetic) computed tomography (CT) and (synthetic) cone-beam CT images, respectively.*

resampled to a uniform voxel spacing of 0.977 x 0.977 x 3 mm^3. Next, the CT images were cropped to the axial range of the corresponding CBCT images, to ensure that the same anatomical region was present in both the CT and CBCT images. Furthermore, non-anatomical information (e.g. treatment couch and patient immobilization device) was removed using a binary mask and the HU intensities of the CT and CBCT images were clipped between -1000 and 2000 HU. Lastly, the dataset was split with a ratio of 90/10/10 for training (n=112), validation (n=14) and testing (n=14).

2.1.2 CBCT-to-CT models

The goal of image-to-image translation (I2I) is to translate an input image from the source domain (CBCT) to the target domain (CT), such that the structure, i.e. content, of the input image is preserved while matching the appearance of the output image in the target domain. Two I2I models, CycleGAN and CUT, were chosen as these allow for unpaired training, i.e. when corresponding images from two domains cannot be obtained. This is also the case for CBCT-to-CT conversion, as there might be anatomical changes between the planning CT and CBCTs due to breathing.
The state-of-the-art network for unpaired I2I is CycleGAN, first proposed by Zhu et al. [9]. In contrast to standard GAN architectures, CycleGAN comprises two generators and two discriminators as displayed in Fig. 1, which learn both forward and backward mapping of the input and output (i.e. from CBCT to CT and vice versa). The generators seek to generate realistic output images from a given input, while the discriminators seek to distinguish real images from generated ones.
The CUT model by Park et al. [10] uses the same generator and discriminator network as CycleGAN but employs only one generator-discriminator pair as displayed in Fig. 2.

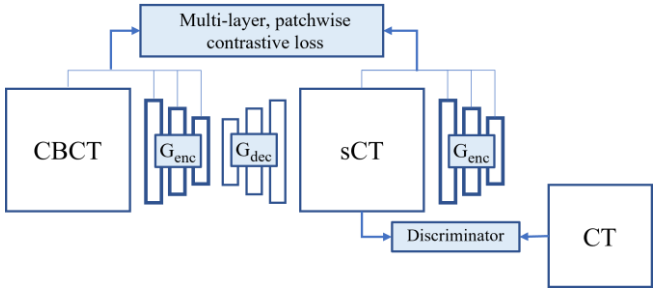

***Figure 2**: Schematic representation of the architecture of the CUT model. G_{enc} and G_{dec} together comprise the generator. CT, sCT and CBCT are the computed tomography (CT), synthetic CT and cone-beam CT images, respectively.*

Instead of learning the backward mapping, it uses a contrastive learning framework, by calculating a multi-layer, patchwise contrastive loss.

2.1.3 Training details

We trained both CycleGAN and CUT with the default configuration of hyperparameters and did not tune these further as this already resulted in a stable training process and satisfactory results. The model was trained with a constant learning rate of 0.0002 for 40 epochs, followed by 40 epochs with a linearly decaying learning rate until zero. Validation based on the Fréchet Inception Distance (FID) was implemented [11]. The best epochs in terms of the FID on the validation set were chosen as the final models.

2.1.4 Evaluation

To obtain a reference CT (rCT) scan for evaluation, image registration of CT to first-fraction CBCT was performed using the Elastix toolbox [12]. A rigid transformation was applied for initial alignment, followed by a multi-resolution B-spline transformation to account for deformational changes between planning CT and CBCT.
The quality of the sCT images was evaluated both on the individual image level, as well as on the group level. On the individual image level, mean absolute error (MAE), structural similarity (SSIM) [13] and peak signal-to-noise ratio (PSNR) were used as image quality metrics.
On the group level, the FID was used, a widely accepted metric for measuring the performance of generative models. It measures the distance between the probability distributions of real and generated images.

2.2 Pectoralis segmentation

2.2.1 Dataset

For pectoralis muscle segmentation, the first axial slice above the aortic arch was selected in the CBCT images from fractions 1, 10, 20, and 30. The best-performing CBCT-to-CT model was used to convert the selected CBCT images

***Table 1**: Median and inter-quartile range of the MAE, PSNR and SSIM for the CBCT and sCT images, compared to the ground truth rCTs. Furthermore, the FID is shown calculated for the CBCT and sCT images, compared to the ground truth CTs.*

Metric	MAE	PSNR	SSIM	FID
CBCT	26.8 ± 12.3	30.5 ± 3.46	0.874 ± 0.053	72.7
CycleGAN	22.8 ± 10.5	30.7 ± 3.58	0.898 ± 0.048	**39.0**
CUT	**22.1 ± 10.8**	**30.8 ± 3.62**	**0.902 ± 0.050**	41.4

to sCT images. Several patients were omitted, as either the first axial slice above the aortic arch was not present in the CBCT volume, or artifacts in the original CBCT were too prominent, rendering the pectoralis muscle indistinguishable. This resulted in a dataset of 326 sCT slices. In these slices, the pectoralis was manually segmented using the Slice-O-Matic software by TomoVision (Magog, QC, Canada).

2.2.2 Model & training details

The U-Net architecture proposed by Ronneberger et al. [14] was used for segmentation of the pectoralis major and minor. The U-Net model consists of an encoding and decoding path, connected via skip connections, to leverage the low- and high-level information within the images. The Combo-Loss (a combination between cross entropy and Dice loss) was used as the loss function [15]. The model was trained for 100 epochs using the Adam optimizer, with a learning rate of $3 \cdot 10^{-4}$ and batch size of 2. On-the-fly data augmentation was performed by randomly scaling (0.95, 1.05), translating in x- and y direction (-25, +25 pixels) and rotating (-5, 5°) the images.

2.2.3 Evaluation

The pectoralis muscle segmentation performance was evaluated based on the Dice Similarity Coefficient (DSC), which calculates the overlap between the segmentations over the total area of the segmentations.

3 Results

3.1 CBCT-to-CT conversion

Figure 3 shows the overall HU distribution of the CT, CBCT and corresponding sCT images generated by the CycleGAN and CUT models. Both CycleGAN and CUT restore the overall HU distribution, as they closely follow the bimodal distribution of the CTs. However, CUT follows the CT HU distribution more closely in the range [-29; 150], which is the range corresponding to muscle tissue.

Table 1 shows the performance of the CycleGAN and CUT model in terms of MAE, PSNR and SSIM. Both CycleGAN and CUT show improvement in terms of MAE, PSNR and SSIM, with CUT displaying the best performance. Both models show increased image similarity between the sCT and CT datasets as a whole, measured by the FID, with

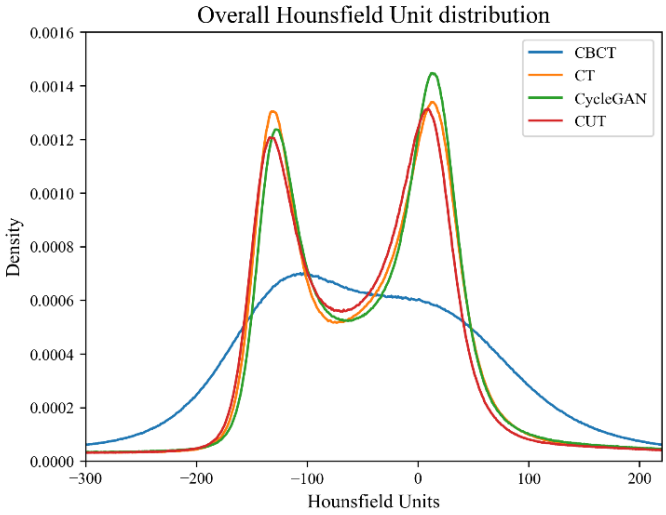

***Figure 3**: Overall Hounsfield Unit distribution across the test set.*

CycleGAN showing the best performance. Ultimately, the CUT model was selected to convert CBCT images to sCT images for pectoralis muscle segmentation.

3.2 Pectoralis muscle segmentation

The U-Net achieved a median DSC of 0.97, 0.94, and 0.88 on the training, validation and test set, respectively (Table 2). Fig. 4 show examples of segmentations with a high and low DSC, respectively. Low DSC is mainly due to oversegmentation at the anterior side of the pectoralis muscle.

Split	Median	Min	Max
Train	0.97	0.90	0.99
Validation	0.94	0.88	0.98
Test	0.88	0.76	0.95

***Table 2**: Median, minimum and maximum DSC for the training (N=260), validation (N=31) and test (N=35) data splits.*

4 Discussion

Both CycleGAN and CUT restore the HU distribution to that of the CT, and reduce artifacts. CUT is chosen as the best performing model as it results in more accurate HU distribution in the range corresponding to muscle tissue, which is relevant for this work and slightly better performance in terms of the quantitative metrics.

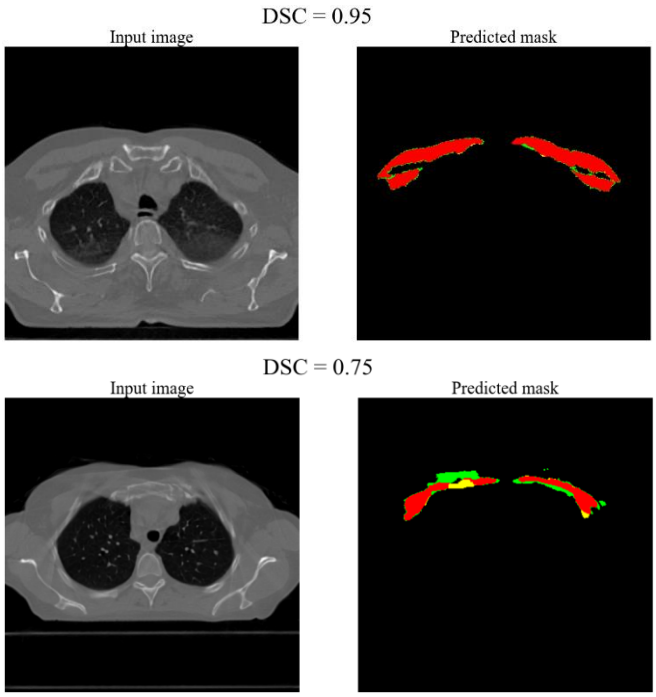

***Figure 4**: High and low DSC segmentation. red, green and yellow areas indicate correct, over- and undersegmentation, respectively.*

The U-Net model shows good performance in segmenting the pectoralis muscle. Fig. 4 shows that artifacts still present after I2I result in a lower quality segmentation. Therefore, it is important to investigate whether the CBCT-to-CT conversion models can be improved, or that artifacts might be too disturbing in some cases.

In order to fully automate the proposed workflow, an additional step needs to be developed to automatically check if the T4 level is present in the CBCT volume and select the corresponding slice.

In addition, robust metrics need to be formulated that indicate performance of CBCT-to-CT conversion and pectoralis muscle segmentation performance during the application of the models in clinical practice, such that the trustworthiness of the final segmentation can be evaluated in a fully automatic workflow, and manual corrections can be performed if needed.

5 Conclusion

This study shows the potential of automatic monitoring of pectoralis muscle area using CBCT, by first restoring HU fidelity and reducing artifacts and then automatically segmenting the pectoralis muscle area. This allows for monitoring muscle wasting during the course of radiotherapy treatment and gaining insights into the dynamics of cachexia.

Abstract Deep learning-based image synthesis techniques, like cycle-consistent adversarial networks (cycleGANs), have improved the image quality of cone-beam computed tomography (CBCT) scans for radiotherapy by generating synthetic CTs (sCTs). By leveraging multi-channel input to provide a cycleGAN with a broader range of information upon training, our approach aims to preserve soft tissue contrast and reduce artefacts. The results demonstrate the successful generation of high-fidelity sCT images, with multi-channel models outperforming single-channel input across various image similarity metrics (mean absolute error, peak signal-to-noise ratio and structural similarity index). Furthermore, our approach demonstrates an ability to generalise to an unseen test data set of CBCT scans acquired from prostate cancer patients. A qualitative assessment, conducted by three expert radiographers, shows promising results in terms of overall image quality and artefact reduction and offers valuable insight into the clinical utility of sCTs. We emphasise the need for standardized qualitative assessments and downstream task evaluations to ensure robust insights.

1 Introduction

On-treatment cone-beam computed tomography (CBCT) is integral to adaptive radiotherapy, yet its image quality often suffers from artefacts such as streaking and noise, diminishing its utility compared to planning CT (pCT) scans. Deep learning-based image synthesis techniques, notably cycle-consistent generative adversarial networks (cycleGANs), have shown promise in enhancing CBCT image quality to a level comparable to pCT scans by generating a synthetic CT (sCT). However, challenges persist due to the wide Hounsfield unit (HU) range (-1024 to 2000 HU) in human anatomy CT scans. Soft tissue, confined to a narrow HU range, and high-density features like metal, often exceeding 2000 HU, present particular difficulties. This impacts the performance of image synthesis models, resulting in a loss of information for radiotherapy, such as soft tissue detail and accurate handling of artefacts. To address this, we propose leveraging a multi-channel input, consisting of multiple contrast settings, to provide the network with a broader range of information. By doing so, we aim to emphasise specific image features and enable the network to learn multiple contrast settings separately. This approach seeks to preserve soft tissue contrast and improve artefact reduction, ultimately enhancing the use of CBCT images in the radiotherapy workflow. By integrating observer testing alongside quantitative image similarity metrics, we aim to provide a comprehensive evaluation of the sCT images. This holistic approach aims to ensure that our method not only enhances image quality according to objective measures but also aligns with the perceptual expectations and clinical requirements of radiographers, thereby validating its suitability for adaptive radiotherapy applications. Additionally, we show that image synthesis models trained on data from independent centres can be applied to CBCT images in an unseen centre.

2 Materials and Methods

2.1 Training Data

For training, we used a publicly-available pelvis dataset consisting of CBCT and pCT scans for patients who underwent pelvis radiotherapy at three Dutch institutions: Radboud University Medical Center, University Medical Center Utrecht and University Medical Center Groningen [1]. A total of 180 CBCT-pCT pairs were available for training. For image acquisition parameters, see [1].

2.2 Testing Data

The test set consisted of CBCT and pCT scans from 42 prostate cancer patients who underwent radiotherapy at The Christie NHS Foundation Trust. The pCT images were acquired on Phillips Brilliance Big Bore CT or Siemens SOMATOM Definition AS (Erlangen, Germany) with 120 kVp. The CBCT images were acquired using Elekta Synergy imaging systems (XVI 5.52, Elekta, Crawley, UK) with 120 kVp. The exposure current was 40mA.

2.3 Pre-processing

Before training and inference, all images were resampled to the same voxel spacing: $1 \times 1 \times 2.5\text{mm}^3$ and a rigid image registration between the CBCT and pCT was performed to align the images. Binary masks based on the patient's pCT contour were generated and applied to the images. We then performed multi-channel range selection and normalisation before padding/cropping the images to Nx448x488 voxels, where N is the number of axial slices. All pre and post-processing were applied to 3D images, however, individual

axial slices were extracted from all image volumes (pCT and CBCT pairs) for training. A random 80/20 split was used to create train-time training and validation sets.

2.3.1 Multi-channel range selection and normalisation

To investigate the impact of training with additional information, the pCT and CBCT scans were normalised into either two or three separate channels using windowing to enhance the contrast of structures within the patient (Figure 1). The channels were then independently scaled to the range $[0, 1]$ using min-max normalisation to improve training stability and concatenated for input into the network.

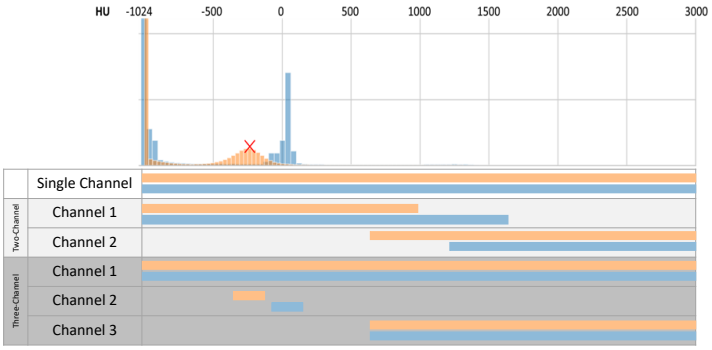

Figure 1: CBCT and pCT image histogram. Below the histogram shows the ranges in HU of each of the three input channels for the three models (single-channel, two-channel, three-channel).

Two channel input In the first channel, the CBCT and pCT were clipped to [-1024, 1000] HU and [-1024, 1600] HU, respectively, while the second channel ranged from [600, 3000] HU for CBCT and [1200, 3000] HU for pCT. Overlapping channels were used to facilitate recombination after sCT generation.

Three channel input In the first channel, we use the full width of the image range $[-1024, 3000]$ HU. In channel two, we use a contrast setting used to view soft tissue structures; for the pCT this was $[-150, 150]$ HU chosen to be centred on the water peak. Due to a lack of calibration of the CBCT images, both within and among centres, an automated peak finder was implemented to set the level to the soft tissue peak, with a fixed window width of ± 150 HU. In the final channel, both the CT and CBCT images were clipped to $[600, 3000]$ HU to capture information about the high-density structures within the patient.

2.4 Image Synthesis Method

Our method is based on a traditional cycleGAN architecture [2] with some specific modifications. CycleGANs consist of two sets of competing generator and discriminator networks trained simultaneously to enable unpaired training. The generators learn to produce CT-like output from CBCT input (a sCT) and vice versa (synthetic CBCT (sCBCT) output from CT input). The discriminators learn to classify CT/sCT and CBCT/sCBCT input as real and fake. Additionally, cycle consistency was enforced by inputting the synthetic image into the reverse generator to reverse the translation back to the original image modality.
The discriminator used in our modified cycleGAN is as described in [2], however, we modified the generator architecture. UNet-like long-range skip connections were added between corresponding down- and up-sampling convolutional levels to preserve contextual information. Finally, attention gates were added to the skip connections to emphasize salient features propagated forward from earlier in the network.
In the multi-channel case, the generator receives multi-channel input and produces multi-channel output. This is performed for ease of implementation of the cycle consistency aspect, where the output of each generator is also sent through the reverse generator.

2.5 Implementation Details

The model was implemented in PyTorch Lightning version 1.5.10 and trained using a single NVidia GeForce RTX 3090 GPU with 24GB VRAM. The batch size was 1. Each model was trained for a maximum of 200 epochs, however, early stopping was initiated if the total generator validation loss did not improve for 20 epochs. The models were trained with Adam Optimiser. The generator learning rate was set to 1e-4 while the discriminator learning rates were set to 2e-4. Upon inference, the trained CBCT-to-sCT generator networks were applied to preprocessed CBCTs to generate a corresponding sCT. The best model was selected according to the total generator validation loss.

2.6 Post-Processing / Channel Fusion

The padding or cropping performed during preprocessing was reversed to restore the sCTs to the original CBCT image size. Next, the HU intensity range of each channel was restored using a linear re-scaling: for example, channel one of the three-channel sCT was rescaled to [-1024, 3000] HU; channel two was re-scaled to [-150, 150] HU and channel three was re-scaled to [600, 3000] HU. For the two-channel sCT, the channels were rescaled to [-1024, 1600] and [1200, 3000] HU, respectively. The information from each channel were then combined into a single representation.

Two-channel fusion Voxels with HU values greater than 1400, as determined by the centre of the overlap region, were allocated the intensity value from the second channel, otherwise, voxels were allocated the value from the first channel.

Three-channel fusion The full-width image (channel one) underwent modifications based on specific conditions: values within the narrow range (-150 to 150 HU) were substituted

with channel two values, and values > 600 HU were replaced with channel three values.

3 Evaluation

Quantitative Evaluation The generated sCTs are assessed according to image similarity metrics, computed between the sCT and the pCT, rigidly registered to the CBCT. We include mean absolute error (MAE), structural similarity index (SSIM), and peak signal-to-noise ratio (PSNR). The Wilcoxon signed rank test was employed to determine whether there were any significant differences between the calculated metrics from each model. A significance level of 0.05 was used.

Qualitative Evaluation To evaluate both the clinical usefulness of synthetic CTs and the impact of multi-channel input, three radiographers, with 7 years or more experience, were asked to score the sCTs a subset of 10 cases from the test dataset (3 sCTs per patient). The radiographers were shown a sCT and corresponding pCT and CBCT, pseudo-randomly to ensure that sCTs generated from the same CBCT were not shown sequentially. They were asked to score the sCT concerning the severity of artefacts present, anatomical accuracy, clinical usability and overall image quality using a five-point Likert scale. The inter-observer variation was assessed by calculating the intra-class correlation coefficient (ICC) based on a mean rating (k=3), two-way random effects, absolute-agreement model.

4 Results

The sCTs generated by our methods are displayed in Figure 3 for an example test patient. Visually, the methods preserve the anatomical structure of the CBCT images and the contrast in soft tissue is enhanced in each of the models. Table 1 summarises the quantitative results obtained by image similarity metrics; MAE, PSNR and SSIM. Our reported image similarity metrics indicate good similarity to the ground truth images for each model, however, both models trained with multi-channel input significantly outperform the single-channel model according to the Wilcoxon signed rank test ($p < 0.05$), with the dual-channel model performing best. There was no significant difference found between the two and three-channel performance for any metric.

Table 1: Image similarity metrics between sCT and pCT.

Input	MAE (HU) ↓	SSIM ↑	PSNR (dB) ↑
One-channel	77.5 ± 10.1	0.91 ± 0.02	29.7 ± 1.5
Two-channel	$\mathbf{62.8 \pm 11.5}$	$\mathbf{0.94 \pm 0.02}$	$\mathbf{30.4 \pm 1.6}$
Three-channel	65.4 ± 10.7	0.94 ± 0.02	30.0 ± 1.4

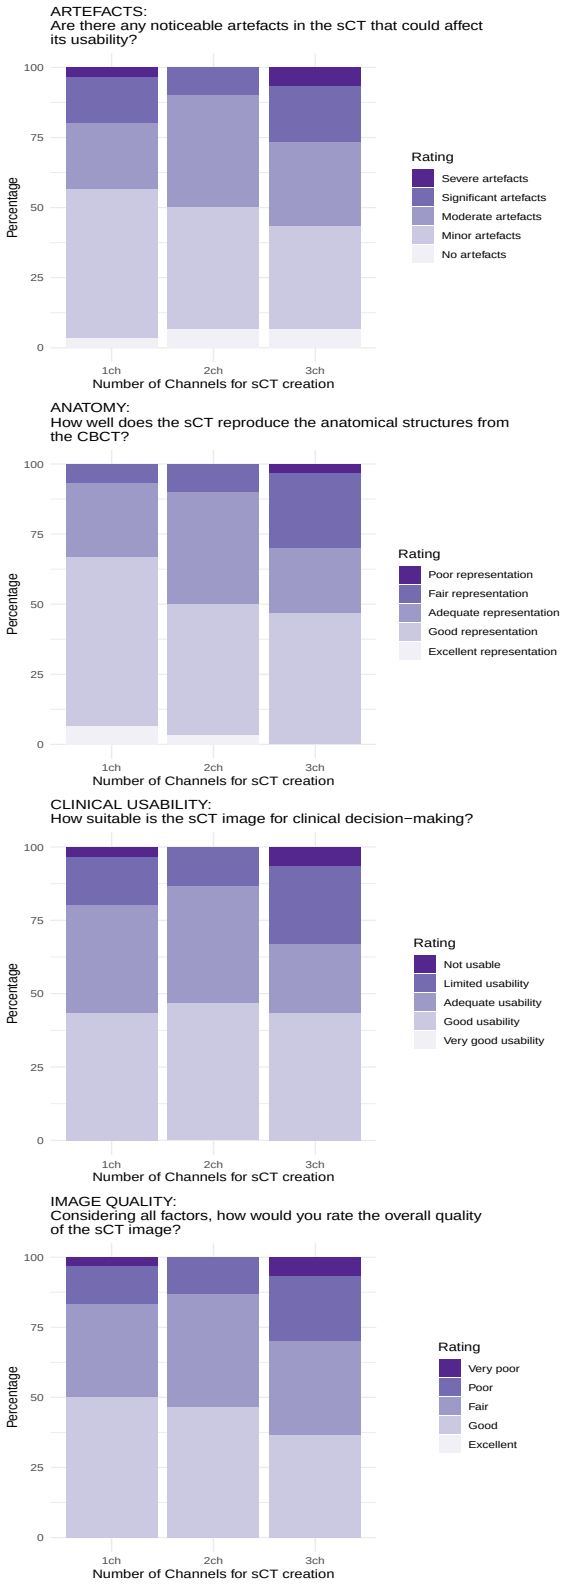

Figure 2: Results from visual grading analysis showed similar scores for single and two-channel approaches across all observers. However, three-channel sCTs performed worse overall.

4.1 Observer Assessment

Observers generally concurred with the image similarity metrics, with the two-channel sCT images receiving the highest ratings for acceptability concerning clinical usability, image quality and artefact reduction although lower in anatomical

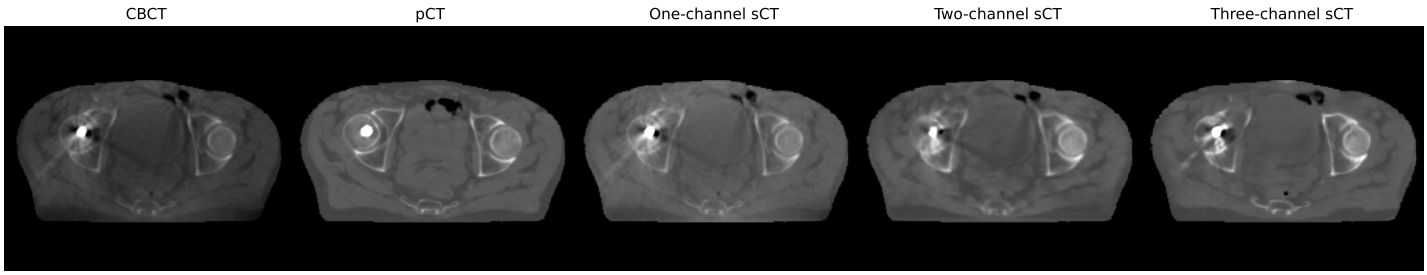

Figure 3: CBCT, pCT and sCTs generated by our methods for example prostate patient with metal implant in the hip. Images are shown with HU scale of [-500,1000] for ease of visualisation.

accuracy compared to the single-channel sCT. Notably, the three-channel sCT was rated less effective, primarily due to the noticeable distortion of organs at risk and the presence of synthetic artefacts, which outweighed any benefits from improved HU accuracy. This suggests the need to improve the ensemble of channels in post-processing. On average, there was minimal difference in score across sCT type for all observers. However, there was limited agreement among observers, with ICC measuring below 0.6 for each category.

5 Discussion

Our approach demonstrates the successful generation of high-quality sCT images from CBCT scans, with over 75% of images rated at least adequate for clinical decision-making for both single and two-channel models. Additionally, more than 75% of the images were rated at least fair in terms of image quality for these models. Incorporating image data at varying windows/levels within a concatenated multi-channel input has enabled us to address challenges inherent in CBCT imaging. Notably, we observed improvements in the suppression of artefacts, clinical usability and image quality with the addition of a second channel. However, in some instances, anatomical distortion was reported, and this was amplified with the three-channel approach. The re-combination of the multi-channel sCT images requires further refinement. Initial attempts at auxiliary fusion networks and other combination methods are ongoing.

Our reported image similarity metrics on the test dataset reveal promising results for the two-channel cycleGAN: a best average MAE of 62.8 ± 11.5 HU, PSNR 30.4 ± 1.6 dB and SSIM of 0.94 ± 0.02, indicate good similarity to the ground truth images, despite the test images being from an institution not included in the training set. This shows a good ability of the multi-center model to generalise. Interestingly, the model's performance in terms of image similarity on this test set surpasses results from the SynthRAD2023 challenge test set, where the three-channel model was tested on data from the same institutions for which it was trained [1, 3].

The image similarity metrics are supported by the observer assessment, where the two-channel model was rated more suitable for radiotherapy. Despite notable reductions in CBCT artefacts, such as streaking shown in Figure 3 with multi-channel models, concerns arise regarding the amplification of synthetic artefacts displaying as discontinuity in the image. This phenomenon may stem from the recombination of channels, leading to unfamiliar artefacts, thereby undermining trust in the images. Moreover, the inter-observer agreement was found to be low. The time taken to complete the evaluation ranged from 30 to 60 minutes indicating differences across observers. At present, there are no established guidelines for the evaluation or use of synthetic images in radiotherapy, and better definitions for the assessment questions may aid future evaluations. Nevertheless, qualitative assessments by experts, like radiographers, are crucial for understanding the potential of CBCT-based sCTs in enhancing adaptive radiotherapy workflows. However, to ensure robust insights, qualitative score sheets should be comprehensive, standardized and task-oriented, given the subjective nature of these evaluations. Both image similarity evaluation and qualitative assessment should also be supported by the evaluation of sCTs on downstream tasks such as dosimetric evaluation and contour propagation.

6 Conclusion

Although the global image metrics show a significant improvement in sCT quality as more information was incorporated into the training protocol, observers found all image reconstructions to be of similar quality. This highlights the need to include human observers in the assessment of image synthesis. Further improvement in combining the multi-channel output may remove the anatomical image discontinuities observed. However, we believe this is unlikely to change the observer rankings significantly.

Evaluating Treatment Delivery Performance of SCINTIX Biology-guided Radiotherapy under non-periodic In-treatment Motions

Chenyang Shen, Thomas Banks, Sagar Ghimire, Yang Kyun Park, Andrew Godley, Steve Jiang, Bin Cai

Department of Radiation Oncology, University of Texas Southwestern Medical Center

Abstract The RefleXion SCINTIX system uniquely enables novel biology-guided radiotherapy (BgRT), providing real-time treatment guidance via on-board positron emission tomography (PET). By directly targeting tumor response via PET, SCINTIX has the potential to substantially enhance the accuracy and efficacy of radiotherapy. This technology was only recently released for clinical usage, however, so its performance when dealing with in-treatment patient motion has not been fully explored. In this paper we report a novel study to investigate the performance of SCINTIX under discrete motions using an in-house developed fluorodeoxyglucose phantom. Ion chamber and film were used to measure point dose and 2D dose, respectively, under various scenarios of different discrete motions. The results show good agreement between delivered dose and planned dose, illustrating the efficacy of SCINTIX in resolving discrete motions during treatment delivery.

1 Introduction

SCINTIX radiotherapy (RT), uniquely enabled on the RefleXion X1 RT system (RefleXion Medical Inc, Hayward, CA), is the first commercially available biology-guided radiotherapy (BgRT) treatment platform [1]. It innovatively integrates a ring-gantry LINAC with a positron emission tomography (PET) scanner to provide functional guidance for treatment delivery. With recent FDA clearance for lung and bone cancer treatment, SCINTIX offers great potential to substantially improve the treatment precision and efficacy by adjusting beam fluence based on the PET signal which is updated every 100 milliseconds during beam delivery [2, 3].

To ensure the safe integration of SCINTIX into clinical practice and maximize its potential benefits, it is imperative to thoroughly assess its performance across a diverse range of motion scenarios. This presents a distinctive commissioning challenge. Generally speaking, in-treatment patient motion can be categorized into two main types: discrete non-periodic motion (such as sudden voluntary or involuntary movements) and continuous periodic motion (such as respiratory motion). These motions may occur independently or concurrently during treatment, adding further complexity to the evaluation process. In this paper we focused on investigating the impact of various discrete motions during treatment delivery.

2 Materials and Methods

2.1. Phantom design and fabrication

To assess SCINTIX delivery robustness against in-treatment motions, we developed an in-house fluorodeoxyglucose (FDG) phantom (Fig. 1). Our objective was to fabricate a phantom capable of holding FDG solutions of varying concentrations to simulate realistic FDG distribution within a patient's body. Specifically, the phantom features a dome-shaped volume for holding FDG, representing the PET-avid treatment target, atop an insert that installs inside a cylindrical water-filled phantom. Additionally, this cylindrical phantom can be filled with FDG at a comparatively lower concentration to simulate surrounding normal tissues in a patient. As highlighted in Fig.1, the insert was designed to also hold a custom-sized Gafchromic EBT3 film for 2D dose measurement. A chamber holder accommodating an Exradin A14SL chamber (Standard Imaging, Inc, Middleton, WI) was also included to facilitate precise point dose measurement.

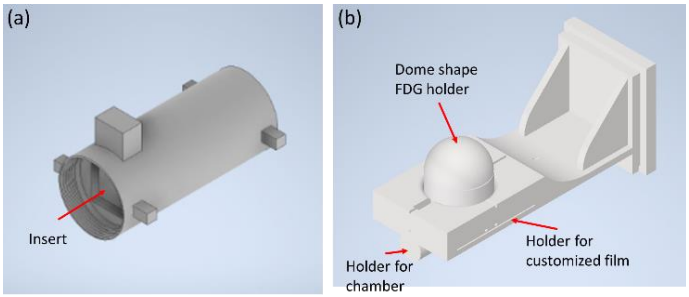

Figure 1. (a) In-house developed FDG phantom. (b) Detailed design for the insert with FDG, film, and chamber holders.

2.2 SCINTIX test plan development

We conducted our motion studies using the aforementioned in-house phantom. To evaluate the dosimetric impact of discrete motions during SCINTIX delivery, two plans were developed for ion chamber (IC) and film measurements, respectively. Specifically, a planning CT scan of the phantom was acquired on our clinical CT simulator with 1 mm in-plane resolution and 2 mm slice thickness. As shown in Fig. 2, the dome-shaped FDG holder was contoured to be the gross tumor volume (GTV) for both plans. Different expansions were then applied to the GTV to create two planning target volumes (PTVs) for the respective IC and film measurements. Note that relatively larger inferior expansions were applied to generate the PTV for the IC plan to ensure the active volume of the chamber remained within the PTV. The biological tracking zone (BTZ), a unique conceptual structure required by SCINTIX planning and treatment, was generated via a uniform expansion of 1 cm from the chamber PTV. The purpose of the BTZ is to filter the real-time PET signal for efficient data processing during treatment delivery. It is required that the PTV always stay within the BTZ during treatment delivery. Note that this BTZ generated from the IC PTV served as the BTZ for both plans since it is sufficiently large for both PTVs. In addition, two cylindrical

pseudo organs at risk (OARs) were contoured anterior and posterior left of the PTVs to make the test plan more realistic.

Prior to initiating SCINTIX planning, an on-board PET image must also be acquired on the RefleXion treatment unit. This PET image is then back-projected to the beam's eye view for each beam angle and convolved with some kernels referred to as “firing filters” to generate fluence maps. The inverse planning process is essentially the optimization process for these firing filters. In our experiment, the in-house phantom was filled with FDG at a target-to-background activity-per-unit-volume ratio of 8:1 for the pre-planning PET scan. This resulted in a target activity of approximately 150 kBq/ml for the preplan PET image, which was subsequently utilized as the planning PET for generating both ion chamber (IC) and film plans. The same experimental setup was maintained across all treatment deliveries.

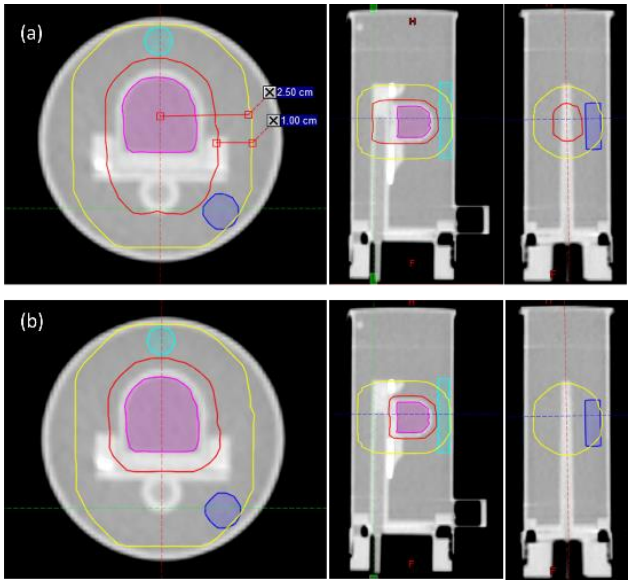

Figure 2. Three views of the planning CT of the in-house phantom for (a) the IC plan and (b) the film plan. Planning structures include the GTV (purple), PTVs (red), BTZ (yellow), and OARs (blue and cyan).

The prescription (Rx) dose to PTV for both plans was set to 100 Gy in 10 fractions with maximal dose objective set as Dmax≤105% of Rx dose. For film plan we considered both OARs and the planning goals were set as Dmax≤ 70 Gy for the anterior OAR and 80 Gy for the posterior left OAR. In contrast, for the IC plan only the anterior OAR was taken into account in the planning process, with an associated planning objective of Dmax≤50 Gy. Snapshots of the dose distributions of the optimized plans are shown in Fig 3. Note that both plans were generated for the purpose of evaluating delivery quality of SCINTIX under different discrete motions, so plan quality was not a major focus.

2.3. Static motion delivery setup

We started the test by verifying point dose accuracy with the IC plan. Specifically, measurements under four different scenarios in the plan delivery were carried out. In the first scenario, the phantom was held still after being set up to the treatment position via the on-board fan beam CT. This was to mimic BgRT delivery without any in-treatment motion. One or multiple shifts of magnitude of 0.5 cm were then applied to the phantom during treatment delivery as the second scenario. Note that the PTV was still well within the BTZ after applying these shifts. This test aimed to evaluate system performance when abrupt voluntary or involuntary movements of the patient occur during treatment delivery.

The third scenario involved shifting the phantom laterally by 2.5 cm during treatment. This was to mimic relatively larger abrupt in-treatment shifts of the patient. In this case, half of the PTV ended up outside of the BTZ, since the lateral dimension of the BTZ was 5 cm. We wanted to test if the machine could identify this issue and stop delivering dose. If the system did stop treatment, the phantom would be set up again to resume delivery, and the overall dose measured would be compared to the planned dose.

For the fourth scenario, we applied an even larger lateral shift of 4 cm during delivery so that the PTV was moved completely outside of the BTZ. This was to further understand the performance of SCINTIX plan delivery under extreme circumstances of very large shift. Similar to the third scenario, if the treatment system could identify this large motion and stop treatment delivery, we would set the phantom up to the planned treatment position again to resume treatment and compare the overall dose with the planned dose.

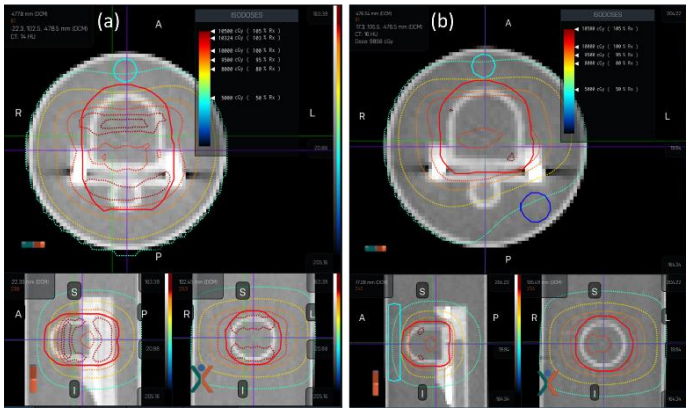

Figure 3. Snapshots of the dose distributions of the optimized (a) IC plan and (b) film plan.

The film plan was then delivered under the aforementioned second and third scenarios to further investigate 2D dose distributions for SCINTIX treatment delivery under discrete motions. We chose these two scenarios as opposed to the fourth one since they are more clinically relevant. Note that the detailed experimental setup, including the directions and magnitudes of the shifts during treatment delivery, was configured to be identical to that used in the IC plan experiments.

3 Results

3.1. Results of IC plan delivery

The point dose measured for the first scenario without in-treatment motion differed by -1.4% compared to the planned dose, illustrating the accuracy of SCINTIX treatment delivery for a static target.

For the second scenario, the phantom was shifted twice at different time points during a single treatment delivery. Specifically, the first shift was lateral, of magnitude 0.5 cm to patient left, when 25% of plan had been delivered. The second shift was superior by 0.5 cm, when 50% of the plan had been delivered. Note that the PTV remained within the BTZ defined in planning stage after these two shifts were executed. The measured point dose was ~0.6% lower than that of the static delivery (i.e. ~2% lower compared to the planned dose). These results indicate the satisfactory tracking capability of SCINTIX in terms of handling abrupt shifts of target within BTZ.

In the third scenario, we shifted the phantom by 2.5cm laterally to patient left when 25% of planned dose had been delivered. The system continued delivering beam until it reached ~35% of plan delivery, at which point an interlock was triggered due to missing target signal in BTZ. After re-setup, we were able to complete the partial delivery and the measured dose was ~4.7% higher than the static delivery (~3.3% higher than planned dose). Based on this test, SCINTIX system was able to detect a large shift and pause the delivery after part of the PTV had moved outside of the BTZ. However, the system response was not instantaneous. Close monitoring for large patient shifts by the treatment team would still be recommended.

We then performed a larger shift of 4cm during delivery to move the PTV completely out of BTZ after 25% of the plan had been delivered. The system suspended treatment after delivering another ~3% of MUs. We then re-set the phantom up and continued the plan delivery till completion. The resulting dose measured was 5% higher than the baseline from the static delivery (~3.5% higher than the planned dose). Compared to the partial-in/partial-out PTV scenario in the previous test, moving the PTV completely out of the BTZ triggered a swifter response of the SCINTIX system. However, the dosimetry results was similar. The experimental setups and the quantitative results of the IC plan are summarized in Table 1.

3.1. Results of film plan delivery

The first film test was carried out using same phantom shifts performed for the second scenario in the IC plan study. The results can be found in Fig. 4 (a). The measured dose generally agreed with the planned dose within 5% of difference according to the line profiles. A relative large decrease in measured dose can be observed in the left side of the horizontal profile. That area is close to the cutting edge of the customized film and hence may introduce a large uncertainty in measurement.

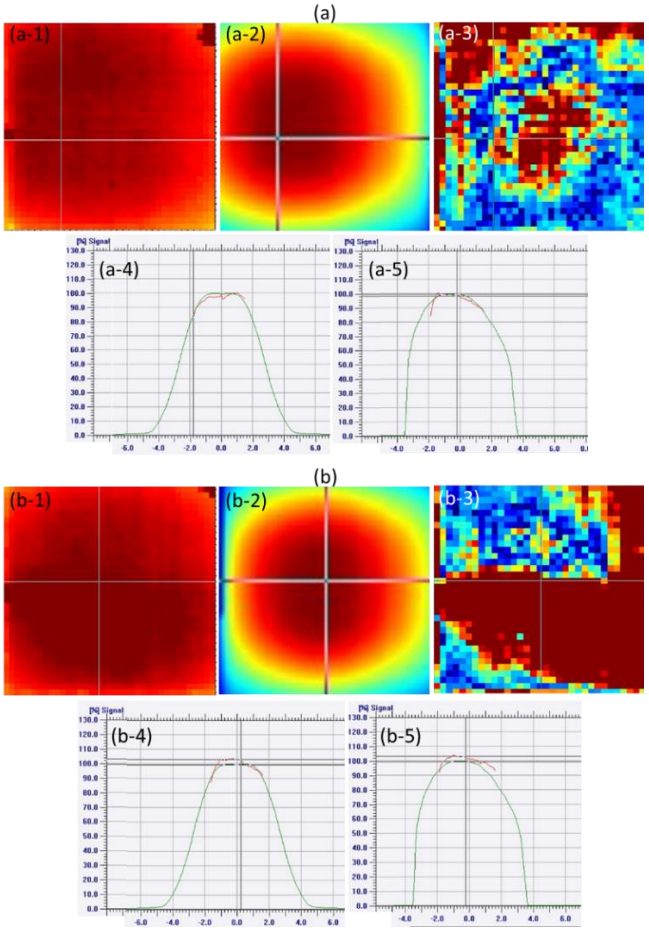

Figure 4. Film analysis results. (a): Two-step shifts with 0.5cm magnitude for each. (b): 2.5cm lateral shift. (a-1) and (b-1): scanned films; (a-2) and (b-2): planned dose; (a-3) and (b-3): gamma analysis (2%/2mm); (a-4) and (b-4): vertical line profile comparisons, (a-5) and (b-5) horizontal line profile comparisons (red: measured, green: planned).

Another film test was conducted with a 2.5 cm lateral shift applied during the treatment, identical to that used in the third scenario of the IC plan tests. The film results have revealed that SCNITIX overdelivered to the target which agrees with the behavior observed in point dose measurement. Similar to the previous film experiment, the measure dose and the planned dose generally match within 5% of difference, although 2D gamma analysis [4, 5] with 2%/2mm shows a relatively large discrepancy. It is also worth mentioning that gamma analysis is not recommended as the evaluation metric for SCINTIX delivery due to the stochastic nature of the PET signals.

4 Discussion

Based on our experimental results, the SCINTIX RT system is capable of recognizing and responding to discrete in-treatment motions. The dose delivery remained accurate for relatively small motions as long as the PTV was still within the BTZ, as evidenced by both point dose (0.6% compared to static delivery and 2% compared to planned dose) and film measurements (well-matched line profiles). When larger motions occurred, moving some or all of the

PTV outside of the BTZ, the SCINTIX system was able to detect the motion and stop the treatment. However, the system did not terminate delivery immediately after the shifts, revealing a continued need for close monitoring of patient movement by the treatment team during SCINTIX treatments. Once delivery had been stopped due to large motions, the system was able to resume treatment after we re-set up the phantom. The point dose measurements differed by 3.2% and 3.5%, respectively, for lateral shifts of 2.5cm (PTV half in/half out of BTZ) and 4cm (PTV completely out of BTZ).

This study only considered relatively simple discrete motions. What could actually happen during treatment could be more complicated than what we have considered here. For instance, in lung cancer treatments continuous periodic motion becomes the major concern. For patients with irregular breathing, abrupt changes in motion magnitude and/or pattern could also occur on top of the periodic respiratory motion. These problems are more challenging and will require further investigations. The study reported here helps us to better understand the behaviors of SCINTIX when discrete movements occur during treatments, and thus lays a solid foundation for future studies on more complex motion patterns.

The gamma analysis results in Fig. 4 depict the difference between measured and planned dose, but this is not recommended for SCINTIX testing. Note that the fluence maps for SCINTIX plan delivery are computed by convolving the back-projected PET signal acquired during treatment with the firing filters optimized on the pre-planning PET. Due to the stochastic nature of the PET signal, the delivered dose will always be different from what was planned. Therefore gamma analysis may not serve the purpose of evaluating plan delivery quality as well as it does for conventional RT. More research is needed to develop a proper metric for 2D dosimetric evaluation of SCINTIX plan delivery quality.

5 Conclusion

We have successfully conducted a discrete motion study to evaluate the performance of SCINTIX RT delivery using an in-house-developed FDG phantom. The results illustrate the efficacy of SCINTIX in recognizing and responding to discrete in-treatment motions to achieve robust delivery.

Detection and correction of rigid patient motion in SPECT with exponential data consistency conditions

My Hoang Hoa Bui[1], Antoine Robert[1], Simon Rit[1], and Ane Etxebeste[1]

[1]INSA-Lyon, Université Claude Bernard Lyon 1, CNRS, Inserm, CREATIS UMR 5220, U1294, F-69373, Lyon, France

Abstract Targeted radionuclide therapy has gained an increasingly important role in cancer treatment in recent years, in which molecular imaging techniques such as SPECT can be employed to plan and monitor the treatment. However, rigid patient motion is degrading the quality of SPECT images and may impact the treatment planning. It has been recently proposed to use exponential data consistency conditions — equations describing the redundancy of exponential SPECT measurements — to detect and correct for patient motion. This study aimed at developing a data consistency-based method to estimate and correct for rigid patient motion during SPECT acquisitions. The proposed method was evaluated on Monte Carlo simulated data of a liver patient. The method led to a significant improvement in the image quality. An activity recovery coefficient above 95% with respect to the reconstructed images from motion-free projections was obtained across all tested cases. In particular, for a motion in the middle of the acquisition, the activity recovery coefficient was improved from 66 % (non-corrected projections) to 99% (motion-corrected projections).

1 Introduction

Targeted radionuclide therapy is a favorable option in cancer treatment thanks to its ability to selectively deliver radiation to cancerous cells, thus minimizing toxicity on surrounding healthy tissues [1]. Functional imaging such as single photon emission computed tomography (SPECT) can be used to optimize the treatment plan, i.e. to adjust the amount of injected radionuclides [2–4].

After injecting the patient, the SPECT scanner collects projections of the emission map with one or several rotating gamma cameras. However, data acquisition requires a long time, typically 5 to 40 minutes. During this time, rigid patient motion is likely to occur [5], potentially leading to artifacts in reconstructed images [6].

Exponential data consistency conditions (eDCCs) are mathematical equations that describe redundancies among measurements modeled by a linear operator called the exponential Radon transform. Recently, Wells and Clackdoyle showed the feasibility of using eDCCs to align the attenuation map to the emission map in pinhole cardiac SPECT [7]. In [8], Robert *et al* studied the ability of eDCCs to detect motion on realistic simulated data in parallel SPECT.

To our knowledge, motion compensation in SPECT exploiting eDCCs exclusively has not been studied yet. This study aimed at employing eDCCs for automated estimation and correction of patient motion, requiring solely the acquired projections and the attenuation map of the patient.

2 Materials and method

2.1 Exponential data consistency conditions

The exponential Radon transform is a two-dimensional (2D) operator and eDCCs can be expressed in 2D. Throughout this study, we express them in a three-dimensional (3D) space for deriving the correction of 3D motions but their 2D expression can be obtained by dropping the third coordinate.

Consider a 3D radioactivity distribution f and an attenuating medium μ. The ideal measurement of f in parallel SPECT geometry can be modeled by the attenuated Radon transform:

$$p_\mu(\theta,s,z) = \int_{-\infty}^{+\infty} f(s\mathbf{u}_\theta + t\mathbf{v}_\theta + z\mathbf{e}_z) \exp\left(-\int_t^{+\infty} \mu(s\mathbf{u}_\theta + t'\mathbf{v}_\theta + z\mathbf{e}_z)\,\mathrm{d}t'\right)\mathrm{d}t \quad (1)$$

where $\mathbf{u}_\theta = (\cos\theta, \sin\theta, 0)$, $\mathbf{v}_\theta = (-\sin\theta, \cos\theta, 0)$ and $\mathbf{e}_z = (0,0,1)$.

Assuming that there is a known convex region K where the attenuation is constant, i.e. $\mu(x,y,z) = \mu_0$ if $(x,y,z) \in K$, and all radioactivity is encompassed inside K, the exponential projections $p(\theta,s,z)$ can be derived from $p_\mu(\theta,s,z)$ by a point-wise conversion, as:

$$p(\theta,s,z) = p_\mu(\theta,s,z)C(\theta,s,z). \quad (2)$$

The conversion factor $C(\theta,s,z)$ was introduced in [9]

$$C(\theta,s,z) = \exp\left(\tau_{\theta,s,z}\mu_0 + \int_{\tau_{\theta,s,z}}^{+\infty} \mu(s\mathbf{u}_\theta + t'\mathbf{v}_\theta + z\mathbf{e}_z)\,\mathrm{d}t'\right) \quad (3)$$

with $\tau_{\theta,s,z}$ the point along the integral line towards the detector where the photon leaves the convex region K.

Range conditions of the exponential Radon transform, known as eDCCs, state that two projections at θ_i and θ_j which are not 180° apart ($\theta_i - \theta_j \neq \pi\,[2\pi]$) are consistent if and only if

$$P(\theta_i, \sigma_{ij}, z) = P(\theta_j, \sigma_{ji}, z) \quad (4)$$

with $P(\theta,\sigma,z) = \int_{-\infty}^{+\infty} p(\theta,s,z)e^{\sigma s}\,\mathrm{d}s$ the two-sided Laplace transform of projection line $p(\theta,\cdot,z)$ and $\sigma_{ij} = -\sigma_{ji} = \mu_0 \tan((\theta_i - \theta_j)/2)$.

2.2 Motion simulation

Using a validated GATE model of the Symbia Intevo Bold scanner [10, 11], we simulated a liver radioembolization patient using a CT image and a voxelized sphere source of 20 mm-radius located inside the liver with a ^{99m}Tc activity of 150 MBq. Data were acquired within a primary energy window of 15% centered around the main photopeak of 140.5 keV and a lower scatter window of 15% centered around 120 keV — later used to correct scatter from acquired primary projections. Several sets of projections were generated, each consisting of 60 projections covering 360°, an acquisition time of 15 s per projection with 256 × 256 pixels of 2.39 mm spacing. The SPECT camera followed a circular orbit with a detector-to-center distance of 38 cm.
In this study, we considered a single rigid patient motion between two successive projections of the acquisition. The rigid patient motion was simulated by shifting simultaneously the attenuation and emission maps. One set of projections was simulated without motion and used as a reference. The performance of the motion detection and correction method was evaluated regarding:

1. Motion index: with a motion vector set to $(20,20,20)$ mm, all possible values of motion index (defined as the first frame index affected by motion), were evaluated.
2. Motion magnitude: with a motion index fixed at the middle of the acquisition, several motions were evaluated: 1, 3, 5, 10, 20 and 30 mm in all three axes.

2.3 eDCCs assessment

To replicate a clinical scenario with the CT image acquired only once before the SPECT acquisition, we used the attenuation map placed at the original position to compute eDCCs. We defined the convex K region covering the whole liver (created with auto segmentation of 3D Slicer on the CT image). To evaluate the consistency of the i-th and j-th SPECT projections p_μ with N detector lines in the axial direction, we employed the noise-aware metric [8, 12]

$$\mathrm{NE}_{p_\mu}(i,j) = \frac{\frac{1}{N}\sum_{l=1}^{N} |P(\theta_i,\sigma_{ij},z_l) - P(\theta_j,\sigma_{ji},z_l)|}{\sqrt{N}\sqrt{\mathrm{Var}(\overline{Pij}) + \mathrm{Var}(\overline{Pji})}} \quad (5)$$

with z_l the discretized z coordinate of the l-th line of the detector, the variance

$$\mathrm{Var}(\overline{P_{ij}}) = \frac{(\Delta s)^2}{N^2} \sum_{l=1}^{N}\sum_{k=1}^{M} C_l^2(\theta_i,s_k,z_l)\, p_\mu(\theta_i,s_k,z_l)\, e^{2\sigma_{ij}s_k} \quad (6)$$

Δs the pixel spacing and M the number of pixels per projection line.
According to findings in [8], rigid patient motion is the main contributor to projection inconsistency, i.e. high $\mathrm{NE}_{p_\mu}(i,j)$, whereas the physical effects have almost negligible (Poisson noise and collimator resolution) or moderate (scatter) impact on eDCCs.

To mitigate the effect of scatter on the motion estimation model, we applied scatter correction with the dual energy window (DEW) with a k factor of 1.1. The value of k was chosen to minimize the inconsistency in the reference motion-free acquisition. Then, a mask, defined as the forward projector of the K region, was applied to scatter-corrected frames after DEW to remove the remaining scattering from outside of the convex region.

2.4 Motion correction

If the patient's displacement is known, motion-free projections can be calculated by compensating for the patient's motion in the projection domain. When both the emission and attenuation maps are shifted by a vector in a transverse plane, the corresponding projections are shifted by a translation along the s-axis. Motion in an orthogonal direction, along the rotation axis z, can be directly interpreted as the same shift along the axial coordinate. Together, any 3D motion shift $\mathbf{a}$ can be corrected in the attenuated projection at a given detector angular position θ by a translation of the projection,

$$p_\mu^{\mathbf{a}}(\theta,s,z) = p_\mu(\theta, s+\mathbf{u}_\theta\cdot\mathbf{a}, z+\mathbf{e}_z\cdot\mathbf{a}). \quad (7)$$

2.5 Motion estimation

Let's define motion index m_0 as the first frame index affected by motion. m_0 divides the acquisition into no-motion projections $p_\mu(\theta_i,\cdot)$ for $i<m_0$ and motion-affected projections $p_\mu(\theta_j,\cdot)$ for $j\geq m_0$. Pairing projections in the second set with projections in the first set should result in non-zero eDCCs. In contrast, if these motion-affected projections $p_\mu(\theta_j,\cdot)$ are corrected by the true shift $\mathbf{a}_0$, the eDCCs should be closer to zero. To estimate m_0 and the shift $\mathbf{a_0}$, we therefore minimized the inconsistency between pairs of motion-corrected projections $p_\mu^{\mathbf{a}}$ of the two sets by solving the minimization problem

$$(\hat{m},\hat{\mathbf{a}}) = \underset{m\in\Omega_m,\,\mathbf{a}\in\mathbb{R}^3}{\operatorname{argmin}} F(m,\mathbf{a}) \quad (8)$$

with $\Omega_m = [2,L]$, L the number of projections within the acquisition, the cost function

$$F(m,\mathbf{a}) = \frac{1}{K}\sum_{i<m,j\geq m} \mathrm{NE}_{p_\mu^{\mathbf{a}}}(i,j) \quad (9)$$

and K the number of evaluated projection pairs (fulfilling $i<m\leq j$ and $|\theta_i-\theta_j|\neq 180°$).
The problem was solved by first calculating

$$\tilde{\mathbf{a}}_m = \underset{\mathbf{a}\in\mathbb{R}^3}{\operatorname{argmin}} F(m,\mathbf{a}) \quad (10)$$

for every $m\in\Omega_m$ with the Nelder-Mead downhill simplex algorithm [13] and then taking the value m that minimizes F, i.e., $\hat{\mathbf{a}} = \tilde{\mathbf{a}}_{\hat{m}}$ with

$$\hat{m} = \underset{m\in\Omega_m}{\operatorname{argmin}} F(m,\tilde{\mathbf{a}}_m). \quad (11)$$

2.6 Quantitative assessment of motion correction

The estimated motion shift was compared to the simulated value. For each projection set, the optimization was repeated 20 times with random initializations to estimate the robustness of the estimation.
The effect of motion correction on reconstructed SPECT images was visually assessed with a (20,20,20) mm shift occurring in the middle of the acquisition. The estimated motion was taken as the median of 20 random initializations. The motion-free projections, non-corrected projections and motion-corrected projections were reconstructed by the ordered subset expectation maximization (OSEM) implemented in RTK [14] using 5 iterations and 4 subsets with attenuation correction. The quality of reconstructed images was assessed via the activity recovery coefficient (ARC) in reference of the reconstructed SPECT images from motion-free projections

$$\mathrm{ARC}(\%) = \frac{A}{A_{\text{motion-free}}} \times 100\%. \qquad (12)$$

The values A and $A_{\text{motion-free}}$ are the estimated activities in the source region obtained respectively from evaluated projections (non-corrected or motion-corrected projections) and from motion-free projections taken as reference.

3 Results

The ability to detect a $(20,20,20)$ mm translation appearing at different motion indices of the acquisition is shown in Fig. 1. Plot A indicates the values of the cost function after optimization for every position $m \in [2,60]$, i.e., $F(m,\tilde{\mathbf{a}}_m)$, while B shows the difference between the estimated $\hat{m}$ and the true motion index m_0 for all possible $m_0 \in \Omega_m$ with two selected examples of motion magnitude. For a 20 mm motion per axis (blue curve in Fig. 1B), the motion index was adequately estimated. For 3D motions below 5 mm per axis, for instance the black curve in Fig. 1B, $\hat{m} - m_0$ was not zero, i.e., the estimation of the motion index was incorrect for several values of m_0.

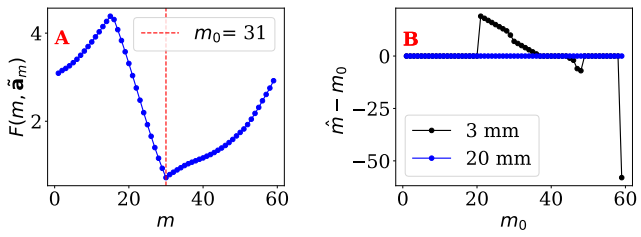

Figure 1: A. Illustration of motion detection with sliding value $m \in [2,60]$ for (20,20,20) mm displacement in the middle of acquisition; B. Performance of motion detection for different motion indices m_0 with respectively (20,20,20) mm shift (blue) and (3,3,3) mm (black).

Fig. 2 illustrates the estimation of (20,20,20) mm translation occurring at different motion index m_0 along the acquisition. The proposed method returned promising accuracy where the absolute differences were close to or below the pixel size of 2.39 mm for each direction. There was also a significant precision at the sub-millimeter level across different repetitions of the optimizer, with only a minor number of outliers.

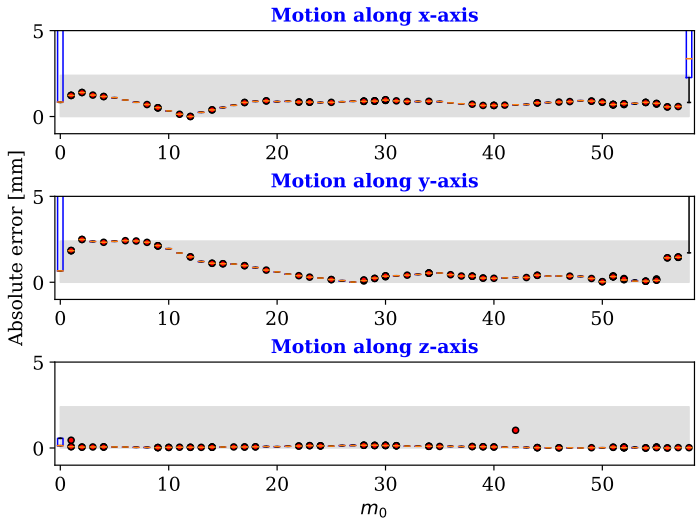

Figure 2: Box and whisker plot (blue) for absolute error of motion estimation at different motion indices m_0 for $\mathbf{a}_0 = (20,20,20)$ mm. Horizontal red lines inside the box represent the median value and circular red dots are outliers with high bias, i.e. values greater than 1.5 inter-quartile range.

In general, motion assessment along z was highly accurate with an error below 1 mm. The mean deviation for all values of motion index m_0 was around 0.05 mm in this axis compared to respectively 1.4 and 2.2 mm in x and y. Also, misestimation in x and y were generally synchronous.
For smaller shifts below 5 mm, the absolute relative errors were larger (data not shown), e.g., up to 10 to 50 % compared to the true values for mid-acquisition motion. When the shift is above 5 mm per axis, these errors are below 10% for all three components. These findings are consistent with the results above.
The ARC before and after motion correction is shown side-by-side in Fig. 3. Without correction, the values of ARC spread in a wide range from 15% to nearly 100%. In contrast, motion correction brought a comparable ARC to motion-free images, i.e. less than a 5% drop for motion occurring early in the acquisition and below 1% for motion occurring after one-third of the acquisition.
The improvement in the reconstructed image is illustrated in Fig. 4. Motion correction greatly mitigated the artifacts, namely blurring and distortion of the sphere.

4 Discussion

In this study, eDCCs were exploited to detect and correct for rigid patient motion in SPECT projections simulated with Monte Carlo simulations using a realistic SPECT scanner model.

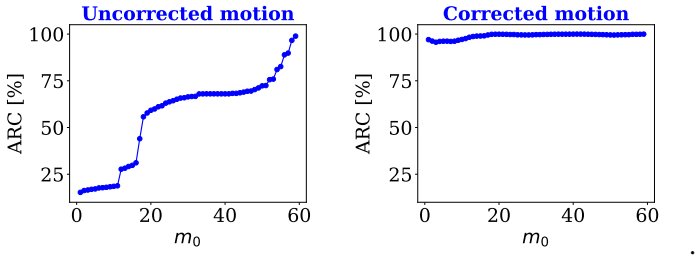

Figure 3: Activity recovery coefficient (ARC) as a function of motion index m_0 for $\mathbf{a}_0 = (20, 20, 20)$ mm.

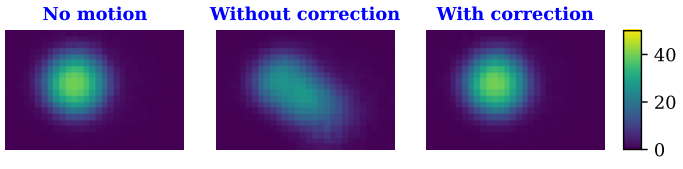

Figure 4: Visualization of reconstruction with motion-free, non-corrected, and motion-corrected projections for $m_0 = 31$ and $\mathbf{a}_0 = (20, 20, 20)$ mm.

The current two-step procedure first showed the reliability of detecting sudden inter-frame translation of (20,20,20) mm happening between any two successive frames of the acquisition, i.e. different possibilities of m_0. For the sliding value of $m \in [2, 60]$, frames after m were corrected simultaneously with the same shift to optimize projection consistency. If $m \neq m_0$, some motion-free ($p(\theta_i, \cdot)$ for $i < m_0$) or non-corrected ($p(\theta_j, \cdot)$ for $j \geq m_0$) projections are wrongly motion-corrected or non-corrected, respectively, and both raised the inconsistency in the cost function (Fig. 1A).
For a known motion index m_0, the motion correction performed on projections from Monte Carlo simulation already achieved quite good agreement with true values. In general, estimation on the z-component, which was independent of motion index m_0, surpassed those in the other two directions in terms of accuracy. Indeed, translation in z is more sensitive to eDCCs than in the other two directions since it directly correlates to the same translation for all angular positions of the detector θ_m.
In good agreement with the findings from Robert *et al.* [8], we observed that the collimator resolution and Poisson noise had a minor impact on the correction of motion with eDCCs using scatter-free simulations obtained by RTK ray tracing modeling these two effects [14] (data not shown). On the contrary, the presence of scatter in the Monte Carlo simulation noticeably degraded the accuracy of our proposed correction method when no scatter correction was performed (data not shown).

5 Conclusions

Rigid patient motion in SPECT has been detected and corrected with an algorithm exploiting exponential data consistency conditions. A two-step process was shown to be practical for SPECT measurements simulating all physical effects which is promising for future application to real scanner data.

Preliminary Study on Residual Motion Evaluation During Breath Hold SBRT

Weihua Mao and Amol Narang

Department of Radiation Oncology and Molecular Radiation Sciences, Johns Hopkins University, Baltimore, Maryland, USA

Abstract Breath hold has been widely used to limit patient respiratory motion for radiation therapy, however residual motions have been reported by many groups. Fiducial markers have been implanted to locate the target for pancreatic cancer treatment at our institution. A new method is presented to locate fiducial positions on every projection image during cone-beam computed tomography (CBCT) scans for patient setup or positioning verification. Data of three pancreatic cancer patients were studied retrospectively. Every patient exhibited residual motions during breath hold maneuvers, with an average drifting range of 6.5 mm observed across 34 CBCT scans. Residual motions within a single CBCT scan ranged up to 10.6 mm, and significant drifting occurred between breath holds. This method does not need any additional equipment or deliver any extra radiation doses to patients. It provides important information on daily residual motions and is invaluable for planning margin adjustments towards online adaptive radiation therapy.

1 Introduction

A key factor in treating pancreatic cancer with stereotactic body radiation therapy (SBRT) is how to manage the motion due to respiration during radiation therapy. At our institution, radio-opaque fiducial markers have been placed endoscopically before radiation therapy. All simulation, patient setup, and beam delivery have been under deep inspiration breath hold (DIBH). However, it has been reported that residual motions occur under breathing holding [1-6]. A novel, cost-effective method is presented to evaluate daily fiducial residual motions during cone-beam computed tomography (CBCT) acquisition.

2 Materials and Methods

Three pancreatic cancer patients treated in the past two months with SBRT were enrolled into this retrospective study under an internal review board protocol (IRB00395200). Two to three fiducial markers were implanted endoscopically in the pancreas for each patient. These cylindrical-shaped fiducials have a diameter of 0.5 mm and a length of 3 mm. Patients were immobilized using Vak-lok (CIVCO Medical Solutions, Coralville, IA, USA) with a wingboard (CIVCO Medical Solutions, Coralville, IA, USA). Active breathing coordination (ABC, Elekta, Stockholm, Sweden) was employed for DIBH. Patients were coached to breath in and hold their breath. Four computed tomography (CT) simulation scans were repeatedly acquired under DIBH using the Brilliance Big Bore CT simulators (Philips Medical Systems, Cleveland, OH, USA). One set of CT images was selected for contouring and treatment planning in RayStation (RaySearch Laboratories AB, Stockholm, Sweden). Slice thickness of CT images was 2 mm while planar pixel size was around 1.4 mm. Fiducials were contoured in the bone window ([450 1600] HU). Volumetric modulated arc therapy (VMAT) with two arcs were planned with prescriptions of 33 to 40 Gy in 5 fractions. Patients were treated by a VersaHD (Elekta, Stockholm, Sweden) linear accelerator. Partial arc (200 degrees) rotation CBCT were used with settings of 120 kV, 40 mA and 40 ms. The source-to-axis distance (SAD) was 1000 mm, the source-to-imager distance (SID) was 1536 mm, the projection image resolution was 512 x 512, and the pixel size was 0.8 mm. Maximum breath hold (BH) durations were 25 seconds for each patient. Each CBCT scan was acquired in two consecutive breath holds (BHs). Reconstructed CBCT images were rigidly registered to the planning CT based on bony structures and finalized using fiducial markers. After multiple reviews, six dimensional corrections were sent to the Hexapod (Elekta, Stockholm, Sweden) to adjust treatment couch. Verification CBCT scans were acquired immediately and/or during the middle of treatment. Treatment beams were delivered under identical DIBH.

Planning CT and structures, CBCT projection data, and ABC results were exported and de-identified from clinical systems. All analyses were performed using Matlab programs (MathWorks, Natick, Massachusetts). Fiducial mass centers were calculated within fiducial structures as fiducial positions in planning CT. Fiducial positions were compared within four sets of simulation CT by registering the planning CT to other three sets of CT focusing on fiducials.

Figure 1 illustrates both linac and imaging coordinate systems. The origin is set at the isocenter. X, Y, and Z axis directions represent the horizontal (lateral), vertical (posterior-anterior), and longitudinal directions, respectively. Projection images are in a two-dimensional (2D) coordinate system (u, v), whose origin is at the center of the imager, which rotates with gantry rotation. Equations (1) and (2) predict the projected location (u, v) of a fiducial at (x, y, z) [7].

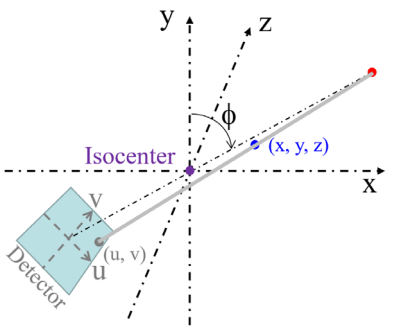

Figure 1: Schematic diagram of the coordinate systems.

$$u = \frac{\mathrm{SID}\cdot(\mathrm{x}\cdot\cos\phi - \mathrm{y}\cdot\sin\phi)}{\mathrm{SAD} - \mathrm{x}\cdot\sin\phi - \mathrm{y}\cdot\cos\phi} \approx \frac{\mathrm{SID}}{\mathrm{SAD}}(\mathrm{x}\cdot\cos\phi - \mathrm{y}\cdot\sin\phi) \quad (1)$$

$$v = \frac{\mathrm{SID}\cdot\mathrm{z}}{\mathrm{SAD} - \mathrm{x}\cdot\sin\phi - \mathrm{y}\cdot\cos\phi} \approx \frac{\mathrm{SID}}{\mathrm{SAD}}\mathrm{z} \quad (2)$$

Projection image analyses focused on regions around fiducial projection locations estimated using Eqs. (1) and (2) for every gantry angle, as shown in Figure 2(a). Relative positions of all fiducials are calculated and used as a pattern (Figure 2(b)) to match and locate the fiducials. Gradients or ridge heights were calculated in four directions (horizontal, vertical, and two oblique directions). Since the thickness of fiducial projection is only one or two pixels, gradients from two sides of a width of one or two pixels were screened by a preset threshold. The square roots of their products were used as heights at every direction (Figures 2(e) – (l)). Final heights were the summation of heights in all directions (Figure 2(c)). They were smeared by a simple average (Figure 2(d)) before matching the pattern (Figure 2(b)).

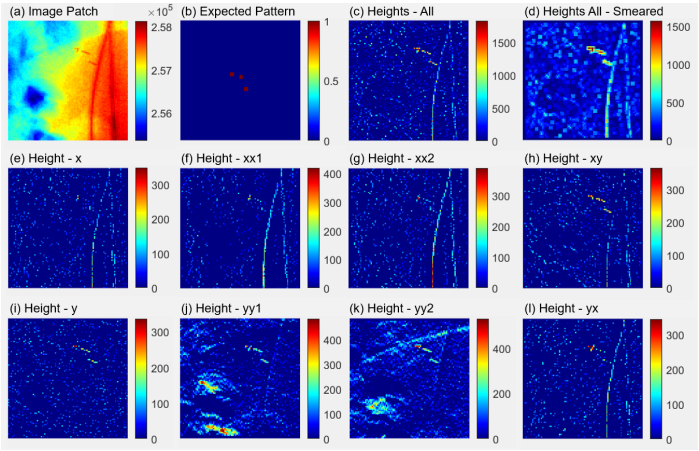

Figure 2. Imaging processing example.

A pre-analysis was performed on 2D fiducial positions to remove outliers based on expected position trendlines in every BH. Three-dimensional (3D) positions were then calculated using projections acquired previous gantry angle 45 degrees apart for two breath holds separately. The fiducial longitudinal positions were calculated in every projection based on Eq. (2). Residual motions in the longitudinal direction were assessed directly.

3 Results

It was found that the fiducials may be off by 3 slices (6 mm) among four sets of simulation CT images acquired under DIBH. CBCT projections from 8 to 16 acquisitions per patient were successfully analyzed. In total, 6697 frames of 2D projection images were acquired and fiducials were successfully detected on 6474 frames of images. 3D positions at two BHs were compared for every scan and their statistic differences on longitudinal positions are listed in Table 1.

Residual motions in the longitudinal direction were observed. Figure 3 illustrates average fiducial longitudinal positions during two BHs in a CBCT scan. Actual fiducial locations are compared in Figure 4 as an example. Significant drift occurred during the same breath hold. Four key positions were defined as the Start and End of each BH.

The drifts in the longitudinal direction were calculated for every scan. The drifting range in every BH and between two BHs was also calculated. Statistic results for every patient are listed in Table 2.

Table 1. List of average fiducial longitudinal position differences between two breath holds from 3D results.

Patients	Scan #	Min	Max	Avg	Stdev
PA01	10	-2.7	0.5	-0.7	1.2
PA02	16	-1.5	2.9	0.3	1.1
PA03	8	-0.2	0.6	0.3	0.3

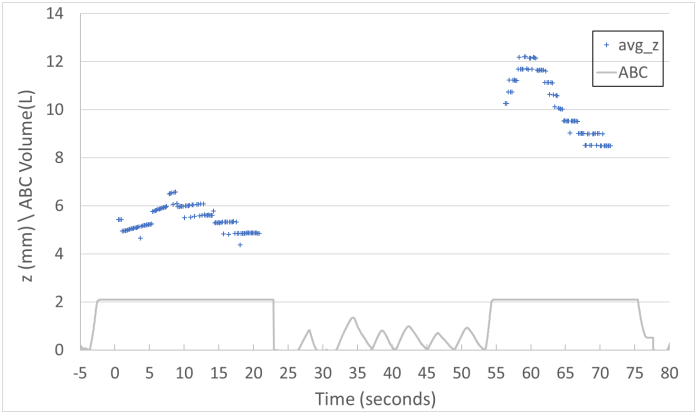

Figure 3. Average fiducial longitudinal positions (z) as functions of time for patient PA01 at scan 4a. ABC signals are illustrated.

Table 2: List of average fiducial longitudinal position differences from 2D results. The E-S of 1st BH and the E-S of 2nd BH results are the statistic differences between the end and start of the 1st BH and 2nd BH, respectively; the Between BHs results are the statistic differences between two BHs (unit: mm).

Patients	Period	Min	Max	Avg
PA01	E-S of 1st BH	-5.5	-0.1	-2.4
	Between BHs	-1.6	7.5	2.6
	E-S of 2nd BH	-4.7	-1.0	-2.7
	Range of 1st BH	2.3	5.4	3.7
	Range of 2nd BH	1.6	5.6	3.4
	Range of 2 BHs	3.1	8.9	5.6
PA02	E-S of 1st BH	-5.2	2.5	-2.9
	Between BHs	0.2	6.8	2.9
	E-S of 2nd BH	-6.2	0.9	-1.8
	Range of 1st BH	3.0	6.1	4.5
	Range of 2nd BH	1.6	6.8	3.0
	Range of 2 BHs	3.1	7.8	5.2
PA03	E-S of 1st BH	-2.5	1.8	-0.6
	Between BHs	-5.9	1.6	-1.6
	E-S of 2nd BH	0.0	5.1	1.9
	Range of 1st BH	4.7	8.9	6.7
	Range of 2nd BH	5.2	8.3	7.2
	Range of 2 BHs	7.3	10.9	8.6

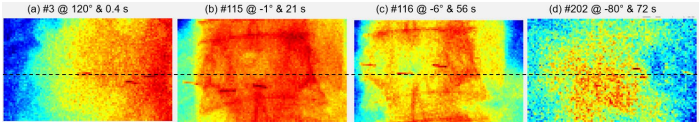

Figure 4. Comparison of fiducial locations at Start and End of each BH for Pt PA01 at scan 4a.

4 Discussion

The projection prediction equations have been simplified. For any fiducials within 20 mm from the isocenter, this may result in an error of 1 pixel on the projection, which is acceptable for this analysis.

Residual motions were observed during multiple simulation CT due to faster CT scan acquisition than CBCT acquisition. CBCT volumetric image reconstruction would smear residual motions. The average drifting during two breath holds were 6.5 mm while the maximum drifts were up to 10.9 mm. Our results also indicate that significant part of the drifts occurred between breath holds.

This is only a preliminary study, with only three patients enrolled. Further studies will continue with more patients enrolled in the near future. This method provides a free assessment of the residual motion during breath hold since it doesn't require any additional equipment or procedures and does not deliver any extra radiation doses to patients. This information will be very helpful for adjusting planning margin for daily adaptive planning.

5 Conclusion

Fiducial residual motions under breath hold could be assessed daily before radiation therapy without any extra cost.

Super Resolution Dose Calculation Via Implicit Neural Representation Based Blind Deconvolution

Siqi Ye, Sheng Liu, Yu Gao, and Lei Xing

Department of Radiation Oncology, Stanford University, Stanford, CA, USA

Abstract In radiation therapy, achieving high-resolution (HR) dose distributions is crucial but time-intensive, posing a significant bottleneck in the clinical workflow of treatment planning. A common workaround is to first calculate a dose distribution at low resolution and then refine it using super-resolution (SR) techniques. Building upon this approach, we introduce a novel super-resolution (SR) technique for fast and high-quality dose calculation. The proposed SR technique leverages a cutting-edge implicit neural representation (INR) network to learn a continuous function that accurately represents the target HR dose distribution image. In such a way, our model can produce dose maps at virtually any resolution. Unlike previous methods which assume a pre-known blurring kernel, we tackle a blind deconvolution problem where the blurring kernel is unknown and thus is estimated together with the HR image. We tested our method on a pancreas SBRT plan using the MRIdian MRgRT system, demonstrating significant improvements in image quality over an existing INR-based SR method that relies on predefined kernels. Our technique offers rapid SR dose calculation, achieving results in milliseconds.

1 Introduction

In the field of radiation therapy (RT), achieving both accuracy and efficiency in calculating dose distribution is paramount. The Monte Carlo or transport-based method stands as the most accurate dose calculation method [1]. However, the intensive computational demands associated with these methods pose significant challenges to the efficiency of treatment planning. As such, speeding up the dose calculation process without compromising on accuracy is highly demanded. A wealth of research efforts has been dedicated to reducing the time required for dose calculation [2–5], a promising avenue among these efforts involves calculating dose distribution at a lower resolution to save time, followed by the application of super-resolution (SR) reconstruction techniques to enhance the resolution of the calculated dose [6, 7]. However, the task of image SR is notably complex due to its nature as an ill-posed inverse problem, where a single LR input may correspond to multiple HR outputs [8, 9]. Importantly, for medical images, the lack of ground-truth paired training datasets further complicates the issue.

The advent of deep learning (DL) techniques has brought significant advancements to the field of medical image processing, including SR. Traditional DL approaches, which rely on extensive datasets of paired LR and HR images, have shown promising results, particularly with natural images [10–15]. However, the rarity of large-scale medical image datasets, especially those containing clinical-quality HR and LR image pairs, poses a significant challenge to these supervised learning methods.

In this context, implicit neural representation (INR) networks have emerged as a powerful tool for encoding continuous functions that accurately represent signals such as sounds, images, videos, etc. By inputting pixel coordinates, INRs can output the image values for those pixels at any desired resolution [7, 16–22], offering a novel solution for SR by only requiring LR images for training. The network can then generate HR images by querying denser pixel coordinates [18], a method particularly advantageous for medical imaging where HR ground-truth data is scarce.

In this work, we focus on super-resolution for dose distribution images. Our work diverges from previous methodologies [22, 23] that assume LR images are the result of pre-known blurring and downsampling operations. Instead, we address the blind deconvolution problem, aiming to simultaneously estimate both the blurring kernel and the HR image. Unlike approaches [24–26] that utilize image generative models for discrete image and kernel generation, our methodology employs two INR networks to continuously represent both the images and the blurring kernel. This approach is particularly suited to medical imaging, where the blurring kernel often represents the continuous point spread function of the imaging equipment [27, 28]. Our innovative use of INR networks for learning both the blurring kernel and HR images not only caters to the unique challenges of medical image SR but also paves the way for advancements in the calculation of dose distribution in radiation therapy without the need for heavy computations and hardware upgrades.

2 Materials and Methods

2.1 Image observation model in SR imaging

A commonly used image observation model of the LR image from a HR image is

$$\mathbf{y} = \mathbf{DGx} + \mathbf{n}, \tag{1}$$

where $\mathbf{y} \in \mathbb{R}^{N_L}$ is the vectorized LR observation degraded from the HR image $\mathbf{x} \in \mathbb{R}^{N_H}$. The typical image degradation operations—downsampling, blurring, and noise corruption—are denoted by operators $\mathbf{D}$, $\mathbf{G}$, and

$\mathbf{n}$, respectively [29].

2.2 Implicit Neural Representation (INR)

The INR represents an image as a continuous function between its spatial coordinates and the corresponding intensity values:

$$\mathcal{M}(\theta) : \mathbb{R}^{dim} \to \mathbb{R}, \quad \mathbf{c}_i \mapsto \mathcal{M}(\theta; \mathbf{c}_i) = x_i, \qquad (2)$$

where $\mathcal{M}(\theta)$ denotes the INR network with parameters θ, $\mathbf{c}_i \in [0, 1)^{dim}$ is the normalized spatial coordinate of the ith pixel, and x_i is the corresponding intensity value. The notation dim is determined by the dimensionality of an image. In this paper, our investigation focuses on two-dimensional images, i.e., $dim = 2$.

The INR network is constructed based on an MLP network, with each fully-connected layer activated by a periodic function to enhance the representation of image details [30]. When representing images with complex textures containing high-frequency signals, an additional step named Fourier feature embedding (FFE) is often deployed before feeding the spatial coordinates into the INR network [17, 22, 31–33]:

$$\gamma(\mathbf{c}_i) = [\cos(2\pi \mathbf{B}\mathbf{c}_i), \sin(2\pi \mathbf{B}\mathbf{c}_i)]^T. \qquad (3)$$

With FFE, the low-dimensional coordinate of a single pixel is transformed into a set of additional points that cover a broader frequency range determined by the "frequency matrix" $\mathbf{B} \in \mathbb{R}^{N_{embed} \times dim}$. The matrix $\mathbf{B}$ is composed of random samples from a Gaussian distribution $\mathcal{N}(0, \sigma_b^2)$. The embedding size N_{embed} and the standard deviation σ_b are tunable hyperparameters in the network training.

2.3 INR-based blind deconvolution SR imaging

The proposed INR-based blind deconvolution utilizes two INR networks to represent the blurring kernel and the latent HR image, respectively, under the assumption that both the blurring kernel and the image are continuous functions in the spatial domain. Referring to the image observation model in Eq.(1), the blurring kernel $\mathbf{G}$ and the HR image $\mathbf{x}$ are entangled, posing challenges in training two INR networks to represent distinct objects separately.

Inspired by [9, 28], we introduce a physics-driven constraint for the blurring kernel. Specifically, in most optical imaging systems, the blurring kernel models a continuous space point spread function (PSF) of the imaging system, and the PSF corresponding to higher-resolution imaging $\mathbf{b}_H$ is a scaled version of the PSF $\mathbf{b}_H$ at lower-resolution imaging, i.e.,

$$\mathbf{b}_H(\mathbf{c}) = \alpha \mathbf{b}_L(\alpha \mathbf{c}), \qquad (4)$$

where α is the scaling factor from the lower-to-higher resolution image. We also introduce the non-negativity and sum-to-one constraints to the blurring kernel based on the non-negative and energy-limited properties of PSF of most imaging systems [26].

Training the two INR networks only utilizes observations acquired at different resolution scales using the same imaging system. The loss function is formulated as follows:

$$\underset{\theta,\phi}{\operatorname{argmin}} \sum_{l=0}^{L} \sum_{k=1}^{K} \|\mathbf{y}_{l,k} - \alpha_l M_b(\phi; \alpha_l \mathbf{c}_{B_L}) \circledast M_I(\theta; \mathbf{c}_{I_H})\|_2^2. \qquad (P0)$$

In this function, $\mathbf{y}_{l,k} \in \mathbb{R}^{N_l}$ is the kth LR image at the lth scale, α_l is the SR scaling factor from the lth level LR image in the training set to the target HR resolution, $\mathbf{c}_{B_L}$ denotes the coordinate grid of the blurring kernel corresponding to the lowest resolution in the training set, and $\mathbf{c}_{I_H}$ denotes the coordinates of the target HR image. The two INR networks, i.e., the "Blur-INR" for the blurring kernel and the "Image-INR" for the HR image are denoted by $M_b(\phi)$ and $M_I(\theta)$, respectively. Figure 1 shows the architecture of the proposed method.

3 Experiments & Results

We selected one pancreas SBRT plan from the MRIdian MRgRT system. The dose was computed with 1mm, 2mm, and 4mm resolutions. The 1mm dose map served as the HR reference for SR imaging evaluation, while the 2mm and 4mm dose maps were used as LR images for network training. We compared the proposed method with a prior work, MLINR, which does not involve blind deconvolution but uses an empirically pre-determined blurring kernel [22]. In the proposed method, we set the the kernel size to be 27×27. The learning was set to 5e-5 for both Blur-INR and the Image-INR networks. For the compared MLINR method, a Gaussian blur kernel of size 27×27 with a standard deviation of 9 was empirically pre-determined for the image of the lowest resolution in the training set, i.e., the dose map with 4mm resolution. The same scaling operation described in eq. (4) was applied to the higher resolution image (2mm resolution). The learning rate in this case was set to 1e-5 for an optimal result.

Figure 2 displays the SR dose maps along with the dose maps generated from the MRIdian MRgRT system. The proposed method significantly improves the image quality compared with the input LR acquisitions. Compared with the MLINR method, the proposed method achieved 4.7 dB and 0.073 improvements in terms of peak signal-to-noise ratio (PSNR) and structural similarity measure (SSIM). It also provide sharper textures with less artifacts compared with the compared MLINR method.

In terms of computation time, obtaining the dose maps of resolutions 1mm, 2mm, and 4mm from the MRId-

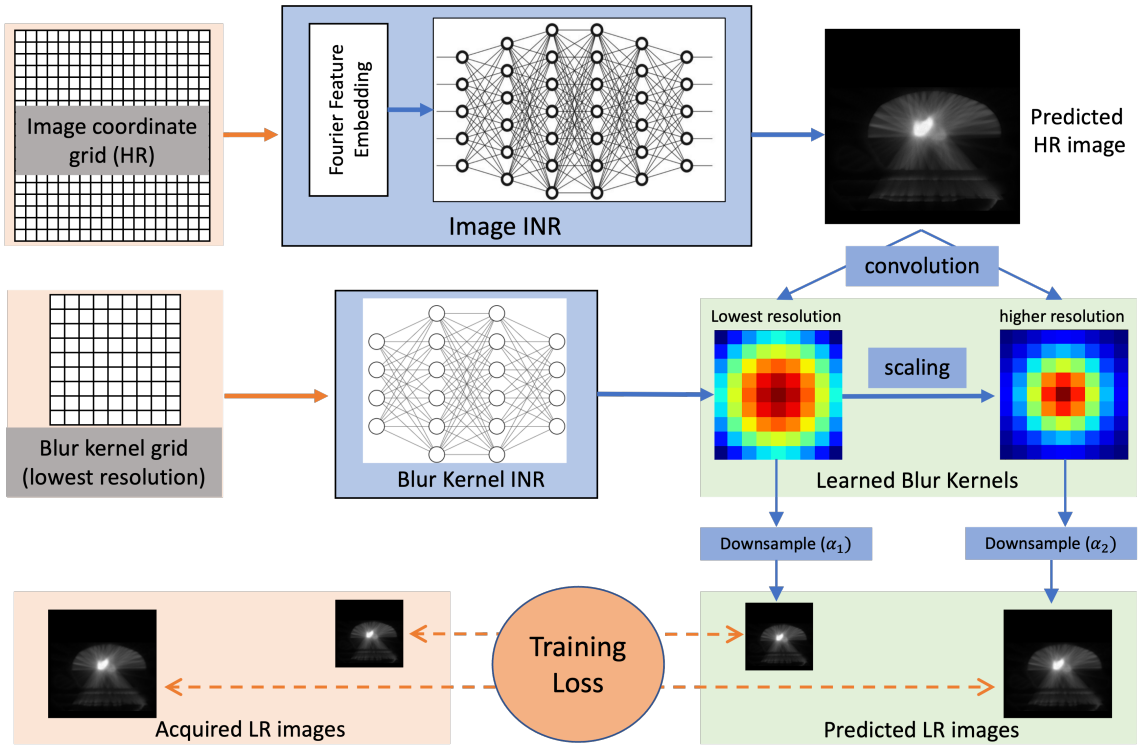

Figure 1: Architecture of the proposed method.

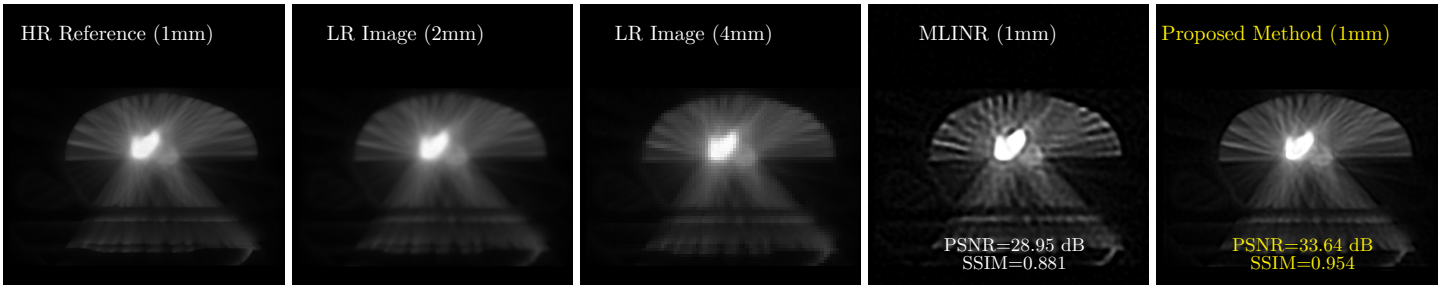

Figure 2: TPS generated dose distributions from a pancreas SBRT plan and the SR dose distribution results of the proposed method and the compared MLINR method [22]. The proposed method outperformed the MLINR in terms of higher PSNR and SSIM values as well as visual qualities.

ian MRgRT system took 2 minutes and 50 seconds, 25 seconds, and 5.5 seconds, respectively. With the proposed method, it took around 3 minutes to train the network and only milliseconds to obtain the HR image at any resolution using a single Nvidia GeForce RTX 3090 graphic card.

4 Conclusion

This paper introduces an innovative blind deconvolution technique based on INR networks for rapid and high-quality SR dose calculation. Leveraging the underlying image observation model and the properties of the PSF of imaging systems, we trained two INR networks to represent the blurring kernel and the latent HR image, respectively. Experiments conducted on dose maps from the MRIdian MRgRT system showcase the effectiveness and efficiency of the proposed method. It's noteworthy that this method doesn't necessitate LR-HR image pairs for model training and is tailored to individual patients. This significantly addresses concerns related to data scarcity and optimizes treatment for patient-specific scenarios in the RT community. Furthermore, while we specifically demonstrate the application of SR dose calculation, the proposed method exhibits versatility and can be readily applied to various biomedical image modalities.

Abstract The purpose of this study was to evaluate the effectiveness of radiation shielding in reducing organ doses was evaluated during liver 3D/4D Simulation Computed tomography (Sim-CT) prior to radiation therapy. A tunnel-shaped acrylic structure was constructed to support the shield, and two lead equivalents of 1 and 3 mm/Pb were used to confirm the dose reduction effect of radiation shielding. Optical stimulated luminescence dosimeters (OSLD) were inserted at 11 locations, including the thyroid, within an anthropomorphic phantom. Under clinical conditions, liver 3D/4D Sim-CT were repeated three times, and radiation shielding was applied to analyze the dose-reducing effects. The use of self-produced tunnel-type shielding tool is more effective in reducing unnecessary effective doses of normal tissue outside the examination site during liver 3D/4D Sim-CT.

1 Introduction

Computed tomography (CT) is a procedure that can easily and quickly produce images of the human body using ionizing radiation. Therefore, it is used in medical diagnosis as well as in nuclear medicine and radiation therapy. CT examinations have become essential worldwide, and the number of national CT examinations belonging to the Organization for Economic Co-operation and Development is increasing annually [1]. However, when performing CT for medical purposes, the As Low as Reasonably Achievable (ALARA) principle does not specify dose limits, but all radiation exposures pose a potential risk for healthcare workers and patients. Therefore, the purpose of radiation defense is to reduce unnecessary radiation and minimize the harmful effects of ionizing radiation [2]. In that sense, efforts are needed to reduce the radiation exposure to patients in all departments using CT. Since radiation dose has a directly impact on image quality [3-5], any attempt to reduce the delivered dose should ensure that the resulting image quality remains suitable for accurate and reliable diagnosis [6, 7]. In recent years, various studies and manufacturers have introduced various methods and technologies to improve image quality while minimizing radiation dose in clinical practice [8-12]. Despite these developments, When the radiation beam is fired towards the target site, the scattering rays scatter to normal organs other than the target site, which may lead to unnecessary exposure of the tissue other than the target site of the patient being tested. This may expose the patient to unnecessary radiation, and the resulting additional radiation exposure may increase the risk of developing cancer in the long run. The patient undergoes multiple CT scans during diagnosis and treatment, which may result in the accumulation of unnecessary radiation in the normal organs. However, CT simulation (Sim-CT) should be performed essentially to determine the treatment site and accurately calculate the treatment dose before radiotherapy [13].

In Sim-CT, the patient's treatment posture is determined, the radiotherapy site is reconfirmed, and the dose is calculated using treatment planning system (TPS) by sketching the outline of normal organs and tumors. In addition, accurate determination of the target and target boundaries in Sim-CT is a prerequisite for successful radiotherapy. Recently, a more accurate radiotherapy plan can be established by selectively using a four-dimensional CT (4D Sim-CT) technique in addition to three-dimensional CT (3D Sim-CT), but previous studies have reported that 4D Sim-CT scan can provide patients with a dose that is 10 times higher than 3D Sim-CT scan [14-16]. This is higher than the CT dose used in the diagnostic field, which can result in increased doses in normal organs outside the therapeutic site. The main difference between 3D Sim-CT and 4D Sim-CT is the technical distinction between CTV (Clinical Target Volume) to ITV (Internal Target Volume) and OAR (Organ at Risk) to PRV (Planning Organs at Risk Volume), which includes the concept of internal motion by tracking the volume change over time of a tumor or a highly mobile part of a normal organ. While 3D Sim-CT provides a detailed view of the patient's anatomy but does not account for organ or tumor motion during the respiratory or cardiac cycle, 4D Sim-CT allows for the assessment of organ and tumor motion due to respiration or cardiac activity. This is particularly important for tumors located in or near organs affected by motion, such as the lungs or liver. In this study, we tried to focus on the dose decrease due to the application of these techniques and the dose reduction effect in terms of radiation protection due to the use of radiation shields, not on the movement of tumors or normal organs themselves.

Therefore, we wanted to evaluate the long-term dose change before and after the implementation of radiation shielding using ATOM® dosimetry phantom (Family Model 701, Sun Nuclear, USA) during liver 3D/4D Sim-CT to evaluate exposure of tissues other than the patient's target site to unnecessary radiation.

2 Materials and Methods

The ATOM® dosimetry phantom imitates the physical characteristics of an adult man and allows for more accurate human absorption dose calculation by considering variations in tissue composition based on age or sex, depending on the model. This facilitates evaluation of the dose weighting affected by radiation exposure specific to different tissues in the human body. In addition, the Phantom family model 701 was precisely divided into 25-mm thick sections, and 271 organs were replicated in these sections. Each dosemeter was designed to be inserted into the corresponding position of the organ, simplifying the measurement of organ-specific doses.

Sim-CT equipment (Aqualion TM LB, Canon Medical Systems, Japan) was utilized in this study, with parameters commonly used for 3D Sim-CT and 4D Sim-CT image acquisition. The parameters used for liver 3D Sim-CT simulation treatment were as follows: tube voltage, 120 kV; tube current, 120 mA; rotation time, 0.5 s; range, 501 mm; fragment thickness, 1.0 mm; total inspection time, 17.8 s; and D-FOV (Digital Field of View), 350. Meanwhile, the parameters for 4D Sim-CT simulation treatment were as follows: tube current, 200 mA; rotation time, 0.5 s; range, 250 mm; slice thickness, 2.0 mm; and total test time D-FOV, 20.2 mm.
The NanoDot® dosemeter (Landauer, France) The NanoDot® dosemeter (Landauer, France) for dose measurements, and calibration was carried out this way [17-18].

The shield was designed as a tunnel-type acrylic structure, divided into upper and lower parts, to provide support and shield the areas outside the CT scan area. The dimensions of the upper and lower shields were 600 × 470 × 250 mm3 and 850 × 470 × 250 mm3, respectively. In addition, to determine the shielding effect based on the lead equivalent, two lead equivalents of 1 mm/Pb and 3 mm/Pb were placed on the acrylic structure to construct an experiment setup (Fig. 1.)

Figure 1: Shielding device (the upper shield was 600 × 470 × 250 mm high, and the lower shield was 850 × 470 × 250 mm high). To determine the shielding effect according to the lead equivalent, lead equivalents of 1 mm/Pb and 3 mm/Pb, respectively, were prepared and placed on an acrylic structure to construct an experiment. (Left) Upper shielding device. (Right) Lower shielding device.

Respiratory gated radiation therapy is used in the treatment of moving tumors, such as lung and liver cancers. These techniques employ a real-time position management respiratory tuning gating system to deliver radiation beams while accounting for organ movement.
Infrared cameras track tumors moving due to the patient's breathing during treatment, linear accelerators increase the accuracy of treatment locations by irradiating tumors with X-rays in a set breathing section. In standard practice, a non-invasive infrared tracking marker box is attached to the patient's body. However, for experimental purpose, an infrared tracking marker box was placed on top of the phantom. The illuminator's infrared rays were reflected from the marker and captured by the camera. This setup enabled precise treatment delivery, while minimizing treatment errors by delivering maximum dose to the tumor and avoiding damage to critical organs. This was achieved by continuously monitoring the chest wall movement during treatment and treating it only within a preset respiration.

In general, the scan range of the Liver 3D Sim-CT was set to the clinical range (from nipple to pubic symphysis), and to measure the dose, an optically stimulated luminescent dosemeter (OSLD) was inserted in 11 locations, including the bladder, testicles, and lens, with 1 cm of bolus attached to the ATOM® dosemetry phantom. The 3D Sim-CT scan was repeated three times for accurate measurements. When applying radiation shielding, it was placed in the upper and lower parts of the hip joint including the heart so that radiation shielding did not directly affect the liver. The dose reduction effect was analyzed for each measurement.
The OSLD analysis involved performing 10 repeated measurements to reduce its inherent errors. The average value of eight measurements, excluding the maximum and minimum values, was rounded to the second decimal place. The reading program used for analysis was InLight microStar Reader Version 4.3.4506.25886, Data Base Version 9.0.0.0, InLight Dose Calc Version 1.13, and Reader Communication Version 1.1.0.3.

(Down,Right) Shielded scan range for the lung during 4D-CT simulation.

3 Results

The main finding of the study revealed that the organ dose was significantly reduced when using radiation shielding in both 3D Sim-CT scans and 4D Sim-CT scans. In 3D Sim-CT scans, the organ dose decreased from 17.1 ± 0.2 mGy to 4.8 ± 0.1 mGy when using a 1 mm/Pb shield and to 4.1 ± 0.02 mGy when using a 3 mm/Pb shield. Additionally, in the 4D Sim-CT scan, the organ dose decreased from 108.3 ± 0.3 mGy to 97.9 ± 0.7 mGy when using the 1 mm/Pb shield and to 96.1 ± 0.2 mGy when using the 3 mm/Pb shield.
The organ dose reduction ratio to shield thickness is presented in Tables 4 and 5. In the 3D Sim-CT scans with 1 mm/Pb shielding, the organ average dose of OSLD increased in the right lens by 42.0%, left lens by 42.4%, right thyroid by 18.3%, left thyroid by 33.4%, esophagus by 32.3%, right lung by 48.5%, left lung by 55.3%, right bladder by 81.5%, left bladder by 82.2%, right testicle by 92.4%, and left testicle by 93.1%. In the cumulative analysis, the doses in the lens, thyroid gland, lungs, bladder, and testicles decreased by 43.85%, 66.30%, 52.07%, 81.84%, 92.74%, respectively. With the 3 mm/Pb shield, the doses decreased by 26.1% in the right lens, 21.9% in the left lens, 21.1% in the right thyroid, 21% in the left thyroid, 16.4% in the esophagus, 14.7% in the right lung, 7.8% in the left lung, 6.6% in the right bladder, 3.2% in the left bladder, 24.9% in the right testicle, and in the 24.1% left testicle. In the cumulative analysis, the doses in the lens, thyroid gland, lungs, bladder, and testicles decreased by 59.0%, 73.91%, 58.53%, 83.84%, and 94.39%, respectively. The total dose decreased by 72.0% and 4.1% with the 1 mm/Pb shield and 3 mm/Pb shields, respectively (Figs. 2–5).

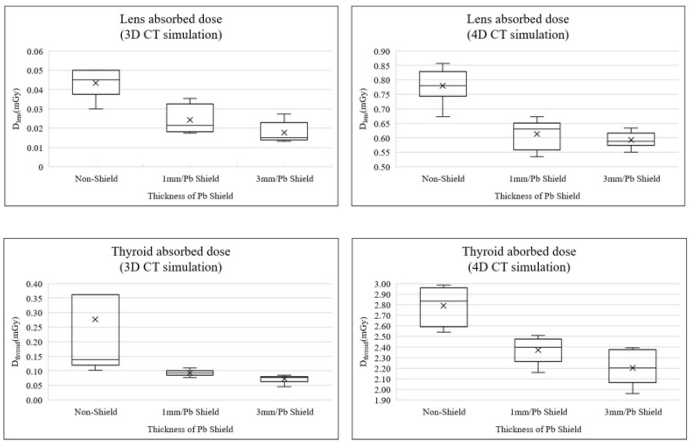

Figure 3. Comparison of the absorbed dose in the lens (up) and thyroid (down) with non-shielding and 1 mm/3 mm shielding in liver 3D Sim-CT and 4D Sim-CT simulation.

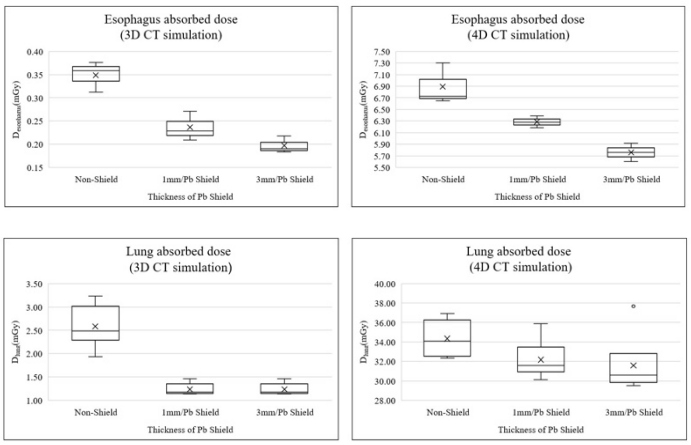

Figure 4. Comparison of the absorbed dose in the esophagus (up) and lung (down) with non-shielding and 1 mm/3 mm shielding in the liver 3D Sim-CT and 4D Sim-CT simulation.

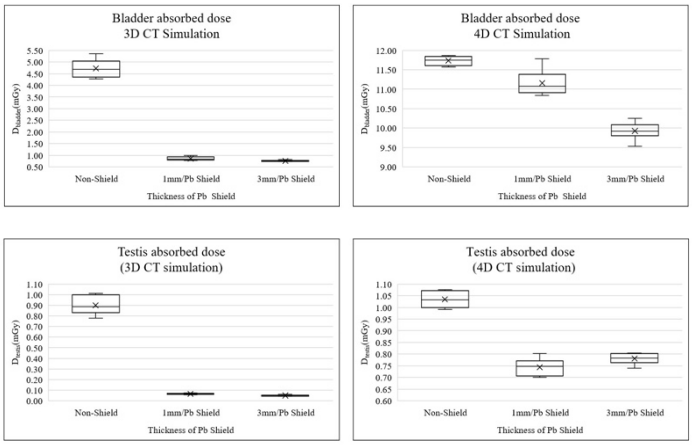

Figure 5. Comparison of the absorbed dose in the bladder (up) and testis (down) with non-shielding and 1 mm/3 mm shielding in the liver 3D Sim-CT and 4D Sim-CT simulation.

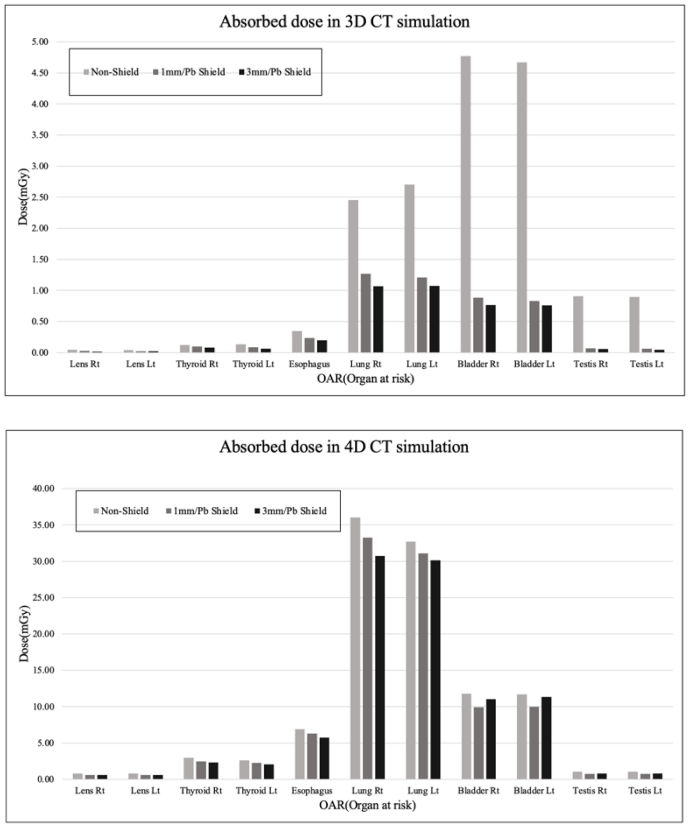

Figure 6. Comparison of total organ absorbed doses between non-shielding and 1 mm/3 mm shielding in liver 3D Sim-CT (up) and 4D Sim-CT simulation (down).

In 4D Sim-CT scans with 1 mm/Pb shielding, the organ average doses of OSLD increased in the right lens by 21.1%, left lens by 21.5%, right thyroid by 16.4%, left thyroid by 13.6%, esophagus by 8.8%, right lung by 7.6%, left lung by 4.9%, right bladder by 16%, left bladder by 14.9%, right testicle by 28.8%, and left testicle by 27.2%. In the cumulative analysis, the doses in the lens, thyroid gland, lungs, bladder, and testicles decreased by 21.3%, 15.07%, 6.32%, 4.9%, and 28.01%, respectively. In the 3 mm/Pb shield, the doses decreased by 26.1% in the right lens, 21.9% in the left lens, 21.1% in the right thyroid, 21.0% in the left thyroid, 16.4% in the esophagus, 14.7% in the right lung, 7.8% in the left lung, 6.6% in the right bladder, 3.2% in the left bladder, 24.9% in the right testicle, and 24.1% in the left testicle. In the cumulative analysis, the doses in the lens, thyroid gland, lungs, bladder, and testicles decreased by 24.0%, 21.06%, 8.04%, 15.41%, and 24.50%, respectively. The total dose was decreased by 9.5% and 11.3% with the 1 mm/Pb 3 mm/Pb shields, respectively (Table 1 and Figs. 2–5).

Region	Non-shield (mGy)	1-mm shield (mGy)	3-mm shield (mGy)	P-value
Lens	0.78 ± 0.05	0.61 ± 0.06	0.59 ± 0.02	<0.001
Thyroid	2.79 ± 0.06	2.37 ± 0.07	2.20 ± 0.10	<0.001
Esophagus	6.89 ± 0.36	6.29 ± 0.10	5.79 ± 0.16	<0.001
Lung	34.34 ± 0.64	32.18 ± 1.62	31.58 ±2.60	<0.001
Bladder	11.73 ± 0.12	9.93 ± 0.21	11.16 ±0.31	<0.001
Testis	1.03 ± 0.04	0.74 ± 0.04	0.78 ± 0.02	<0.001

4 Discussion

Previous studies examining the organs at risk and associated cancer risk in patients undergoing 3D Sim-CT and 4D Sim-CT examinations have reported an average dose of 7.82–11.84 cGy and 0.64–0.85 cGy per 4D Sim-CT scan and 3D Sim-CT scan, respectively. The average dose per 4D Sim-CT scan was 12.8 times higher than that of 3D Sim-CT scans. Organ dose decreased linearly with the effective diameter function of the patient, and 4D Sim-CT scans were expected to increase the relative risk of cancer compared to that with the 3D Sim-CT scans [16]. The results of the previous studies have demonstrated that 4D Sim-CT scans during Sim-CT tests result in higher dose increases compared to that of the 3D Sim-CT scans. This is particularly concerning for children and young patients who are more sensitive to radiation. In this study, tunnel-type shields were designed to minimize the potential harmful effects of ionizing radiation by reducing unnecessary radiation exposure in 3D Sim-CT and 4D Sim-CT tests. The aim was to evaluate the benefits of these shields by comparing the difference in absorbed doses with or without their application using the ATOM® dosemetry phantom. The effectiveness of dose reduction using self-produced tunnel-type radiation shielding tools during 3D/4D Sim-CT simulation treatment was evaluated. Previous studies explored the application of shielding bodies on patients. These studies have employed various shapes of shielding bodies [19], including those that reduce the dose delivery to the gonads during hip imaging [20]. Additionally, researchers have investigated shielding methods involving the use of bismuth to reduce the dose delivered to the thyroid, eyeball, and breast [21].

In this study, a tunnel-type shield was designed to provide simultaneous front and rear shielding for the patient during the 3D/4D Sim-CT test prior to radiation therapy, aimed at confirming the unnecessary dose reduction effect for major organs outside the test site, such as the rear scattering line. The shield's shape was designed to be comfortable and does not interfere with the test when applied to patients in clinical practice, and the content of lead equivalent was changed to 1 mm/Pb and 3 mm/Pb. The shielding effect according to lead equivalent was also studied.

However, because the posture of CT patients is the same as that of radiation therapy patients, there is a limitation that radiation shields cannot be used together if they are large, such as immobilization used for breast therapy. Therefore, in the next study, we plan to find a solution for the clinical application of radiation shield.

The results of this study also showed that the mean dose per 4D Sim-CT scan was higher than that of the 3D Sim-CT scan [16], although it varied from site to site when no shield was used, as in previous studies. In addition, it was confirmed that the long-term dose decreased linearly with the effective diameter of the patient, and the 4D Sim-CT scan is expected to increase the relative risk of cancer compared to the 3D Sim-CT scan, which is thought to require active shield use.
Furthermore, when tunnel-type shields were used, the shielded organ dose significantly reduced with the use of radiation shielding in both 3D Sim-CT scans and 4D Sim-CT scans. This finding suggests that increasing the lead thickness from 1 mm to 3 mm in the 3D/4D Sim-CT test can effectively reduce radiation dose. However, using 3-mm shields in 4D Sim-CT simulations led to higher organ doses in the bladder and testis compared to that of 1-mm shield. This may be attributed to scattered lines generated within the thicker shield (Fig. 4). To reduce the scattering line in this area, applying additional shields or using shields of appropriate thickness was considered necessary. Further, the image quality of the 3D/4D Sim-CT inspection area before and after the shield application as well as the organ dose of the scanned area needs to be evaluated. Thus, further research is needed in the future.

5 Conclusion

This study confirmed the use of self-produced tunnel-type shielding tools in effectively reducing unnecessary radiation exposure during CT examination, which is crucial for medical diagnosis and treatment. The effectiveness of a shielding device is particularly noticeable in 3D Sim-CT examinations, where it significantly reduces the radiation dose outside the patient's examination area. Moreover, more active shielding may be required when applying it to CT for general diagnosis purpose.

Abstract The study proposed a data-generating method for training a deep learning (DL) model to the boost pencil beam (PB) algorithm accuracy of the dose, and comparable to Monte Carlo (MC). The study only involved 43 clinical cases but generated 11278 pairs of beam dose data for training, validating, and testing. The DL model showed significant ability in converting PB dose to MC dose, which improved the GPRs (1mm/1%) from 83.73±6.55%, 84.28±6.55% and 82.72±6.75%, to 96.07±2.22%, 96.17±1.90% and 95.31±2.80%, for training, validating and testing data. Moreover, the DL model has an ultra-speed with 180ms calculation time cost. The study successfully realized fast-accurate photon dose calculation by DL model.

1 Introduction

Cancer remains the leading cause of death globally[1]. Treatment modalities comprise radiation therapy, surgery, chemotherapy, immunotherapy, and hormonal therapy. Radiation therapy remains an essential component of cancer treatment with approximately 50% of all cancer patients receiving radiation therapy during their course of illness[2]. The most commonly used technology is intensity-modulated radiotherapy (IMRT)[3, 4].

Treatment planning is based on inverse planning algorithms to generate treatment beams with varying intensities across the beam section. Inverse optimization searches for the most suitable target through predefined dose limits and many iterations. In this process, an accurate dose calculation engine is required to make the final optimization result reliable. The Monte Carlo(MC) algorithm can accurately perform dose calculations, but the excessive calculation makes it challenging to reduce the time consumption. Although much work has been proposed based on GPU Monte Carlo[5, 6], and the time consumption of a single calculation has been reduced from hours to minutes, but still cannot meet the speed requirements of reverse optimization. In addition to the MC algorithm, dose calculations based on analytical algorithms are usually high-speed, but these algorithms sacrifice high accuracy, for example, the pencil beam(PB) algorithm. Many studies have optimized PB to improve the accuracy of dose calculation, but there are still differences compared with MC, especially in areas with uneven density changes[7, 8].

Neural networks have developed rapidly in recent years, and many studies have used deep learning(DL) to accelerate dose calculations[9–11]. However, the effect of neural networks is generally based on the amount of data during training. A dataset that is too small will lead to poor generalization ability of the model, making it perform well on the same dataset but not be usable in practice. However, clinical data are very scarce, and collecting massive datasets for training like natural images is challenging.

Therefore, we proposed a training method based on virtual planning, which can quickly generate a dose distribution equivalent to MC dose calculation by inputting the less accurate PB dose calculation results.

2 Materials and Methods

We proposed a training method based on the virtual plan to quickly complete the MC dose calculation by inputting the initial dose of PB, thus accelerating the plan optimization process, and, validating the clinical plan. Many single-beam PB and MC doses were generated through virtual planning and then trained using 3D Dense-U-Net. The training process takes the PB single-beam dose as the input, the MC single-beam dose as the label, and MSE as the loss function. Finally, a clinical plan was used for verification, and the Gamma passing rate(GPR) of AI and MC doses were compared. The Gamma criteria was 1mm/1%.

2.1 Clinical Data

A cohort of lung cases was collected for the study. The CT images of the cases were taken by Philips Brilliance Big Bore CT Scanner, with a pixel spacing of 1mm × 1mm × 5mm and slice size of 512 × 512. All cases had a seven-beam IMRT plan made by the Eclipse treatment planning system; the D_{95} of the planning target volume (PTV) for the cases was 60Gy. All plans were clinically implemented, and the RTSTRUCTURE DICOM files were collected.

2.2 Virtual Plan

Virtual plans are automatically generated using CT images of actual patients and a set of optimization rules. Specifically, the optimization rules consist of three parts. The first is to generate a random plan. Compared with clinical plans, random plans bring more possibilities, thereby improving the robustness and generalization of network training. The second is the automatic optimization of random plans. Traditional plan optimization needs to meet specific clinical goals, which is difficult to achieve in a fully automatic way. However, only differential dose distribution intervals need to be generated for random plans without considering the dose in organs at risk. Finally, the dose of each single beam is calculated through the traditional PB and MC dose calculation engine.

The automatic optimization process is based on fluence map optimization(FMO). The optimization operations are preset to generate random plans with various dose distributions. The optional gantry angle settings were [0,40,80,120,160,200,240,280,320] or [20,60,100,140,180,220,260,300,240]; the target area was sequence set at PTV, Lung-L, Lung-R, and esophagus, with isocenter at the geometry center of the target area; the optional wight of optimization for normal tissue were 100, 500, 1000, and the optimization target was 0. Meanwhile, the optimization target of PTV D_{95} was 60Gy, and the weights was 2000. Finally, perform a fixed number of rounds for FMO. It should be noted that such optimization conditions must not be achieved, and due to different beam angles between different plans, the dose obtained will be very different. Even if the two groups of beam angles are similar, because of the weight ratio of normal tissue and target interval, the differences lead to widely varying optimization results.

2.3 Network Structure

The 3D Dense-U-Net was chosen for this research[12, 13], with additional information in figure 1. The CNN utilizes a 5-stage U-Net-like backbone to capture global and local features. It entails four instances of down-sampling through max pooling (stride = $2 \times 2 \times 2$) and four instances of upsampling through deconvolution (kernel shape: $2 \times 2 \times 2$). Each stage of the CNN comprises three 'Denseblocks' with dense connections. The computation flow of a Denseblock entails using Relu, convolution, and batch norm. The convolution kernel size is $3 \times 3 \times 3$, except for the final convolution layer, which uses a $1 \times 1 \times 1$ kernel. Zero padding is applied in each convolution operation. The convolution layers have eight channels that serve as dense connections. As the features exit a Denseblock, the number of feature channels increases by 8.

3 Results

A total of 43 clinical patients' images were used, and 24 virtual plans were generated for each patient. The number of beams in each plan was randomly between 9 and 18 (due to the beam split optimization algorithm). In the end, we obtained 11,278 pairs of PB and MC single-beam doses.
The GPRs (1mm/1%) of training, validating, and testing for the PB and AI-boosting dose, with MC dose as reference. The corresponding mean GPRs for the PB dose were 83.73±6.55%, 84.28±6.55%, and 82.72±6.75%; in contrast, the mean GPRs for the NN-boosting dose were 96.07±2.22%, 96.17±1.90% and 95.31±2.80%. The average passing rate in the test set increased by 15%, the calculation times of an AI-boosting was 0.18 s. The results showed that the CNN significantly improved the accuracy of PB dose, with an ultra-fast speed. The GPRs were summarized in figure 2.

4 Discussion

In the age of large-scale models, the big-size dataset is significant for AI in medicine. In the study, we proposed an auto-generating method for the dataset, which can get nearly infinite training data, based only on a tiny primary dataset with 43 cases. The valuable data generation method can be applied in further research, not only in photon dose calculations. The study only involved lung cases, but it showed that applying the method in building an AI dose calculation model for cases with another cancer site is feasible. In future studies, we look forward to adding cases with other cancer site, such as the head and abdomen. Moreover, the corresponding treatment tech can also be broadened from IMRT to VMAT, SBRT, and even proton therapy. Another significant research in the future is to explore the performance of DL models in TPS, such as an FDA-passed commercial TPS MOZI (Manteia, China), which uses PB in D_{ij} calculations and MC to calculate the final dose. We are supposed to insert our DL model after PB to eliminate the difference between the optimized and final dose, which is toward stable and accurate planning.

5 Conclusion

The study established an auto-generating method for building a training dataset, of dose-boosting DL models in radiation therapy. The method significantly reduced the demand for many clinic-implemented cases but achieved outstanding accuracy.

Abstract Head and neck cancer patients under radiotherapy treatment are prone to anatomical changes due to the effects of weight loss on non-rigid structures, such as inflammation and tumor shrinkage. Across several treatment fractions, these changes may become significant enough to render the initial treatment plan invalid and require treatment replanning. However, replanning often demands a high amount of resources and may be poorly timed in radiotherapy workflows with competing priorities. To address this, we aim to identify and generate parameters extracted from three-dimensional radiotherapy structures, that can describe anatomical alterations and can affect the decision for replanning. These parameters are intended to be used in the development of a machine learning classification model to predict if and when patients should undergo replanning, taking into account the progression of the information over time. In our study, we have considered a cohort of 105 head and neck cancer patients, and more than 20 parameters have been created. Currently, we can begin classifying patients as requiring replanning or not from the first week of treatment.

1 Introduction

Head and neck cancer (H&N) is a common disease in many regions of the world, accounting for 900,000 cases and over 400,000 deaths annually [1]. Primary risk factors include tobacco use, alcohol consumption, the human papillomavirus infection, and the Epstein-Barr virus infection [2].

When H&N cancer patients go under radiotherapy (RT), they may experience significant anatomical changes, a consequence of associated side effects, that may invalidate the original treatment plan due to unacceptable variations in dose coverage in normal structures and defined target volume. Image-guided radiotherapy techniques have made possible the identification of the changes with considerable reliability and treatment replanning is regularly done in the clinic.

H&N RT replanning is relevant as it may maintain tumor coverage leading to tumor control, and it may improve patient quality of life by helping to avoid toxicity [3]. However, there has been no definitive method established to define the amount of weight loss or anatomical change in the H&N region that necessitates a replan, even though the replanning process requires a significant investment of effort and is usually delayed, which can impact many patients [4]. Therefore, it is important to identify as early and as reliably as possible which patients will most likely need replanning.

This research aims to develop and evaluate parameters related to anatomical structures, that are used and known in the clinic or related to them, to predict if and when patients will need replanning ultimately.

2 Materials and Methods

2.1 Patient and clinical data characteristics

Our retrospective study incorporates 105 H&N patients treated at McGill University Health Centre within the RT department from 2017 to 2023, who were diagnosed and biopsy-proven with Squamous Cell Carcinoma (HNSCC) or Adenocarcinoma, and with different sites of diagnosis, such as Oropharynx (52.4%) and Nasopharynx (8.57%). This cohort consists of female (28.6%) and male (71.4%) patients who were treated with a total prescribed dose of 60 Gy (10.5%), 66 Gy (3.8%), and 70 Gy (85.7%), with curative or palliative treatment intent, and delivered with a conventional dose of 2 Gy per fraction. Treatment regimes included radiotherapy alone as well as combined with systemic therapies, such as chemotherapy and targeted therapy.

Computed Tomography simulation (CT sim) images, taken at the beginning of the treatment planning, and Cone Beam CT (CBCT) images, taken on a daily or almost daily basis, were collected from the treatment planning system at our institution. Each patient was required to have had a CT sim image and at least 2 CBCT images taken on two distinct fractions. CBCT images were used during treatment to track patients' anatomical changes and to identify if a new plan was needed. Our initial sample size counted 61 replanned patients and 44 non-replanned patients. The latest fraction at which patients were replanned in this cohort was 25, while the most frequent fraction for replanning was 15.

At present, additional patient data are being assessed to reach an intended sample size of around 300 patients.

2.2 Anatomic 3D structure and parameters definition

For each patient, the CT sim image along with its structures was registered with each CBCT image. Each patient's

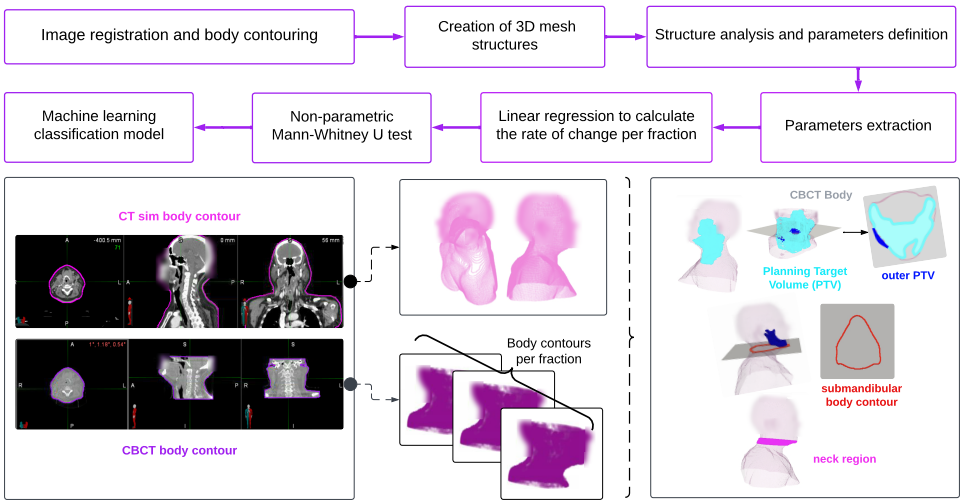

Figure 1: Pipeline diagram of the presented work. Images have been defaced to preserve patient anonymity.

outer body structure was generated by the commercial image registration software MIM MAESTRO (MIM Software Inc. Cleveland OH), using its automatic body contour and thresholding tool. Each slice was examined to ensure that the structure was correctly encompassed. The files were saved in a DICOM-RT Structure Set format.

To obtain geometrical information from the RT structures, we used `Python v3.7` and the open-source library `Pyvista v0.43.2`. Certain structures were rendered in a 3D format by a mesh creation of the corresponding RT structure that allowed us to analyze them interactively, and the creation of surfaces by using a surface marching cubes algorithm.

Based on the 3D shape and 2D contours of the body and Planning Target Volume (PTV) structures, we defined a series of parameters to describe anatomical changes throughout treatment delivery. These parameters were intended to describe body shape features associated with weight loss, such as skin separation, and the body shrinkage between treatment fractions, by calculating the Chamfer distance. We also included parameters related to the PTV, to detect when the target was not being covered correctly for treatment. For instance, by examining the minimum distance between the PTV and the body contour. A complete list of the parameters that were created and studied is presented in Table 1.

2.3 Univariate statistical analysis

Incorporating the data of all patients, a statistical analysis was performed for each extracted parameter, involving the calculation of the rate of change of the parameter to see how it changed across fractions. As it was discovered in previous studies [5, 6], weight loss and decrease in neck area are more prominent for replanned patients than non-replanned patients. Thus we hypothesized that the rate at which the parameters change may provide useful information. A linear regression model was applied by using the open-source library `skcit-learn` to obtain the slope value that the parameter had obtained up to each fraction. Thus every parameter p presented in Table 1, had a fraction-specific slope version of it, denoted as $\dot{p}$.

Graphs were generated to visually represent the longitudinal data across treatment fractions and to show the progression of the parameters over time. Each parameter was analyzed using the non-parametric Mann-Whitney U test to determine if the distributions corresponding to the classes replanned vs non-replanned were statistically different. A Bonferroni correction was applied due to the application of several hypothesis tests (p-value$<$ 0.002, 24-25 tests) [7]. Preliminary classification models were built using the Logistic Regression classifier: at the 1st fraction that successfully passed the test and at fraction 15. A Repeated (n = 100) Stratified 5-fold Cross-Validation technique was used, with the Area Under the ROC Curve (AUC) as a training metric. The 95% Confidence Interval (C.I) was calculated.

3 Results

By applying the pipeline presented in Figure 1, a series of statistical results was obtained. The most important results are presented in Figure 2. In general, we observe that the averages of the longitudinal data of the two classes behave differently, indicating that the parameters can be used to characterize the classes; replanned versus non-replanned. We noticed that the parameters $\dot{R}_{mean}$ and $\dot{VO}_{PTV}$- Body ratio (a particular case of VO_{PTV} normalized by the volume of the body) presented significant differences between replanned and non-replanned from an early fraction with p-value$<$ 0.002 (after Bonferroni correction), starting from as early as fraction 3 in the case of $\dot{VO}_{PTV}$- Body ratio and fraction 5 for $\dot{R}_{mean}$, corresponding to the 1st week of treatment. The statistical difference tends to increase at higher fractions. Thus, we can state that it should be possible to start predicting whether some patients may need a replanning from fraction

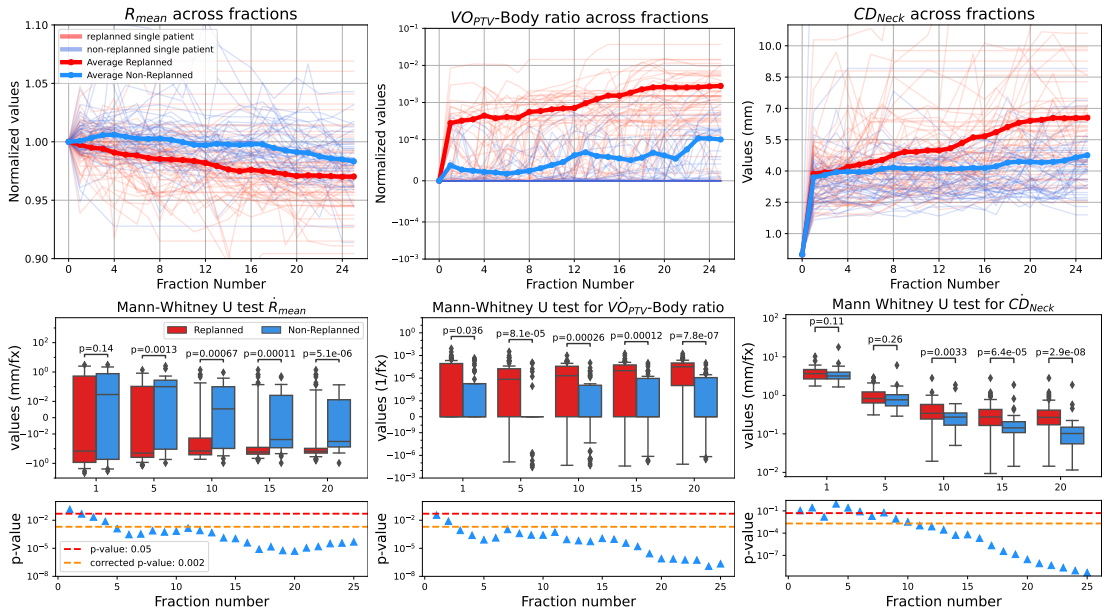

Figure 2: Results obtained by our analysis. In the top row, the longitudinal data pertaining to three parameters are presented, and in the middle and bottom rows, the results from the Mann-Whitney U test for the rate of change of the parameters at five specific treatment fractions and p-values for all treatment fractions are shown respectively.

3. The estimated AUC values for $\dot{VO}_{PTV}$-Body ratio were 0.67 [0.52-0.84] for fraction 3. While $\dot{R}_{mean}$ showed an AUC value of 0.68 [0.52-0.88] for fraction 5.

We also noticed that the $\dot{CD}_{Neck}$ showed statistically significant differences between the replanned and non-replanned populations from fraction 11 (3rd week), with an estimated AUC of 0.69 [0.52-0.88]. A preliminary multivariate model using the three parameters mentioned above at fraction 15, resulted in an AUC of 0.82 [0.62-0.97].

4 Discussion

Head and neck cancer patients are subject to significant anatomical changes during treatment due to tumor shrinkage and weight loss. Owing to clinical workflow and economic factors, it is important to identify as early as possible which patients are likely to be replanned and when. Our research aims to find standardizable metrics that may distinguish replanned and non-replanned patients and combine them in multivariate machine learning models. These models should help clinical personnel to determine from as early as possible which patients will need treatment replanning and when.

As part of our ongoing and upcoming work, we are examining additional parameters that may be associated with weight loss. This includes the contour of the radiotherapy head mask relative to the body contour, which has the potential to not only track weight loss but also detect when the device is not fitting properly for treatment. Moreover, we are considering the movement of the parotid glands as a potential parameter in our study, as it has been shown that their spatial orientation appears to shift during treatment [4].

5 Conclusion

The combination of 3D and 2D geometrical information from radiotherapy structures, related to anatomical changes, has the potential to serve as a predictor for radiotherapy replanning.

Table 1: Parameter definitions that were created to analyze the anatomical changes of replanned and non-replanned patients. The neck region was based on the common region between z = 0 mm and z = -18 mm, referenced to the plane of the submandibular contour.

Parameter	Symbol	Definition
PTV related		
Minimum distance from PTV to Body	x_{min}	Minimum value of the distances measured from the planning target volume drawn in the CT sim to a body contour
Average distance from PTV to Body	x_{ave}	Average value of the distances measured from the planning target volume drawn in the CT sim to a body contour
Median distance from PTV to Body	x_{med}	Median value of the distances measured from the planning target volume drawn in the CT sim to a body contour
Volume PTV outer	VO_{PTV}	Volume of the PTV section outside a body contour
Volume PTV inner	VI_{PTV}	Volume of the PTV section inside a body contour
Body related		
Hausdorff distance	HD_{Body}	Maximum distance between the body contour of the CT sim and a body contour
Chamfer distance	CD_{Body}	Average distance between pair nearest neighbor points from the body contour of the CT sim to a body contour
Average distance (2D)	$\bar{D}_{Body}$	Average distance between a body contour and the CT sim body contour, across each plane z
Maximum distance (2D)	D_{Body}	Maximum distance between a body contour and the CT sim body contour, calculated across each plane z
Body volume	V_{Body}	Volume enclosed by a body contour
Neck related		
Neck volume	V_{Neck}	Volume of a defined neck region
Minimum radius (3D)	R_{min3D}	Minimum 3D radius between the center of CT sim's neck region and a neck region
Maximum radius (3D)	R_{max3D}	Maximum 3D radius between the center of CT sim's neck region and a neck region
Mean radius (3D)	R_{mean3D}	Average 3D radius from the radius distribution between the center of the CT sim's neck region and a neck region
Chamfer neck distance	CD_{Neck}	Chamfer distance between CT sim's neck region and a neck region
Hausdorff neck distance	HD_{Neck}	Maximum distance between CT sim's neck region and a neck region
Surface area	SA_{Neck}	The amount of space enclosing the outside of a neck region
Compactness	C_{Neck}	Ratio between the surface area and the volume of a neck region
Submandibular plane related		
Area	$Area$	Total space covered by the submandibular body contour plane
Minimum radius (2D)	R_{min}	Minimum radius between the center of the CT sim submandibular body contour plane and a submandibular body contour plane
Maximum radius (2D)	R_{max}	Maximum radius between the center of the CT sim submandibular body contour plane and a submandibular body contour plane
Mean radius (2D)	R_{mean}	Average radius between the center of the CT sim submandibular body contour plane and a submandibular body contour plane
Maximum longitudinal chord	L_y	Maximum distance that can be drawn from the outermost points of a submandibular body contour plane in a longitudinal direction
Maximum lateral chord	L_x	Maximum distance that can be drawn from the outermost points of a submandibular body contour plane in a lateral direction

Software-Assisted Optimisation of Linear Accelerator Energy Consumption

Genotan Reggian[1] and Catherine Stanford-Edwards[1]

[1]South West Wales Cancer Centre, Swansea Bay University Health Board, Swansea, United Kingdom

Abstract

In the pursuit of environmental sustainability within healthcare, this study introduces a pioneering approach to optimise the energy consumption of linear accelerators using a software-based approach. Through a comprehensive analysis at the South West Wales Cancer Centre, the energy utilisation of various linac models was scrutinised, as well as stereotactic ablative body radiotherapy (SABR) and hypofractionated radiotherapy (HFRT) treatment methods. The findings reveal that SABR and HFRT treatments exhibit significantly lower energy consumption compared to conventional methods, indicating the potential for substantial energy savings. Furthermore, the newer Agility and Versa HD Elekta linacs had significantly decreased energy consumption compared to the older Precise linac demonstrating that replacement of linac technology can also lead to substantial energy savings. Further research and collaboration targeted at sustainability in radiotherapy can facilitate the optimisation of treatment delivery while maintaining a commitment to sustainability within radiotherapy.

1 Introduction

The UK's National Health Service (NHS) is at the forefront of integrating sustainability into healthcare delivery, aligning with global objectives. This aim is particularly pertinent in the context of linear accelerators (linacs), which, although being a fundamental method of treatment of cancer through radiotherapy, is a significant contributor to the NHS's carbon footprint.

The need to reduce the NHS's environmental impact is set by legislative requirements to deliver a healthcare service with a 'net-zero' carbon footprint by 2040 [1]. The impetus of this legally binding agreement arises from the NHS's carbon footprint being 4-5% of the UK's carbon footprint and 40% of the UK's public sector emissions and therefore a 'net-zero' NHS would significantly decrease national emissions [2].

Linacs are a pivotal technology in cancer treatment, not only being an advanced medical treatment but also as a focal point for energy consumption optimization. The operation of these machines is energy-intensive, with varying power demands depending on their operational states. As 2040 approaches, by which the NHS aims to operationalise its 'net-zero' commitment, the need to interrogate the energy usage of linacs has become increasingly pressing.

Recognising the dual necessity of maintaining clinical efficiency while enhancing energy efficiency, this study introduces an innovative software-based approach to monitor and optimize the power usage of linacs. Doing so addresses the critical gap in the management of healthcare technologies. This initiative is not only a technological challenge but instead represents a larger paradigm shift towards a greener, more sustainable healthcare model that other healthcare providers globally can implement.

2 Materials and Methods

The core of this research is the Linac Energy and Power Analysis Software (LEPAS), an innovative desktop application designed to utilise data analytics in pursuit of optimising the energy efficiency of linacs. LEPAS was engineered with a Python-based graphical user interface using a cross-platform Qt toolkit that provides a user-friendly point of interaction. Through the system, energy consumption data was captured across various operational linac states such as standby and treating states – each having unique energy profiles and patterns.

Data acquisition was facilitated by the Fluke 1738 3-Power Logger, an instrument selected for its precision and reliability. The Fluke Logger was configured to capture energy usage at one-second intervals, providing a high-resolution data stream, critical for assessing the dynamics of linac energy consumption as time passed. This granular data capture allowed for highly detailed analysis, enabling the identification of peak energy consumption periods as well as opportunities for energy-saving interventions [3].

Treatment data was extracted from the oncology information system Mosaiq using Crystal Reports exports. The data retrieved from Mosaiq consisted of multiple variables, including but not limited to, treatment techniques, beam energies and numbers of fractions. Additionally, linac data was procured from linac log files which were decrypted by Elekta. The linac-specific data yielded insights into variables such as operational states, gantry angles, and monitor units among others.

The LEPAS system facilitated the synchronisation of data streams from energy consumption, treatment details and linac operations. A rigorous time calibration process to ensure the integrity and accuracy of the synchronisation process. Subsequent to synchronisation, LEPAS provided functionalities for data filtration predicated on various treatment and linac parameters which enabled the generation of a filtered dataset. LEPAS' analytical capabilities were leveraged to interrogate the filtered dataset. This process using LEPAS allowed the simple

analysis of different treatment options, machines and other variables.

The data utilised within the scope of this paper was sourced from the South West Wales Cancer Centre (SWWCC). At the time of data collection, the centre was equipped with three Elekta linac models: Agility, Versa HD and a Precise model fitted with an Agility head. An analytical comparison of energy consumption across these models was conducted to determine their relative energy efficiencies.

In addition to conventional external beam radiotherapy, the centre also regularly performed stereotactic ablative body Radiotherapy (SABR) lung treatments and hypofractionated radiotherapy (HFRT) prostate treatments. An analytical comparison of energy consumption was performed between SABR and conventional lung treatments, as well as between HFRT and conventional prostate treatments. The energy consumption of both SABR lung treatments and HFRT prostate treatments were compared to their conventional counterparts.

For the purposes of the comparisons, only Volumetric Modulated Arc Therapy (VMAT) treatments with an energy of 6 MV were considered. Active energy consumption was sampled at one-second intervals to ensure high-resolution data capture.

3 Results

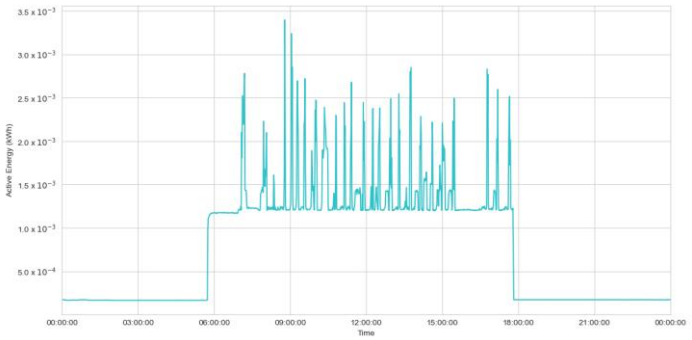

Fig. 1: Line graph displaying the active energy during a treatment day at the SWWCC. Times of interest include linac engineers' run-up at 07:00, radiographers' QC at 07:50, DIBH treatment at 10:15 and SGRT staff training at 15:30.

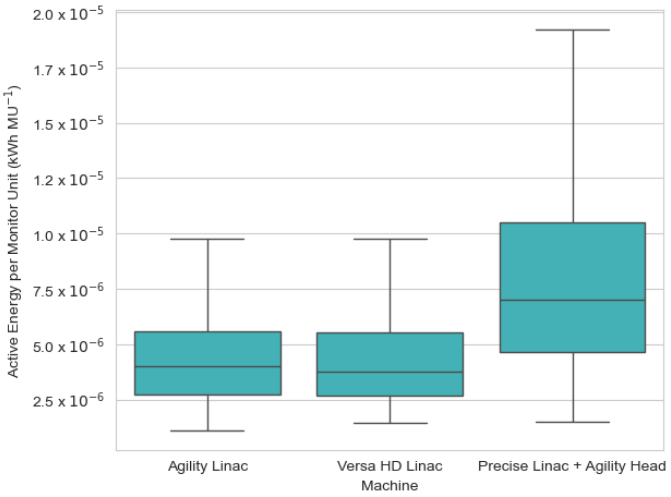

Fig. 2: Box-and-whisker plot displaying the distribution of active energy per monitor unit for three different types of Elekta linacs used at SWWCC.

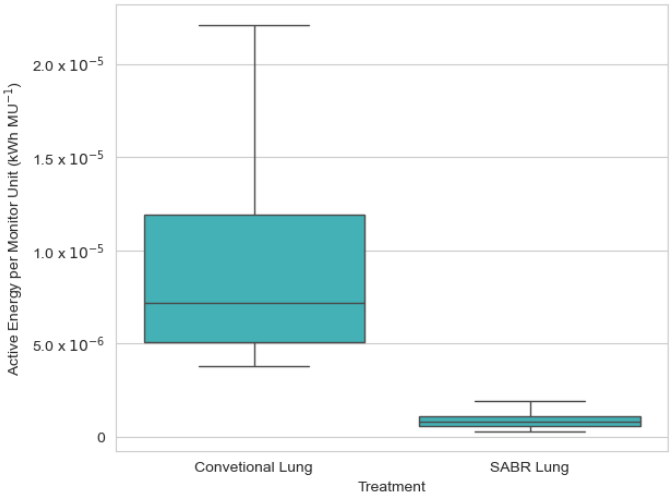

Fig. 3: Box-and-whisker plot displaying the distribution of active energy per monitor unit for conventional lung and SABR lung treatments.

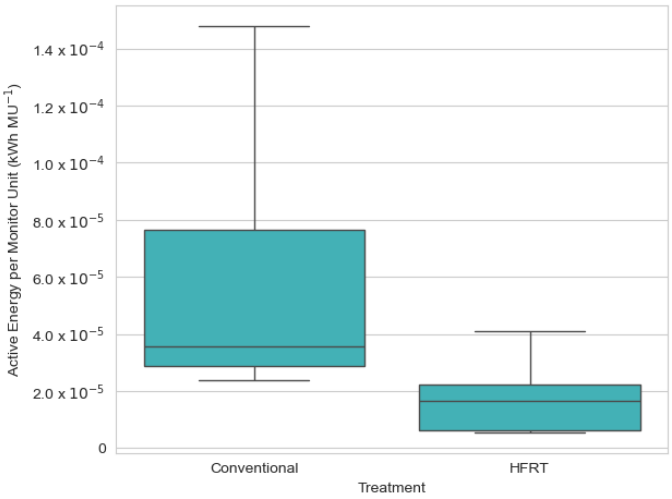

Fig. 4: Box-and-whisker plot displaying the distribution of active energy per monitor unit for conventional prostate and HFRT prostate treatments.

4 Discussion

The analysis of energy consumption during a typical treatment day (Fig. 1) illustrated energy demands during

deep inspiration breath-hold (DIBH) treatment techniques was larger than conventional treatments, suggesting that patient-specific treatment adaptations could yield energy savings assuming that clinical effectiveness is not affected. This is likely since between breaths, the surface-guided radiotherapy (SGRT) system forces the beam to pause until the next breath-hold which consumes more energy than if the beam was simply initiated and terminated [4].

Examining the energy consumption patterns among linac models reveals that the newer iterations, such as the Agility and Versa HD, exhibit much more favourable energy consumption profiles than the Precise. The improvements in energy consumption in newer models are likely due to technological improvements, and newer components.

SABR treatments for lungs demonstrated a substantial reduction in active energy consumption per monitor unit in comparison to conventional lung treatments. This observation could be attributed to the omission of a flattening filter in SABR treatments. The inclusion of a flattening filter in conventional treatments necessitates increased beam energy to achieve the desired therapeutic dose, as the flattening filter's presence attenuates the beam [5].

Similarly, HFRT treatments for prostates also demonstrated a reduction in active energy consumption per monitor unit per treatment course in comparison to conventional prostate treatments. The increased efficiency could be due to the reduced frequency of initiation and termination sequences when fewer fractions are used [6]. HFRT treatments not only align with sustainable healthcare practices by reducing the energy expenditure for treatments but also reduce emissions from patient travel. This, in turn, significantly enhances patient convenience and can make radiotherapy treatments more available to patients by increasing machine availability [7].

Despite the clear advantages that HFRT treatments demonstrate, careful implementation is necessary to ensure treatment efficacy is not compromised by the reduction in the number of fractions [8]. Brunt et al. (2020) found that HFRT for breast patients had an equal efficacy as conventional treatments [9]. The guiding principle should be to administer a minimal number of fractions while maintaining treatment effectiveness and patient safety.

These outcomes highlight the potential for software tools like LEPAS to facilitate more nuanced areas concerning medical technologies. Such tools can provide healthcare administrators and policymakers with actionable insights, enabling the development and innovation of departments to reduce the total energy consumption within departments.

The aggregation of datasets from a multitude of treatment centres presents a unique opportunity to broaden the comparative framework to include an array of treatment methodologies. It would also facilitate the evaluation of emergent advanced technologies such as magnetic resonance linacs (MR-linacs) and proton linacs. Upon full development of LEPAS, access to the private repository can be extended to other departments. This collaboration would lead to a robust database that is reflective of the diverse array of treatments that centres offer so the radiotherapy community can optimise treatment delivery while maintaining a commitment to environmental sustainability within radiotherapy.

5 Conclusion

In conclusion, LEPAS represents an instrumental advancement for the energy optimisation of linacs. This study has provided empirical evidence of its potential to significantly inform energy management strategies in radiotherapy thereby supporting the NHS in its net-zero aim. As LEPAS and other energy consumption-focused software evolve, they will become essential components of the sustainable healthcare infrastructure, facilitating not only immediate operational efficiencies but also long-term strategic planning for environmental sustainability in healthcare both within the UK and internationally.

Deep reinforcement learning for custom applicator design in personalised high dose rate brachytherapy

Cédric LOISEAU[1], Philippe BEREJNY[1], Marlon SILVA[2], Juliette THARIAT[2], and Alain BATALLA[1]

[1]Department of Medical Physics, Comprehensive Cancer Centre François Baclesse, Caen, France
[2]Department of Radiotherapy, Comprehensive Cancer Centre François Baclesse, Caen, France

Abstract Brachytherapy is a radiotherapy technique that uses radiation from a radioactive source to treat a tumour. In personalised brachytherapy, the source is guided by an applicator adapted to the patient's anatomy and the positions of the source (PoS). The dwell time (DT) associated with the PoS are the spatial and temporal parameters to be optimised, which govern the dose distribution. This distribution must comply with dosimetric constraints: coverage of the tumour and minimum dose to organs at risk. Usually, to meet the dosimetric and geometric constraints of applicator manufacture, the definition of PoS and DT is long and laborious. Our project exploits deep reinforcement learning models and 3D printing technology to design custom applicators. For a simplified case of a virtual patient, we have demonstrated the feasibility of our model, trained on virtual data, to offer PoS by dealing with spatial and temporal optimisation to meet constraints.

1 Introduction

Brachytherapy is a radiotherapy technique in which a radioactive source is placed within a body cavity or inside the tissue to be close to the tumour. It allows steep dose gradients and protects healthy tissues very well due to accurate source positioning and the inverse square law [1]. To improve brachytherapy treatments, personalised applicators can be generated using 3D printing. Moreover, their design phases can be optimised using artificial intelligence (AI) based methods. The applicator is a device that allows the source to be positioned according to the patient's anatomy. The degree of customisation varies from standardised modular applicators to customised personalized applicators made to conform to each patient's analtomy with a high fidelity. The Comprehensive Cancer Centre François Baclesse (CFB), located in Normandy (Caen-France), has a 30-year long expertise in customised brachytherapy and has been involved in innovations including AI to improve patient care.

The current state of the art for customised brachytherapy treatments is the use of an applicator tailored to the patient's anatomy [2]. The radioactive sources can be guided along multiple source paths within applicators. The sources stop at defined positions (PoS position of source) along each path. The problem with personalised brachytherapy is to produce an applicator for a given patient that satisfies several constraints: geometric constraints, dosimetric constraints and constraints on the fabrication of the final applicator, which has to comply with medical device regulations. At present, the manual production of an applicator that complies with all constraints involves two optimization stages (yellow box in figure 1).

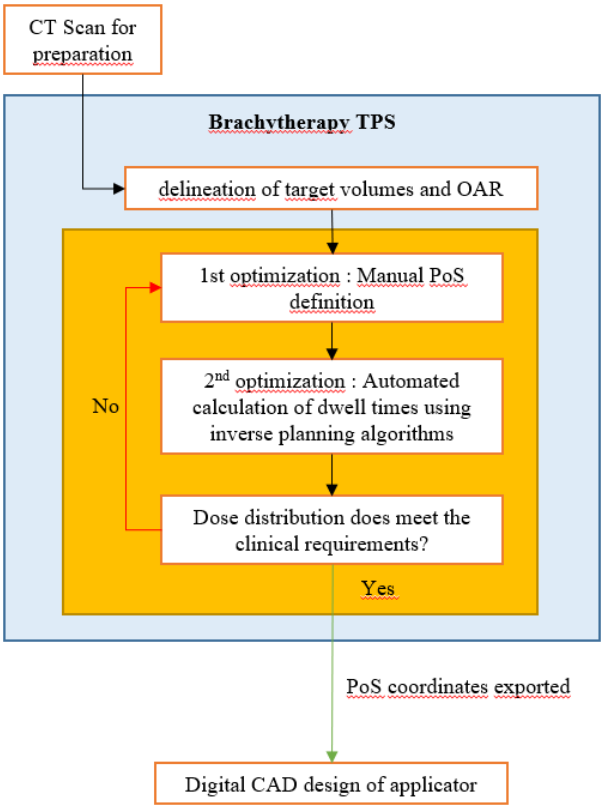

Figure 1: The calculation of PoS and DT is carried out in CE-certified dose calculation software (treatment planning system TPS). The steps are shown in a yellow box. When done manually, they are time consuming and laborious. Our AI model aims to automate these two steps.

The geometric constraints are the distances between the PoS and the topology of the treatment area (tumour and healthy organs/tissues). The first step is therefore to propose a solution. This solution defines PoS that respect the geometric/anatomic and dose-distance and manufacturing constraints (mechanical properties of materials and 3D printers). For example, the source may not circulate if one of the paths is too curved. Due to the lack of dedicated tools, this phase is currently done manually but is time-consuming and laborious. It is necessary to work empirically and iteratively on the applicators before clinical application. There is no guarantee that the result will be optimal. At this stage, there is no informa-

tion about the distribution of the dose, so the expert works by experience and deduction, assuming that the applicator will fulfill the dosimetric needs. This is the first stage of the optimisation process.

A second step is necessary to find the source stop times that respect the dosimetric constraints. Current brachytherapy planning involves constraints on both the tumor and surrounding healthy tissues. For example in the case of treatment of a skin tumor, international recommendations are to deliver at least 36 Gy to the tumor but less than 140% of 36GY to avoid necrosis and as little as possible to healthy skin [3, 4]. This means that the dose distribution has to be shaped by adjusting DT of each PoS. This means that the dose distribution must be shaped by adjusting the DT of each PoS. Two elements are involved in calculating the dose, the source-point of interest distance and the stopping time. The variation with the stopping time is linear, while the dose varies inversely squared with the distance [1]. Solving this requires complex mathematical methods[5]. Clinicians and physicists are therefore assisted by certified CE-marked dose calculation softwares relying on mathematical algorithms chosen by software vendors. This is the second step in the optimisation process as does today.

The third step is to evaluate the final result and check that all the constraints have been met: If they are met, the manufacturing process is initiated to build the applicator. If they are not, the current process requires that physicists and clinicians go back to the first step and test a different PoS solution. The full process is therefore time-consuming and depends on the experience of the operators.

The H3DMED project stems from the need to streamline the previously described processes by leveraging AI.

2 Materials and Methods

Up to now, no research has successfully amalgamated the two optimization steps into a single process, primarily due to their inherent complexity. The multitude of constraints, both temporal and spatial, poses a significant challenge, with the risk of computational explosion being a major concern. Addressing this challenge constitutes a central point of the H3DMED project.

Conventional machine learning methods require substantial datasets for effective learning. However, in the realm of medical data, stringent privacy regulations pose formidable legal hurdles. Implementation necessitates meticulous procedures, including impact assessments to mitigate data risks, obtaining patient consent, and potentially securing regulatory approvals from commissions such as "CNIL" and "CESREES" in France. Moreover, even with adherence to these protocols, access to data remains limited to information managed by medical institutions, often insufficient for robust model training.

Consequently, we opted for a specialized branch of machine learning: reinforcement learning. Reinforcement learning circumvents the data bottleneck by creating a virtual environment to simulate physiological organs and the dose distribution resulting from various positions and dwell times of the radioactive source. Here, an agent is trained to perform actions such as catheter movements, deformations, or adjustments of dwell times, iteratively improving its performance through interactions with the environment. A catheter consists of a sequence of multiple source positions that must adhere to geometric constraints.

This approach draws upon statistical principles described in the seminal work of Sutton and Barto [6].

During the training phase, the simulated environment mirrors a diverse patient database, providing a rich substrate for agent learning. In the simulation, the environment dynamically adjusts the parameters of the target tumor volume (TV) and organs at risk (OAR) for each episode. Initially, the study is limited to a 2D model, focusing on catheter movement within one plane while the TV and OAR are situated in another plane. This step validates our approach before transitioning to a 3D model.

The development of the 2D model involves addressing various complexities such as calculation points (TV and OAR) and dwell points, while adhering to dose constraints and tissue protection criteria. Inspired by [7] and, to start, utilizing the DQN reinforcement learning algorithm, the 2D model employs simplified catheters.

Benchmarking using test cases leads to the selection of algorithm as the most efficient agent, offering continuous actions for better control. A simplified spherically symmetrical dose calculation model is adopted for its speed and directness, compared to a slower, more accurate directional model extracted from the TG43 standard [8].

Each catheter, representing a basic unit, consists of a set of dwell points spaced 5 mm apart and movable within the same plane. The learning process involves simplified catheters with up to 3 dwell points, enabling rotation orders and deformation akin to the movement of a snake. The 2D model comprises two parallel planes separated by 5 mm: the first plane contains the OAR and TV, while the second plane contains the dwell points, each color-coded to indicate its affiliation with a catheter.

Transitioning to 3D involves introducing a thick TV and optimizing for multiple catheters while managing inter-catheter distances and adjusting time thresholds. Expansion to 3D requires adjustments to initial conditions and training steps, emphasizing control of curvature radius and additional actions for modifying dwell times.

3 Results

The study developed an environment that allows agents to activate catheters to irradiate the clinical target volume (CTV) while minimizing damage to organs at risk (OAR). The train-

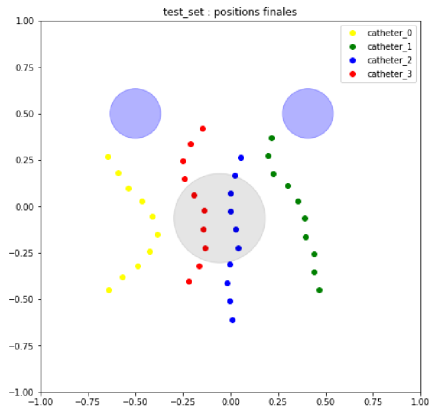

Figure 2: elements of the 2D demonstrator. They are distributed on two parallel planes separated by 5 mm. The first plane contains the OARs (blue) and TVs (gray), and the second plane contains the dwell points, whose color indicates the catheter to which they belong.

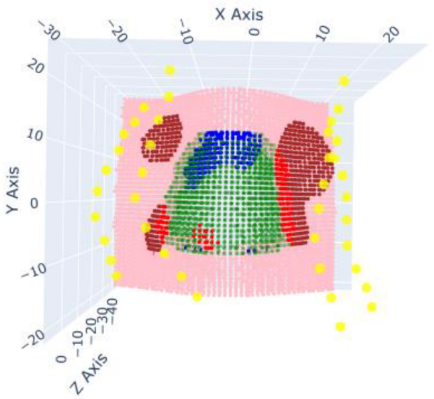

Figure 3: 3D representation of the catheters around the phantom. The catheters are shown in yellow. On the TV: in green, dose between 100 and 140%, in blue less than 100% and in red greater than 140%. On healthy skin: in pink, dose < 140%, in brown > 140%. The skin must be protected.

ing sessions simulated 100,000 patient cases, incorporating constraints to reflect real-world conditions: preventing the catheter from bending below a bend radius of 1.3 cm, imposing a minimum distance of 1 cm between catheters and varying downtime requirements (figure 2).

In the most complete configuration, the training calculation time was several days, the model inference was fast (of the order of a minute).

The performance of the model was evaluated using a 3D digital phantom (figure 3), showing that the model was capable of irradiating the TV between 100% and 140% of the prescribed dose and best preserving the OARs.

The transition to 3D planning has increased complexity and computational burden. However, integrating skin protection into the modele effectively reduced skin exposure to radiation. Further research is needed to optimize the accuracy and complexity of the model.

4 Discussion

We have developed a 3D simulation environment for radiotherapy, enabling an AI agent to manipulate catheters by controlling position, orientation, and dwell time. The agent's objective is to deliver the prescribed dose (between 100% and 140%) to the target volume while minimizing dose exposure to surrounding organs at risk. Realistic constraints have been integrated to enhance clinical validity, including minimum catheter curvature, inter-catheter distance, and dwell time thresholds. Protecting patient data is paramount, governed by stringent regulations such as the Data Protection Act, GDPR, and Public Health Code. Obtaining authorization to use such data involves navigating complex procedures with regulatory bodies. Alternatively, generating virtual data circumvents these challenges, allowing for an expansive dataset with customizable parameters. In our study, each training session simulated 100,000 patient cases, demonstrating the potential for our AI model to generalize across diverse practical scenarios, essential for comparison against professional expertise. The underlying algorithm leverages reinforcement learning, where the AI agent learns optimal dose distribution by receiving rewards for its actions, guided by geometric and dosimetric constraints. Initially applied in a simplified 2D context, the technique was subsequently extended to a more realistic 3D scenario. This proof of concept paves the way for AI to autonomously propose PoS to healthcare professionals, streamlining preparation time. However, it's essential to acknowledge that AI remains a decision-making tool and cannot replace CE-marked software. Final validation involves importing PoS into certified dose calculation software for patient treatment. This Proof of Concept showcases an AI model capable of predicting PoS for a simplified virtual patient case. The model successfully proposes PoS that adhere to anatomical and dosimetric constraints for brachytherapy treatment without relying on patient-specific data. By 2023, 60 patients had undergone personalized brachytherapy treatment at the CFB, with at least one applicator manufactured per week by dedicated healthcare professionals. The use of AI, derived from this proof of concept and generalized to realistic cases, coupled with 3D printing technology, promises a substantial reduction—between 50% and 80%—in staff time dedicated to applicator manufacturing. The utilization of additive manufacturing technology by i3D ensures precise reproduction of AI-proposed dose paths, surpassing the accuracy achievable through manual manufacturing methods. This integration underscores the potential synergy between AI-driven treatment planning and advanced manufacturing techniques, promising improved treatment outcomes and efficiency in clinical practice.

5 Conclusion

The H3DMED project represents a significant advancement in the field of personalized brachytherapy, offering a proof of

concept grounded in innovative technologies tailored to meet the genuine needs of healthcare professionals. Leveraging AI to optimize the design process of 3d print personalized brachytherapy applicators marks a pioneering approach, potentially groundbreaking in its application. Our proof of concept aims to refine the design process by utilizing AI to predict the positioning of radioactive sources in alignment with geometric and dosimetric constraints. While previous literature explored AI's role in determining stopping times for a fixed distribution of Points of Service (PoS), our project expands this scope by introducing spatial degrees of freedom, augmenting the AI model's complexity. Despite the current simplicity of the cases examined, our project illustrates the feasibility of obtaining clinically relevant results in reasonable computational times. Training times, although spanning several days per 100,000 cases, align favorably with clinical applicability, with inference requiring only minutes. Nonetheless, further improvements are imperative to produce a solution suitable for clinical deployment, which requires exploring methods to accelerate training calculations as data volumes increase with case complexity. These achievements surpass the current state of the art in the field, laying the groundwork for future research and development efforts aimed at clinical implementation. However, realizing these prospects will require substantial investment in both technical and regulatory domains.

Angle Dependence on Positional Radioisotope Source using Monte Carlo Simulation in Brachytherapy

Moo-Jae Han[1], Sang-Won Kang[1], Woong Cho[2], Dong-San Kang[3], and Jin-Beom Chung[1,*]

[1]Department of Radiation Oncology, Seoul National University Bundang Hospital, Seongnam, Korea
[2]Department of Radiation Oncology, Seoul National University Borame Medical Center, Seoul, Korea
[3]Department of Biomedical Engineering and of Biomedicine & Health Sciences, College of Medicine, The Catholic University, Seoul, Korea

Abstract In this study, Monte Carlo Simulation was employed to investigate the angle dependence for tracking the location of a radioisotope (RI). The analysis revealed margin of error values for the top 10% of each slope, with measurements of 5.90% at 0°, 8.08% at 30°, and 20.90% at 60°. The total absorbed dose ratio was observed at 83.77% (30°) and 53.36% (60°) relative to 0° (100%), exhibiting a tendency to decrease with increasing slope. Notably, the maximum value for all gradients was consistently observed at 30° No. 9 pixels, with a corresponding 7.24% decrease at No. 10 pixels. The study highlights a substantial degree of angle dependence, leading to the recommendation that maintaining a proper distance of at least 1 cm between the RI and dosimeters is essential to minimize these effects.

1 Introduction

Brachytherapy is a vital treatment modality involving the introduction of a radioisotope (RI) source into the body to optimize radiation delivery to target lesions [1]. However, the precision of source positioning is crucial to avoid excessive radiation to normal tissues, necessitating rigorous evaluation of dwell position and dwell time as part of quality assurance (QA) measures [2,3]. Traditional methods relying on visual inspection, such as ruler and film analysis using a camera, lack quantitative error data and are prone to inaccuracies [4,5].

This study investigates the potential of digital dosimeters, focusing on reproducibility, linearity, distance dependence, and, notably, angle dependence [6]. Angle dependence is known for its sensitivity to variations in RI position, necessitating an accurate measurement setup despite the inherent challenges in achieving precision.

To address this, Monte Carlo simulation was employed in the analysis, utilizing the FLUKA (FLUktuierende KAskade) tool developed by CERN. The dosimeter material selected for the study is Mercury (Ⅱ) Iodide (HgI_2), chosen for its relatively high signal generation efficiency. The research aims to provide insights into the trend of angle dependence for unit-cell dosimeters in the context of brachytherapy QA, shedding light on the potential advantages of digital dosimeters and advancing the understanding of measurement accuracy in this critical medical application.

2 Materials and Methods

Radiation Monte Carlo simulation codes, such as FLUKA, involve a series of crucial steps, including geometry modeling, source term definition, scoring, and data analysis. This study focuses on the foundational step of geometry modeling to realistically represent radiation exposure and the irradiation environment. Using the FLUKA code, we executed the geometry modeling of the unit-cell dosimeter, as illustrated in Figure 1, to assess angle dependence.

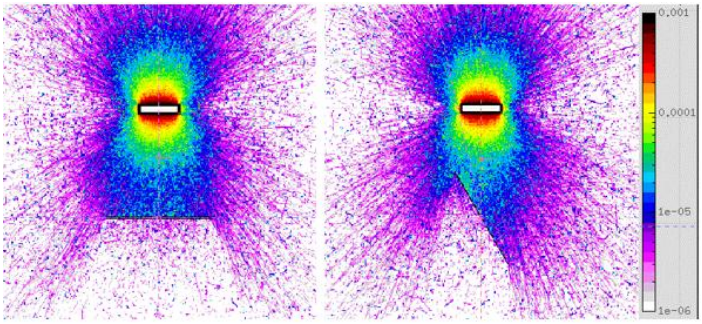

Figure 1: Geometry and dose distribution of 0° and 60° angle

The unit-cell dosimeter, with dimensions of 1 cm × 1 cm, was subdivided into 100 pixels of size 0.1 cm × 0.1 cm for comprehensive evaluation of dose distribution. Meeting the minimum thickness requirement for measuring energy above 6 MV, the dosimeter had a thickness of 200 μm.

In terms of RI sources, the unit-cell dosimeters were strategically positioned 1 cm apart from the center of the designed unit-cell dosimeter, with measurement angles set at 0°, 30°, and 60°. Source term information for the Ir-192 source, as implemented in the FLUKA code, is presented in Table 1.

RI Information	Z (Atomic Number)	77
	A (Mass Number)	192
	Energy	Approximately 300 KeV
RI Size	Type	Cylinder
	Diameter	0.65 mm
	Length	3.60 mm
RI Shield	Material	AISI316L steel
	Diameter	0.90 mm
	Length	4.50 mm

Table 1. RI Source term

This research contributes to advancing the understanding of radiation exposure analysis through precise geometry modeling and simulation methodologies, providing valuable insights for applications such as brachytherapy quality assurance.

In the context of radiation exposure analysis using Monte Carlo simulation, the scoring methodology is a critical aspect. In this study, a unit-cell dosimeter was utilized in conjunction with a USRBIN card for scoring purposes. To comprehensively capture the absorbed dose distribution, the scoring type was configured as dose (GeV/mass), employing a 10 × 10 binning strategy designed to yield 100 absorbed doses in 1 mm × 1 mm size.

For the subsequent distributional analysis, each slope result was normalized to the maximum value, providing a comparative framework for understanding dose distribution patterns. Additionally, an error rate is presented for the top 10% of the distribution, highlighting the magnitude change in the region of high dose distribution. To facilitate a comprehensive view of the total absorbed dose values for all angle, normalization was performed relative to the total absorbed dose at 0°.

Numerical comparisons are provided for each slope across various angles, considering the x-axis located at the center of the unit-cell dosimeter. The comparisons are further normalized to the No. 9 pixel value at 30°, representing the highest absorbed dose value. This methodology enhances our understanding of absorbed dose distribution trends and provides a quantitative framework for evaluating the impact of different measurement angles in radiation exposure simulations.

3 Results

This study delves into the examination of the angle dependence trend by analyzing dose distribution plots at tilts of 0°, 30°, and 60° relative to the central axis of the unit-cell dosimeter, utilizing a fixed Ir-192 source. Figure 2 provides an overview of the distribution plots corresponding to each measurement angle.

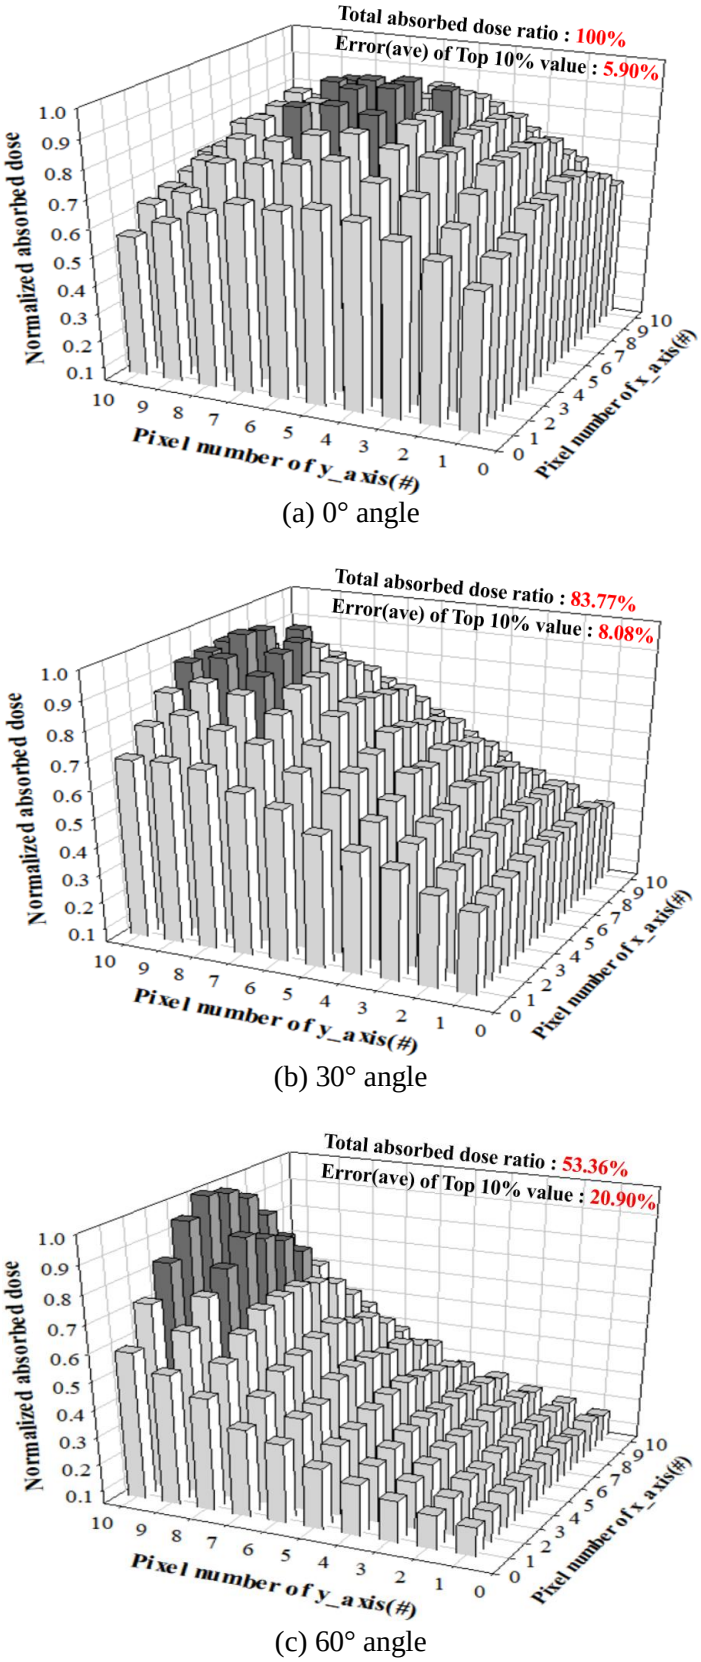

Figure 2: Absorbed dose distribution according to each angle.

Within Figure 2, (a) corresponds to 0°, (b) to 30°, and (c) to 60° measurement angles. The observed error rates for the top 10% of readings were 5.90% at 0°, 8.08% at 30°, and 20.90% at 60°, indicating a substantial increase in distribution towards regions proximal to the RI. The

percentage of the total absorbed dose exhibited a trend of 83.77% at 30° and 53.36% at 60° relative to 0° (considered 100%), revealing a diminishing absorbed dose trend with increasing angles of the unit-cell dosimeter.

For a quantitative comparison at each angle, the study focused on pixel values along the y-axis, specifically the center point (No.5) of the x-axis. Figure 3 depicts normalized values for absorbed dose at 0°, 30°, and 60°. At 0°, the maximum dose value was localized at No. 5, representing the center point. At a 30° angle, absorbed dose displayed a linear increase, while at 60°, it exhibited a rapid quadratic rise.

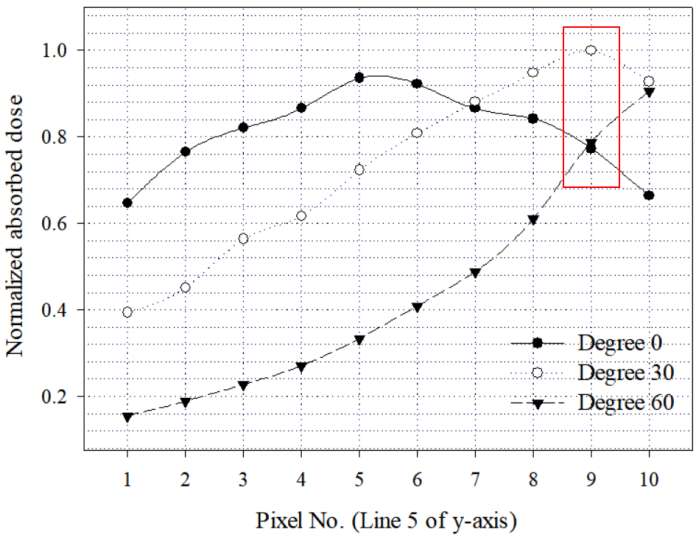

Figure 3: Absorbed dose about line 5 of y-axis.

The peak absorbed dose occurred at No. 9 pixel at 30°, with a subsequent 7.24% decrease at No. 10 pixel. This suggests that the maximum measurement point is at the No. 9 pixel at 30°. Remarkably, the No. 9 pixel at 0° and the No. 9 pixel at 60°, despite being at different distances from the source, demonstrated similar absorbed doses, indicating comparable measurement outcomes. The findings contribute valuable insights into the nuanced angle dependence in brachytherapy dosimetry.

4 Discussion

This study systematically assessed the inclination of angle dependence in brachytherapy QA by employing Monte Carlo simulation techniques facilitated through the FLUKA code. The results illuminate a notable trend: as the dosimeter measurement angle increases, the distance from the RI becomes more substantial in the nearby region. However, as illustrated in Figure 1, the dose is effectively transmitted in the immediate area, leading to an overall lower absorbed dose.

In Figure 2, a discernible reduction in the top 10% area is observed. The diminishing number of pixels in the top 10% of the dose distribution as the angle increases suggests a significant variation in absorbed dose between pixels, potentially influenced by disparities in the size and shape of the irradiation surface.

Based on these findings, the study recommends maintaining the unit-cell dosimeter at an appropriate distance, aligning with the reference distance of 1 cm for High Dose Rate (HDR) brachytherapy treatment planning systems, to mitigate angle dependence [7]. Further exploration into thickness variations to enhance the absorbed dose of the dosimeter is suggested, offering potential reinforcement for the current research. It is emphasized that the dosimeter's construction material plays a crucial role, influencing the transmitted dose based on its physical properties and thickness. These insights contribute to a more nuanced understanding of angle dependence considerations in brachytherapy QA.

5 Conclusion

This study unveils that variations in dosimeter absorbed dose stem from disparities in the size and distance of the irradiation field, influenced by the angle of RI measurement. Depending on the dosimeter's shape, these variations can yield diverse measurement outcomes owing to absorbed dose discrepancies at distances less than 1 cm. Consequently, the angle dependence of the dosimeter becomes a crucial consideration for HDR brachytherapy QA, particularly for materials with high low-intensity and optimal dosimeter thickness. This research contributes to a deeper understanding of the nuanced factors affecting dosimeter measurements in HDR brachytherapy, emphasizing the significance of accounting for angle dependence in QA protocols.

Abstract Computerized tomography (CT) scan uses X-rays and is the primary material for defining ROIs delineated by radiation oncologists for radiotherapy (RT) planning and radiotherapy quality assurance (RTQA). Additionally, doses are calculated from the CT electronic densities of tissues, but CT quality varies. CTs often exhibit blur, noise, or artefacts stemming from metals, which can be remedied by super resolution (SR) and metal artifact reduction (MAR) models, respectively. A literature search on AI models that can exploit the latest computer vision algorithms and combine both tasks is presented. An interesting approach is based on a content consistent super-resolution (CCSR) model, which utilises Stable Diffusion. The two tasks can be conducted by this model by simulating both SR and MAR distortions in the training data.

1. Introduction

Computerized tomography (CT) scan uses X-rays and stands as one of the preeminent medical imaging techniques for screening and diagnosis in many diseases including cancer, as well as radiotherapy (RT) planning and radiotherapy quality assurance (RTQA). Low quality CT scans may obscure the borders of structures considered as regions of interest (ROI, such as organs at risk (OAR) and tumour), hindering the delineation of ROIs. CTs with high resolution and high signal-to-noise ratio hold the potential to augment the precision of radiological features. Imaging quality contributes to more accurate definition of ROI and their delineation by radiation oncologists in their part of the RT planning. Super resolution (SR) reconstruction from deep learning approaches is an auspicious method of SR to increase the visual quality of images.

Metals in the area imaged by the CT scanner can degrade the quality by introducing artefacts. Linear inverse problem algorithms, such as filtered back projection, induce artefacts in CT images [1]. Deep learning based methods have achieved respectable performances for metal artefact reduction (MAR) tasks. These are based on sinogram domain enhancement, image domain enhancement, or dual domain (joint sinogram and CT image) enhancement.

SR and MAR are addressed by different models. A model that removes noise, blur or metal artefacts, or improves the visuals based on the deficiency of the CT has not been studied. Such a model may improve the quality of ROIs so that radiation oncologists can better delineate them during RT planning, and better assess delineations during RTQA processes as part of clinical research.

2. Materials and Methods

We reviewed the literature on the academic research website Scinaps [2] using the search keywords *CT super resolution* and *metal artifact reduction CT*. Only the articles that used AI on CT scans that surpassed previous models across the scores they presented were selected. Also, the latest algorithms on computer vision were investigated on the following websites: Stability AI Research Blog [3], Metal AI Research on computer vision [4], Microsoft research on computer vision [5], NVIDIA publications [6], Google Publications on machine intelligence [7], and Papers With Code on super resolution [8] and metal artefact reduction [9]. In all cases, the results earlier than 2023 were filtered. The most suitable models elected based on their potential to be adapted to the geometry and the unit of CT scans (3D and HU).

3. Results

Among AI methods, KerSRGAN [10] introduced a feature extractor in Generative Adversarial Networks (GAN) [11] in an unsupervised manner. Residual feature attentional fusion network [12] incorporated a feature extraction block to elevate visual acuity. Multi-scale Attention Mechanism [13] uses convolutional layers with various kernel sizes to capture information with different sizes. These papers used bicubic resizing to reduce the resolution rather than simulating long slice thickness. A more recent method named Linking In-Plane and Through-Plane Transformers [14] simulates longer slice thickness to reduce the quality.

For MAR, most methods published in 2023 were deep learning based. Standard vision transformer was tested for MAR [15] in image domain. A generative AI was attempted using Res-U-Net GAN [16] in the image

domain [17]. Polyner [18] took an unsupervised approach using implicit neural representation [19] on image domain. Plugging Diffusion Priors in dual domains [20] used patch diffusion [21] for unsupervised training.

Outside medical AI, there have been major developments in computer vision and SR. Stable Diffusion [22] generates realistic images based on text. It incrementally refines noise from the vector representation from which the images are decoded. Its derivatives prevailed in many applications such as segmentation [23], anomaly detection [24] etc. Other models based on Stable Diffusion, such as Content Consistent Super-Resolution (CCSR) [25], Pixel-Aware Stable Diffusion (PASD) [26] outperformed other metods for SR [25]. PASD surpasses CCSR on image quality that aligns better with human perception [25]. Still, it could be unsuitable for RT. Generative AI models give a different output at every run. PASD score varied more than CCSR between runs for the same image. Frechet inception distance (FID), the score inversely related to the fidelity of generated output to real data, was high [25] for PASD i.e. it created non-existent details to have higher quality. On the other hand, CCSR made use of ControlNet [27], to confine the outputs to a narrower distribution for score consistency and lower FID score [25] compared to PASD on RealSR [28]: 105.55 vs 123.08 [25].

4. Discussion

A network that can manage MAR and SR simultaneously should be complex enough to model both but reasonably fast for training and inference. PASD was did not only fail to give consistent results and low FID score but also its very complex network may have a very costly training and inference load. In addition, for medical context it would be necessary to replace CLIP [29] with medCLIP [30], CLIP for medical context. Nevertheless, medCLIP is not mature enough for practical use because it has not been trained with enough data [30]. A modified version of CCSR for SR and MAR on CTs could overperform previous models in modelling both tasks with high fidelity to actual radiological features and consistency in quality throughout executions. For both SR and MAR, training data creation start with simulation of noise, blur, or metal artefact. By creating instances of CT scans that can have any combination of these in the training data, a model may gain the ability to conduct SR or/and MAR depending on the issue. Nonetheless, in real practice, there may be distortions that were not taken into account during training data creation.

5. Conclusion

One of the latest algorithms in computer vision, Stable Diffusion, has not been implemented in RT planning. Adapting Stable Diffusion-based CCSR model to 3D CT data and training with SR and MAR distortions may conceive a model that implements both simultaneously and consistently contingent upon CT deficiency with superior performance. A satisfactory model would improve the visual distinction between tissues and remove the metal artefacts before a radiation oncologist works defining ROIs during RT or RTQA in clinical trials.

Abstract Deformable image registration (DIR) is an important tool to enable the assessment of prior radiation doses in the reirradiation (reRT) setting. However, the effect of geometric uncertainties on dose mapping from previous treatments onto the reRT planning scan remains a key challenge, which limits its clinical application. We propose a novel tool for individualised dose mapping uncertainty quantification in the reirradiation setting for head and neck cancer. The tool includes a Graphical User Interface (GUI) and creates a report on the uncertainties using a commercially available treatment planning system, RayStation (Version 11B-R, RaySearch Lab, Stockholm, Sweden). We demonstrate the use of this tool in a dataset of eight patients, evaluating both a serial and a parallel organ, i.e., brainstem and parotid glands. 87.6% of 1524 registrations for all eight patients' organs at risk were deemed plausible (met AAPM TG 132 threshold of 0.3cm) and used in dose mapping. However, this was very patient and organ-specific. For example, 100% of registrations for the brainstem were plausible, while 91.7% were plausible for each of the parotids. Overall, this tool will allow for the assessment of mapped radiation doses following repeat registrations with differing parameters.

1 Introduction

Deformable image registration (DIR) in the reirradiation setting is used to enable the assessment of prior radiation doses. The use of DIR in the clinic setting is, however, challenged by the lack of assessment of the effect of geometric uncertainties on dose mapping from previous treatments [1]. This reduces the confidence in the mapped doses by the treating physicians, often leading to more conservative treatment prescriptions which may affect treatment outcomes.

We propose a novel tool for individualised dose mapping uncertainty quantification in the reirradiation setting. The tool includes a Graphical User Interface (GUI) and creates a report on the dosimetric impact of geometric registration uncertainties using a commercially available treatment planning system, RayStation (Version 11B-R, RaySearch Lab, Stockholm, Sweden). We demonstrated the use of this tool in a set of patients who underwent head and neck reirradiation.

2 Materials and Methods

The GUI is shown in Figure 1. A user selects the initial and reirradiation CT scans based on the examination dates. The GUI then gives the user an option to select relevant organs at risk (OARs) from drop-down menus populated from all structures under the same name in both CT scans. These are populated by pressing the button, "Find Common Structures". The threshold value to determine locally plausible registration (based on the mean distance to agreement between mapped and delineated structures) is then set in the text box, with a default of 0.3cm as suggested by AAPM TG-132 [2]. The GUI gives the user an option to add relevant OARs using the "Add row" button. On each row, an OAR is selected. This OAR can be included as a controlling structure in the registration if the checkbox is selected. The report can then be customised to include: 1) DVH estimate uncertainty, 2) DVH uncertainty, plotting DVH curves of all plausible registrations, and 3) voxel-wise spatial uncertainty, computing the standard deviation (SD) of the mapped doses in all voxels within the OAR.

The user then clicks the "Run Registration" button. This allows the script to run six registrations as defined in the methods. Once this is complete, the user clicks on "Run Evaluation". This performs the geometric and dosimetric evaluation of the OARs added to the table in the GUI and generates a report. The report shows a summary of the patient's details (such as the patient ID, disease sites, initial planning CT date and reirradiation CT date), results from the geometric and dosimetric assessment carried out on the selected OARs in the form of tables, and the DVH plots of the mapped dose distribution which were selected to be included in the report. Other details such as the plausible registration threshold, the type of registration performed, and the date and time the report was generated are also included.

Data from eight patients with head and neck cancer who were reirradiated (six Type I and two Type II according to ESTRO-EORTC consensus on reirradiation [3]) were used. Both initial and reRT planning CTs were automatically contoured using Limbus Contour (Limbus.AI v 1.7.0-B3) to ensure consistency. Planning CTs, dose distributions and

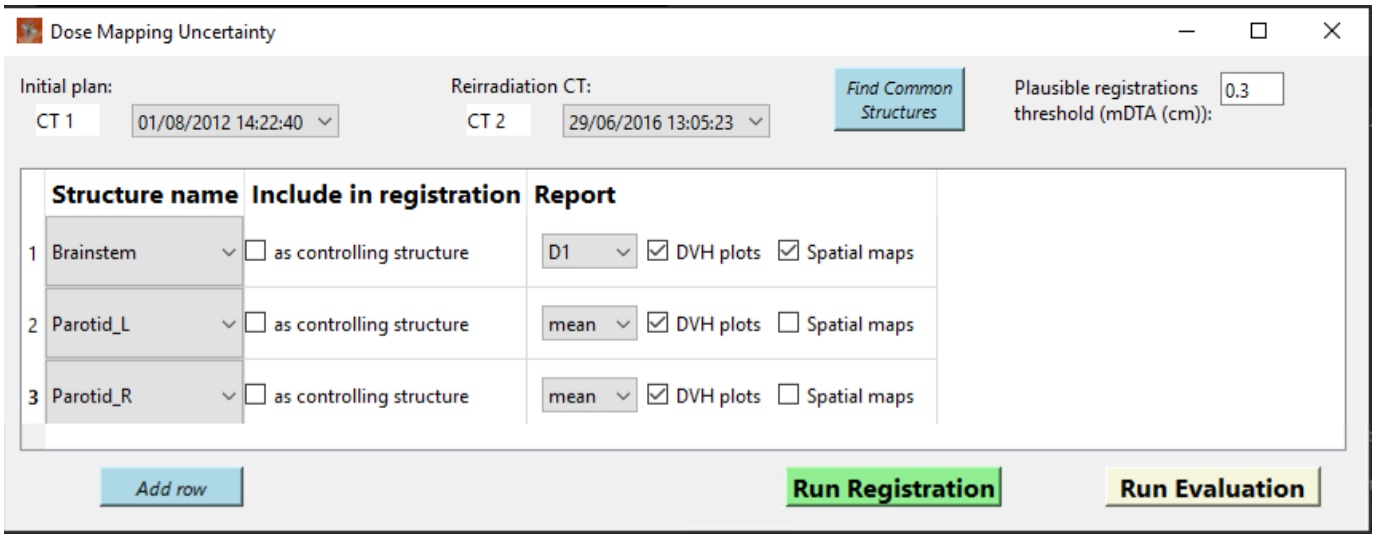

Figure 1: A screenshot of the GUI showing the interface the user interacts with. A Python script runs in the background to perform DIR, dose mapping and an assessment of the registrations performed and the resulting mapped doses.

contours for the initial and reRT course were then imported into RayStation.

To demonstrate the use of this tool, we used it to map the dose of a previous radiotherapy course into a reirradiation planning CT for the eight patients, exploring the impact of geometric registration uncertainties on the mean dose of the parotid glands and the near maximum (D1%) for the brainstem. We also recorded the time it took to run the entire pipeline on a system with NVidia Quadro RTX 6000 GPU, 6.4GHz Intel(R) Xeon(R) CPU and 64GB RAM.

Patient	Brainstem	Left Parotid	Right Parotid
Patient 1	6	6	6
Patient 2	6	6	6
Patient 3	6	6	6
Patient 4	6	6	6
Patient 5	6	6	6
Patient 6	6	2	2
Patient 7	6	6	6
Patient 8	6	6	6

Table 1: Number of registrations passing for the brainstem, left and right parotid glands. For each organ, a total of six registrations were carried out. The number of registrations passing with mDTA of $\leq$ 0.3cm are shown.

3 Results

Figure 2 on Page 4 shows the report generated for patient 6 using the configuration presented in Figure 1. Table 1 shows the number of registrations that met the AAPM TG 132 suggested threshold of 0.3cm. Table 2 shows the dose mapping uncertainty results for the 8 patients in the cohort for the brainstem and parotid glands. On average, for all patients, the script runs in 11.9$\pm$4.5 minutes.

For our selected use case, an example of a sample report for Patient 6 is presented in Figure 2. The report includes patient details, registration uncertainty details and dose mapping uncertainty details for the brainstem and the parotid glands. The mapped doses for all three OARs varied greatly from the initial treatment plan's dose to these organs. The DVH maps also showed the variation in the mapped doses for each of the plausible registrations.

4 Discussion/Conclusion

We demonstrated a novel tool for individualised dose mapping uncertainty quantification in the reirradiation setting for head and neck cancer. The tool is developed on RayStation's scripting interface and consists of a GUI and generates a report (see Figure 2). The tool performs six DIRs followed by the quantification of the mapped dose uncertainty through the assessment of the registrations performance and the impact these had on the resulting mapped dose for OARs selected by the user in the GUI.

Reviews by Murr et al 2023 and Nenoff et al 2023 [1, 4] recommend researchers repeat registrations with differing parameters for the assessment of uncertainties. However, this process can be time-consuming and may introduce errors when carried out manually. Here, we ran six registrations for each patient.

Our tool quantifies the impact of plausible registration uncertainties on mapped dose distributions in an automatic and consistent way that can be extended to patients in the clinic.

Patient	ReRT type	Time (min)	mean mDTA of passing registrations ± standard deviation			mean mapped dose ± standard deviation		
			Brainstem	L. Parotid	R. Parotid	Brainstem	L. Parotid	R. Parotid
Patient 1	I	22	0.06 ± 0.03	0.08± 0.03	0.16 ± 0.01	34.31 ± 0.82	8.64 ± 0.07	45.90 ± 1.32
Patient 2	I	12	0.05 ± 0.01	0.13 ± 0.02	0.16 ± 0.03	44.31 ± 0.92	40.78 ± 0.90	26.26 ± 0.90
Patient 3	I	9	0.15 ± 0.01	0.13 ± 0.02	0.25 ± 0.02	13.38 ± 0.59	3.87 ± 0.06	23.89 ± 0.06
Patient 4	II	9	0.09 ± 0.02	0.13 ± 0.01	0.10 ± 0.01	24.61 ± 0.14	5.35 ± 0.05	18.42 ± 0.30
Patient 5	I	9	0.13 ± 0.02	0.07 ± 0.01	0.28 ± 0.01	24.40 ± 0.34	6.61 ± 0.39	44.40 ± 0.41
Patient 6	I	14	0.11 ± 0.01	0.39 ± 0.08	0.36 ± 0.09	41.77 ± 0.58	41.18 ± 1.61	41.43 ± 2.06
Patient 7	I	9	0.11 ± 0.02	0.12 ± 0.08	0.12 ± 0.08	0.52 ± 0.01	0.75 ± 0.02	0.89 ± 0.03
Patient 8	II	11	0.12 ± 0.02	0.12 ± 0.03	0.21 ± 0.03	3.21 ± 0.13	31.87 ± 0.93	5.61 ± 0.22

Table 2: A summary of dose mapping uncertainty for all patients in our cohort.
ReRT - reirradiation; min - minutes; mDTA - mean distance to agreement

It can be argued that running only six registrations may not generate enough spread to reveal trends, therefore we are currently working on creating registration templates to allow users to run more registrations for a more granular analysis (for example, cases with extreme dose gradients in the region of interest). Further work is also being carried out to incorporate the assessment of cumulative doses with a consideration of biological factors and perform external validation of this tool.

In conclusion, the development of this tool would allow us to systematically and consistently assess dose mapping uncertainty for patients at the reirradiation planning stage.

Spatial uncertainty map, Brainstem

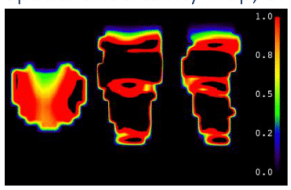

Figure 2: A copy of the generated report for Patient 6 adapted for this abstract. The report follows Figure 1 and is generated when the script completes running. It includes a summary of the patient's details, and results from the geometric evaluation as well as dosimetric assessment, based on the options selected by the user from the GUI. All the registrations for the brainstem were plausible, but only two registrations for both parotids were plausible. The script took 14 minutes to run for this patient, including interacting with the user interface.

Robustness of Radiomics features to reconstruction kernel batch effect: How bad is the situation?

Elfried Salanon[1], Aditya Apte,PhD[1], Anqi Fu,PhD[1], Usman Mahmoud,PhD[1], Zehor Belkhatir,PhD[1],Amita Shukla-Dave,PhD[1], Joseph O.Deasy,PhD[1]

[1]Department of Medical Physics, Memorial Sloan Kettering, New York, NY, USA

Abstract

The aim of this study was to evaluate the impact of kernel batch effect on radiomic features extracted from CT scans. Radiomic features extracted from CT scans of a 3D printed phantom using CERR, comprised 282 features. Batch effects were assessed via principal component analysis (PCA) and correlation measures. Robustness was measured using the concordance correlation coefficient (CCC) and Pearson correlation coefficient, with a CCC threshold of ≥ 0.9. Statistical analysis was performed using R software. PCA identified two clusters: Standard, ASIRs, ASIRV, and Soft kernels in one, and Lung and Bone Kernels in the other. A gradient from ASIR10 to ASIR50 and ASIRV1 to ASIRV5 was observed in the distance to the Standard Kernel. Correlation matrices revealed little change in ASIRs, ASIRVs, and the Standard Kernel but significant changes in Bone and Lung Kernels. Combat-based correction improved robustness, particularly in first-order statistics, mitigating batch effects in ASIRs and the Standard Kernel. 40 robust features were identified. However, challenges persist in harmonizing Bone and Lung kernels. The robustness of central tendance parameters in contrast to the lack of robustness in dispersion parameters, suggest a non-constant and a nonlinear batch effect influencing specific image regions.

1 Introduction

Repeatability and reproducibility challenges persist in omics sciences, limiting the generalizability and translation of biomarkers and signatures [1–3]. In omics, where data acquisition occurs in sequences or batches, the non-biological variation between sequences, known as batch effects, are well-documented and affect the statistical power and introduce strong bias in cross validation [2, 4]. The field of radiomics, which focuses on the extraction of features from radiographic imaging, faces similar challenges due to non-biological variations occurring throughout the acquisition process [5–9]. This paper considers a batch as a group of images sharing an acquisition parameter; - the reconstruction kernel in the context of this paper - with batch effect defined as the resulting non-biological variation from that parameter. The complexity of batch effect correction in radiomics is emphasized, given the multistep analysis process, numerous changing factors, and the retrospective nature of data [10]. Studies addressing this issue fall into three categories: identifying sources of batch effects, determining robust radiomics features, and developing correction methods for data harmonization such as *Combat* [6, 11–15]. Despite these multiple studies, consensus is lacking, leading to unresolved questions such as the mechanism behind different batch effects, the impact on various classes of radiomics features, and the effectiveness of correction methods in preserving relevant biological information. To contribute to resolving these gaps, this study evaluates the impact of kernel batch effects on various classes of radiomics features. Additionally, based on identified robust and non-robust features and statistical distribution assumptions, we propose a hypothesis on the mechanism of the studied batch effects. Addressing these questions is crucial for the development of better harmonization tools and refining data acquisition and analysis workflows to facilitate, clinical use.

2 Materials and Methods

The phantom data used in this study, was published by Usman et al[16]. To build this phantom, a multimaterial 3D printer (PolyJet Objet 260 Connex 3, Stratasys, Eden Prairie, Minnesota) equipped with Voxel Print software was employed to deposit droplets of UV-curable photopolymer resins in a layer-by-layer manner. Two base photopolymer resins, TangoPlus and VeroWhite, were used, with attenuation ranging from approximately 65 Hounsfield units (HU) to 125 HU at 120 kVp. The printer's resolution was on the order of 48×84×30 μm, finer than that of typical CT scanners. To replicate contrast differences observed in tumor-specific patterns on patient CT scans, multiple resin droplets were mixed in a single voxel using the Floyd Steinberg dithering algorithm. Four pancreatic ductal adenocarcinoma tumors were printed that captured the different morphological appearances and intensity patterns seen on CT scans. Prior to dithering, the HU values of each tumor and background were separately converted to double precision intensities within a range of 0 to 1. After 3D

printing, the phantom underwent 30 repeat scans using a 64-slice CT scanner (HD750, General Electric, Madison, Wisconsin) with the following parameters: 120 kVp, 0.7 s, 0.984; and the standard, bone, soft, ASIR and ASIRV kernels was applied to the data and two different tube currents were used (*100 mAs and 280mAs*). [16]

Radiomic Feature Extraction

The features were extracted from the original image using the computational environment for radiobiological research (CERR)[17]. 282 radiomics features were extracted on CT images, including first order statistics (FOS), gray-level co-occurrence matrix (GLCM), gray-level run-length matrix (GLRLM), gray-level size-zone matrix (GLSZM), neighborhood gray-tone difference matrix (NGTDM), and neighboring gray-level dependence matrix (NGLDM). CT images were discretized using a fixed bin width of 5. The minimum, maximum, mean, mean absolute deviation, and standard deviation for each of the texture feature were computed over all 13 directions to obtain rotational invariance. A patch-wise volume of 2 × 2 × 2 mm voxels was used for neighborhood gray level dependence features.**Statistical analysis**

- **Assessment of batch effect**

Two approaches were used to evaluate the batch effects. A PCA was conducted on a matrix of all the features and on the separated by class. The correlations within matrix were visualized for each data matrix separately to visualize the change in term of correlation using the Pearson correlation coefficient.

- **Robustness**

The assessment of the robustness was based on two dimensions: (1) the concordance and the (2) correlations. The concordance correlation coefficient (CCC) of Lin [18] was estimated to identify robust features [18, 19]. A threshold of ≥ 0.9 was used for the CCC based on McBride et al (*McBride et al, 2005*).

In addition, one of the goals of radiomics being to identify signatures, the Pearson correlation coefficient was calculated and used to identify the features that had the most stable correlations (Less than 10% change in correlation coefficient) with respect to the other features. All data analysis was carried out using R software version 4.1.3.

Combat batch effect correction methods

Combat works by modeling and removing batch-specific variations from the data through empirical Bayes frameworks. It adjusts expression values to create a harmonized dataset, reducing batch-related biases and enhancing the biological signal in high-throughput experiments.[12]

3 Results

Plotting the first two principal components of the full feature matrix revealed two clusters. The first cluster consisted of the standard kernel, ASIRs, ASIRV and soft kernel, and the second cluster consisted of the lung and bone kernels. Focusing on the standard, ASIR and ASIRV kernels, we found a gradient in the distance of these kernels to the standard kernel. This gradient grows from ASIR10 to ASIR 50 and from ASIRV1 to ASIRV5. Moreover, similarity found between ASIR20 and ASIRV1, and also between ASIR30 and ASIRV2 (Figure 1). The correlation matrix was still globally conserved with few changes in the ASIRs, the ASIRVs and the standard kernel; these small changes were more visible in the *skewness features*. However, very important changes appeared using the bone kernel and the lung kernel. These changes were larger for the *range, kurtosis, and skewness statistics*. The correlation between the energy, total energy and dispersion features were enhanced by the bone kernel and the lung kernel. In the other features class, the same trend was observed with very small changes in the ASIR. These findings highlight the ability of the ASIR and the standard kernel to conserve the functional relations between the first order statistics. In the neighborhood gray tone difference matrix, the correlations between the *contrast and the busyness, and the coarseness and the strength* were unstable, with a change of sign across different kernels. In addition, an analysis of the

correlation matrix of the neighborhood level dependance matrix showed notable changes in the *energy, entropy, gray level variance, and gray level non-uniform norm*. The correction of this batch effect by Combat resulted in kernel patterns disappearing after the application of the Combat correction on the ASIRs and the standard kernel. However, on the bone kernel and the lung kernel, Combat produced less improvement. Moreover, as shown in Figure 1, the application of the Combat correction methods to the kernel-related batch effects significantly improved the number of robust features from *13.7% to 73.2%*, where the first order statistics were still the most robust *(improvement from 22.72% to 81.82%)* and the size zone matrix features and the neighborhood gray level features were less robust.

4. Discussion

In this study, we have identified 40 features to be robust to CT image reconstruction kernels. The kernel batch effect affects the concordance and the correlation between the features in the same class. The application of Combat significantly improves the proportion of robust features. However, visual inspection reveals that its performance.

its performance is better when applied to ASIR, ASIRV and standard kernels, while bone and lung kernel harmonization still needs improvement.

The ability of Combat to improve the robustness of features has already been discussed and demonstrated in previous studies [12, 20, 21].

Evaluation of the robust features before correction revealed that the centrale tendance parameters were robust to the type of kernel. This robustness suggests that the batch effect does not significantly influence the centrale tendance and the global dispersion, although the dispersion parameters and skewness were changing. These measures detect variations in the shape of the distribution, suggesting changes in dispersion and symmetry of the intensity distribution between batches. Moreover, this contrast between the centrale tendance parameters and the dispersion and shape parameters highlight a non-linear and non-constant batch effect, with specific impact on certain regions of the image. This finding is consistent with the process of radiomics. In the processing, it is the voxels and the texture of an image that are affected by the batch effect not the extracted features directly.

Radiomics compared to some omics, extract features to characterize different aspect of an image. Generating then features that are mathematically related. However, most batch effect harmonization methods apply a form of feature-wise correction. Moreover, the batch effect takes a nonlinear and non-constant form. In this environment, the application of a linear or a constant correction model may overcorrect and unintentionally remove relevant radiomic features.

One of the main limitations of this study is the exclusive use of phantom data, as the findings must be validated in independent human datasets. In addition, the data analyzed in this study was extracted from a single scanner.

Future directions include the validation of these findings in a patient dataset and further exploration of the non-robust and robust feature sets.

5 Conclusion

In this study, we found that ASIRs and ASIRV were most similar to the standard kernel, while bone and lung kernels were dissimilar. Almost 14% of the features were robust to image reconstruction- kernel batch effects. This batch effect conserved the global voxel intensity distributions and the texture related distributions, while primarily affecting the dispersion parameters. From this pattern, we suggest a nonlinear and non-constant kernel batch effect model.

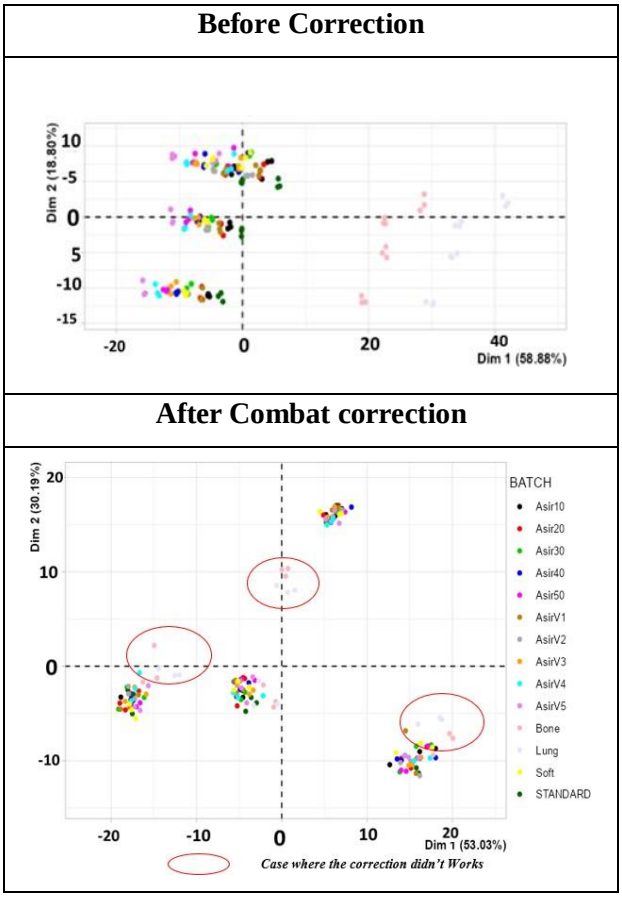

Figure 1: Principal components analysis before and after batch correction.

Table 1: Robust features before and after Combat

	ASIR					ASIRV				
	10	20	30	40	50	1	2	3	4	5
Before Combat	151	127	113	97	77	117	97	81	73	65
After combat	227	226	238	253	249	238	238	242	251	248

Abstract An estimated 20% of stereotactic radiosurgery (SRS) patients relapse and experience tumour progression (TP) within 6 months of treatment. SRS patients may also be afflicted by radionecrosis (RN), a radiation-induced tissue injury virtually indistinguishable from TP via routine treatment follow-up scans. Invasive histopathology remains the only "gold-standard" TP/RN diagnostic method: non-invasive image-based protocols are urgently required to stratify patients while minimizing harm. Our study proposes leveraging FLT-PET/MR to achieve a superior diagnostic accuracy versus historical image-based protocols. Preliminary results suggest that the dynamic FLT-PET modelling-derived kinetic parameters Ki and Pf, as well as 10 MR-derived radiomic features, can significantly distinguish TP from RN. However, an increased sample number is required to confirm the generalizability of these findings. Our study underscores the potential of FLT-PET/MR in classifying metastatic brain lesions and suggest a path towards non-invasive diagnostic protocols to enhance patient stratification and favour outcomes in brain metastasis patients post-SRS.

1 Introduction

Despite excellent local control of brain metastases by the means of stereotactic radiosurgery (SRS), an estimated 20% of patients relapse within 6-months post-treatment[1]. Intracranial metastatic tumour progression (TP) is currently associated with a dismal overall survival rate of 8.1% at 24 months[2]. TP can be diagnosed by a combination of medical image-based diagnostic tools and behavioural tests, with patients exhibiting neurological symptoms including headaches, seizures and somnolence[3,4]. Conversely, patients exhibiting these symptoms may instead be afflicted by radionecrosis (RN), a necrotic tissue breakdown within the treatment region-of-interest (ROI) resulting from radiation exposure. RN is typically symptomatically indistinct from TP and is usually confined to the lesion treatment ROI, yet may appear in any irradiated region of the brain[5]. RN has been reported to affect up to 24% of radiosurgery patients[6]. Although the incidence of RN has been loosely correlated to the use of immunotherapy alongside SRS, there are no confirmed risk factors that may be employed as a predictor for susceptibility to RN[7]. Radionecrotic lesions are virtually indistinguishable from tumour progression when visualized using routine medical imaging, further complicating diagnosis[8]. Proper patient stratification is key in achieving positive treatment outcomes for cases of TP or RN, as either condition requires a significantly distinct regimen within which effective treatment options are available[9,10]. Currently, invasive histopathology remains the only "gold-standard" method of TP/RN differentiation[11]. The adoption of image-based diagnostic protocols with reduced harm has been hampered by poor diagnostic performance, with historical TP/RN differentiation efficacy lying at a modest 54%[12]. Thus, there is an urgent need for a strong non-invasive diagnostic protocol for TP/RN differentiation to improve patient stratification while minimizing harm. We propose leveraging a hybrid imaging platform, consisting of 18F-Fluorothymidine positron emission tomography (FLT-PET) to achieve improved diagnostic performance. FLT, a radiolabeled nucleotide precursor, functions as a non-invasive biomarker permitting the quantification of cellular proliferation, correlating strongly with the immunohistochemical proliferation marker Ki-67[13]. Additionally, we employ co-acquired anatomical magnetic resonance (MR) data from which radiomic features have been extracted to achieve a complimentary classification method. Radiomics permit the retrieval of quantitative metrics from medical images to be used as distinctive and informative features for tumor characterization[14]. Our study utilizes FLT-PET data fitted to compartmental models of tracer exchange alongside radiomics features extracted from co-acquired MR sequences with the aim of devising a protocol capable of achieving ≥80% diagnostic accuracy/sensitivity/specificity across all implemented classification methods.

2 Materials and Methods

To date, 8 adult patients with confirmed TP or RN have been enrolled in the context of a research ethics board-approved clinical study. Inclusion criteria for this study consist of a minimum age of 18 years old, a confirmed single or multiple brain metastasis diagnosis post-SRS treatment and a planned surgical resection. Lesion samples were collected from all enrolled patients during surgery, allowing histopathological confirmation of TP/RN. All patient datasets were co-acquired within the same session using the SIEMENS mMR Biograph hybrid PET/MR imaging platform (SIEMENS Healthineers, Erlangen, Germany). 18F-Fluorothymidine (FLT) was employed as a radiotracer with approval for experimental use, being produced jointly by the Centre for Probe Development and Commercialization (Hamilton, Canada) and CanProbe (Toronto, Canada). Patients were imaged immediately post-injection (p.i.) and surveyed over 20 minutes p.i. in a single bed position. Two PET datasets were acquired per patient:

a multi-timepoint dynamic PET (dPET) acquisition captured over the course of the entire imaging session in increasing intervals as well as a standard static PET acquisition at a 20 min p.i. (final timepoint). Attenuation-corrected PET datasets were analyzed using the PMOD software suite v.4.303 (PMOD Technologies LLC, Fällanden, Switzerland). PET datasets were registered to t2-weighted MR datasets to assist lesion contouring, using Normalized Mattes' Mutual Information as a cost metric. Volumes of interest (VOIs) were created on dPET data to match patient lesion contours available on planning t1-weighted MR datasets, with thresholding applied to lesion VOIs to reduce data outliers resulting from machine noise at early acquisition timepoints. Time-activity curves (TACs) describing lesion FLT uptake were generated from dPET data within the ROI and fitted to compartmental models. Arterial input functions were determined using an image-based method, via the creation of TACs from VOIs encompassing the common carotid artery. Lesion VOI uptake data were fitted to irreversible and reversible two-compartment models in the PMOD PKIN module. Kinetic parameters (K1, k2, k3 and k4) were derived from the best fitting model, determined via comparison of the Akaike Information Criterion. Additional kinetic parameters were calculated from the parameters obtained directly from modelling: influx rate (Ki), volume of distribution (Vd) and phosphorylation fraction (Pf) were inferred according to the following formulae:

$$Ki = \frac{K_1 \times k_3}{k_2 + k_3}$$

$$Vd = \frac{K_1}{k_2 + k_3}$$

$$Pf = \frac{k_3}{k_2 + k_3}$$

Kinetic parameters extracted from dPET modelling were subjected to analysis via the Pearson Correlation Coefficient to assess correlations between parameter values and histopathological ground truth lesion states.

Lesion contouring was performed anatomical MR sequences (t1w or t2w) used to plan radiotherapy treatment by a clinician with three years experience. All complimentary MR datasets were converted to Nearly Raster Raw Data format for integration into the Python 3 Simple ITK (sITK) open-source image analysis platform. Within sITK, complimentary MR datasets were resampled to align with the voxel spacings of the target planning image on a per-patient basis. All complimentary MR datasets were registered to the planning image to permit direct transposition of planning contours on co-acquired MR sequences. Three-dimensional rigid registration was achieved by maximization of Mutual Information using gradient descent optimization. Registered MR datasets were directly integrated into PyRadiomics, an open source radiomic feature extraction package. A comprehensive set of 107 radiomic features were extracted per dataset, forming a database of statistically mineable elements. Extracted radiomic features include spatially independent voxel intensity characteristics, referred to as first-order features, as well as spatially-correlative characteristics derived from computed gray-level matrices, referred to as higher-order features. Computed gray level matrices include gray-level co-occurrence matrices (GLCM), gray-level run-length matrices (GLCM), gray level size zone matrices (GLSZM), neighboring gray tone difference matrices (NGTDM) and gray level dependence matrices (GLDM). To improve computational efficiency, prevent range or scale-induced feature importance skewing and favour parameter interpretability, extracted radiomics data were normalized per-feature to a fixed range of [-1, 1]. Subsequently, a one-way ANOVA analysis was performed on each extracted radiomic feature with respect to the ground truth patient condition (TP/RN). The top 10 most correlative radiomic features were identified through inverse sorting of all collected ANOVA f-scores, with strict adherence to a predetermined two-tailed significance threshold.

3 Results

The FLT-dPET derived kinetic parameters Ki and Pf suggest that dPET analysis can distinguish TP from RN in post-SRS lesions significantly (0.063±0.043 and 0.304±0.204 versus 0.002±0.0 and 0.004±0.001 respectively, $p < 0.05$), whereas RN cannot be separated from background FLT uptake in healthy tissues ($p > 0.05$).

Table 1: Kinetic parameters obtained from dynamic PET data fitting to both reversible (2TK4) and irreversible (2TK3) two-compartment models describing tracer distribution within target lesion ROIs. Model fitting performed on patients (p#) harbouring lesions with confirmed tumour progression (TP, n = 7), confirmed radionecrosis (RN, n = 1) as well as a healthy contralateral brain tissue control (Hlthy, n = 1).

Features were extracted from six out of eight patients within the study cohort; patient 1 was excluded owing to data unavailability, and patient 5 was excluded due to substantial artefacts within the dataset. One-way ANOVA analysis of radiomic datasets extracted from registered t2-weighted SPACE sequence images resulted in 10 significant features capable of differentiating TP from RN ($p < 0.05$). A

maximum f-score of 185.06 was produced by the NGTDM-extracted texture complexity feature.

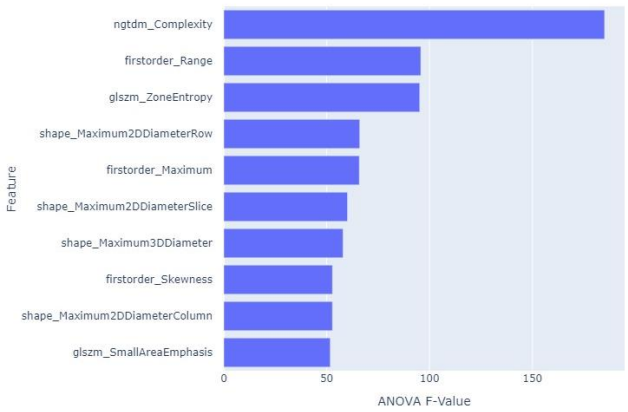

Figure 1: Top 10 significant radiomic features extracted from t2w-SPACE sequence MR datasets for TP/RN differentiation. Radiomic extraction performed on raw input images as well as gray level matrices computed from input images.

To increase result confidence and to permit further classification of data, expanding patient accrual to achieve a larger sample size (n) is required.

4 Discussion

In the exploration of parameters for stratifying TP and RN, Ki and Pf emerge as the most distinctive factors. k2, while approaching significant differentiation, is not fully capable of discerning TP from RN, but may achieve improved differentiation once an increased sample size is processed. Conversely, Vd, K1, and k3 show limited effectiveness in separating TP/RN cases. The absence of k4 in certain models renders it non-evaluable for TP/RN differentiation. Kinetically, FLT can operate reversibly within the tumour compartment, which theoretically warrants the use of a reversible model representing radiotracer de-phosphorylation (k4) across all cases[15]. Most FLT-PET kinetic studies presented in the literature employ a 60-minute dynamic acquisition window at minimum; our study protocol is constrained to a 20-minute acquisition due to the inclusion of hybrid magnetic resonance (MR) imaging alongside PET acquisitions, resulting in a requirement to reduce overall inter-modality and inter-sequence scan time to balance data depth with patient comfort. The use of a relatively short dPET acquisition time prevents cases with intrinsically slower tracer kinetics from achieving a full steady state, where the reverse step towards equilibrium is insufficiently captured. As a result, the value of k4 becomes negligible in select cases, allowing for the application of an irreversible model that excludes k4. While FLT may excel in distinguishing tumour recurrence extent in TP or mixed pathology cases, modelling radionecrosis proves challenging due to contouring requirements; while lesions composed mainly of TP are easily distinguishable from background signal, lesions containing primarily RN cannot be visually separated from healthy brain. FLT-PET remains a powerful diagnostic tool yet must be supplemented by MR scans to permit contouring and favour diagnosis, amending well to hybrid imaging platforms such as PET/MR. Overall, FLT-PET favours diagnosis of tumorigenic tissues presenting high radiotracer uptake, and lesions without specific FLT uptake and thus indifferentiable from background signal can be reasonably assumed to be radionecrotic on this platform.

Of the radiomic features extracted from the dataset, NGTDM-computed complexity was the most distinctive factor in differentiating TP from RN when considering the entire contoured region, followed by voxel intensity range and GLSZM-computed zone entropy. The top feature selected, NGTM complexity, alludes to a significant difference in the presence of specific irregular voxel intensity patterns between lesions harbouring TP versus RN. Notably, the top three features selected, as well as six out of the top ten features presented, do not directly relate to physical measurements or geometric characteristics of the lesion, aligning with challenges experienced by physicians in visually distinguishing TP/RN from geometric features on anatomical MR alone. Conversely, our results indicate that intensity-based features, which capture voxel values across various areas within the lesion, may harbor concealed higher-order information that could prove valuable in the differentiation of TP from RN. Utilizing these higher-order features, automated lesion classification may be feasible, facilitated by platforms such as machine learning or deep learning AI algorithms.

5 Conclusion

Our study examines the effectiveness of FLT-PET in categorizing metastatic brain lesions following stereotactic radiosurgery (SRS). While FLT-PET demonstrates high accuracy in identifying lesions primarily consisting of progressing tumors, it exhibits lower sensitivity in detecting radionecrotic areas, highlighting the necessity to incorporate data from additional imaging modalities to permit an accurate diagnosis of the condition of each lesion. Ultimately, the presented findings constitute a preliminary outlook at the proposed hybrid imaging protocol, as the current sample count is too small to draw significant conclusions regarding the true performance of the underlined imaging and data mining techniques. By increasing patient accrual and ultimately implementing machine learning and deep learning data classification methods within our protocol, we aim to advise future development of non-invasive diagnostic protocols for accurate differentiation of TP and RN; such advancements can potentially enhance patient outcomes through improved stratification of individuals post-SRS.

Abstract: Current approaches for dose optimization of proton arc therapy (PAT) plans suffer from optimization times ranging from several minutes to hours. In the context of adaptive proton therapy, we aim to speed up the plan reoptimization process. To achieve this, instead of optimizing a new PAT plan from scratch for each adaptive fraction, we propose to update the initial spot positions and their corresponding energies to the new anatomy of the day. Following this, we proceed to re-optimize only the most pertinent spot weights (less than 50% of all the spots). This results in less parameters to tune and thus in an accelerated plan adaption.

1 Introduction

Proton arc therapy (PAT) is an emerging modality that aims at delivering a continuously rotating proton beam around the patient, in opposition to the classical intensity modulated proton therapy (IMPT) which delivers beams on fixed angles. Consequently, PAT theoretically beneficiates of more degree of freedom than IMPT and has thus the potential to achieve better dose distribution. However, the problem of determining optimal energy layers for each angle is not trivial since it is necessary to minimize the treatment time (energy switch-ups are much slower than energy switch-downs for most of the proton installations), while at the same time, ensuring optimal dosimetric objectives [1]. This has given rise to several optimization approaches for PAT energy layers [1-5]. While approaching the problem from different perspectives, these methods suffer from optimization times ranging from several minutes to hours. In the context of adaptive proton therapy, we aim to speed up the plan reoptimization process. Instead of creating a new plan for each fraction, we propose updating spot positions and energies based on the daily anatomy. Following this, we then proceed to select only the most relevant spots to be re-optimized on this new anatomy, resulting in less parameters to tune and thus in an accelerated plan adaption. This follows an approach similar to what has been done by Botas et al. for IMPT using a different spot selection criteria [6].

2 Materials and Methods

The study has been retrospectively conducted on 3 head and neck patients who initially underwent a plan adaptation on a repeated CT acquired several days after the start of their treatment due to major anatomical changes. Local ethics committee approval by the CEHF (Comité d'Ethique hospitalo-facultaire) was obtained for the use of all patient data under the agreement "Learning from the past: the MIRO treatment planning database".

PAT plans were generated for the initial and repeated CT. Plans on repeated CT were generated in two different ways: classical, where a new PAT plan was optimized from scratch; and fast-adapted where the adapted plans resulted from re-optimization of a part of the initial spots that were displaced according to the new anatomy described below. Each plan featured a single 360-degree arc. Energy layers were defined with the ELSA algorithm [4] integrated in the RayStation treatment planning system (Raysearch Laboratories).

The fast-adaption method consists in the following steps:

1) Displace the initial spots on the new patient anatomy according a deformation vector field obtained by registering the initial CT on the repeated CT.
2) Update the energy of displaced spots according the new patient anatomy. Note that here the PAT energy layer pattern is constrained to be conserved i.e., energy switch-downs and switch-ups with respect to irradiation angles are preserved (see Figure 1).

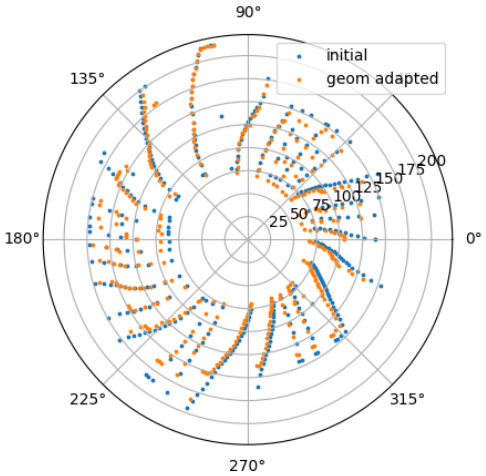

Figure 1: Example of polar plot for PAT energy layer pattern adaption (initially determined with ELSA here). Blue points denote the initial energy layers for each irradiation angle. Orange points denote the adapted energy layer while ensuring the initial PAT pattern. The angular position denotes the angle of irradiation while the radial position denotes the energy of the layer.

3) Select the most relevant spots for the re-optimization. The relevance criterion is defined by $\frac{\partial F_{obj}}{\partial w} > t$ where F_{obj} is the objective function of the optimization problem, w is the vector of spots weights and t is an arbitrary chosen threshold.
4) Continue the spot-weight optimization on the new anatomy only with the selected spots (the non-selected spots keep their dose contribution but their weights are not updated).

Planning of the different PAT plans as well as implementation of the fast adaption method was done on an open-source Python treatment planning system (TPS) [7].

Robust optimization was used for all cases with a range error of 2% and a setup error of [4.0,4.0,4.0] mm following a worst-case optimization approach. The robust constraints concerned the max and min dose to the CTV_p and CTV_n as well as the max dose to the spinal cord.

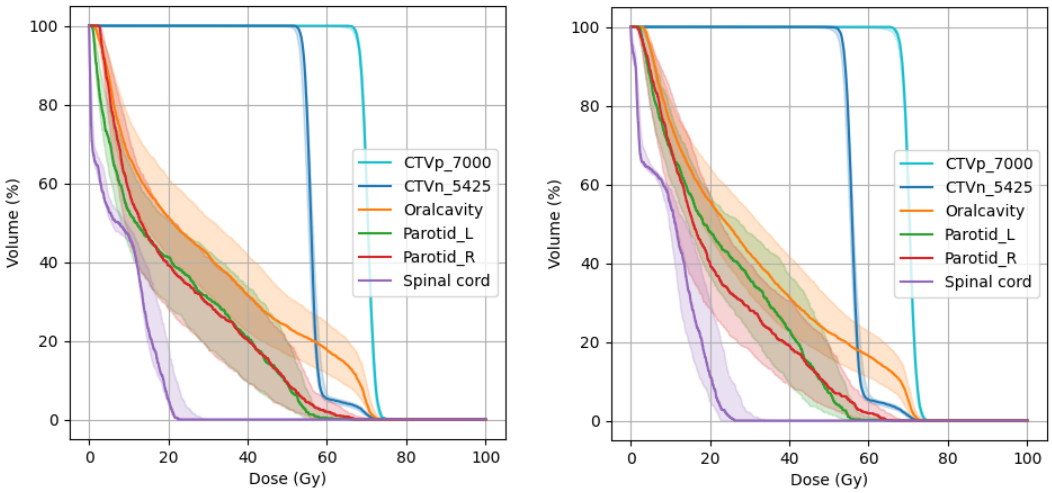

Figure 3: DVH for robust scenario of patient_1. Right: classical optimization; Left: fast-adaption

Concerning the optimization constraints, contraints from initial plan were re-used for the plan adaption. Comparison were thus done for both approaches (classical and fast-adaption) using these initial constraints.

3 Results

Early results show very similar dose distributions of fast adapted plan compared to classical optimization, e.g., no more than 2.44Gy difference to spinal cord max dose, 0.30Gy to CTV_n D95% or 0.55Gy to CTV_p D95%. Figure 1 illustrates this for the nominal case of patient_1. A similar trend for robust scenarios is observed and illustrated in Figure 2. Notice the respect of the robust constraints for every scenario in both plan optimization approaches.

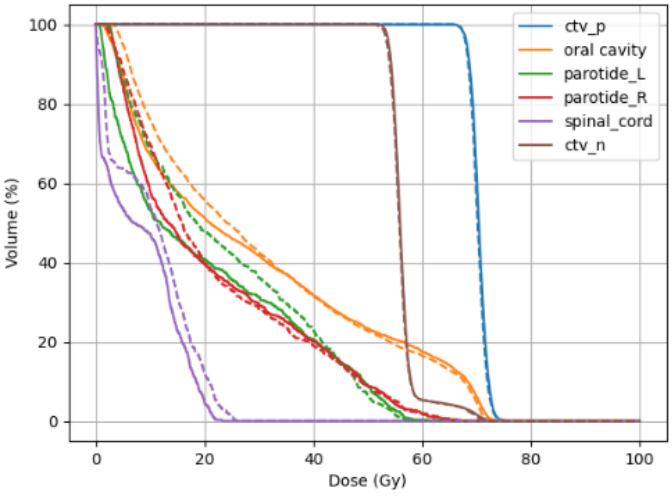

Figure 2: example of dose-volume histogram for PAT plan of patient_1. Solid lines represent the classical optimization. Dashed lines represent the fast-adaption.

Concerning the spots selection, currently the fast-adaption approach leads to re-optimizing less than 50% of them. This represents an acceleration of the optimization time from 3.5 to 5 times compared to the classical optimization.

4 Discussion

The goal of this study was to demonstrate the efficiency of our proposed fast-adaption method for PAT plan. We compared it to plan re-optimization fully from scratch. Results showed similar dose distribution achieved when comparing the two different optimization methods. Concerning the optimization time, limiting the number of spots to be re-optimized, substantially decreased the necessary time of optimization. However, future investigations should evaluate the results on a larger database to increase the confidence in the proposed method.

Besides, future investigations could include other energy layer determination approaches as their energy-angle pattern might drastically change from the ELSA one.

Finally, another interesting point would be to confront our method with other methods that have proven their value on IMPT, e.g., those based on analytical algorithm [8], those dose restoration-based [9], … on PAT plans in order to clearly highlight the strengths and weaknesses of each.

5 Conclusion

The proposed method successfully reduced the optimization time for PAT plan adaptation while achieving similar dose distribution showing that PAT could also beneficiate of faster plan adaption.

[3]The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Joint Department of Physics, London, United Kingdom.

Abstract Intensity Modulated Proton Therapy (IMPT) is susceptible to uncertainties in patient setup and proton range. Robust optimization is therefore employed in IMPT treatment planning to ensure sufficient coverage of the Clinical Target Volume (CTV) in predefined scenarios, albeit at a price of significantly increased planning times.
We investigated three Deep Learning (DL) strategies for dose predictions in all separate robustness scenarios for the chosen robustness settings in head-and-neck (H&N) cancer robust IMPT treatment planning: 1) a separate prediction model per scenario, 2) a separate model per scenario, but using transfer learning, and 3) an integrated single model for all scenarios.
We introduced scenario specific isocenteric distance maps as input to the models, to cope with resolution differences in the planning Computer Tomography (CT) scans and to account for different setup error scenarios.
For 392 H&N cancer patients, high-quality 9-scenario ground truth (GT) robust plans were fully automatically and consistently generated with wish-list driven Multi Criteria Optimization (MCO).
DL strategy 3, using a single prediction model for all scenarios, acheived best correspondence to the GT plans, with the predicted $V_{95\%}$ of the voxelwise minimum dose (VWmin) for the low dose CTV, within 1%-point of agreement with the GT for 91% of the test patients, compared to only 8% and 56% for strategies 1 and 2 respectively. For the high dose CTV, the within 1%-point agreements were 80%, 20% and 0% for strategies 3, 2 and 1 respectively.
With the current implementation (for 9 robustness scenarios), an IMPT dose distribution can be generated and assessed on robustness in under one minute.

1 Introduction

Intensity-modulated proton therapy (IMPT) enables highly conformal tumor coverage with improved sparing of adjacent normal tissues compared to photon therapy. IMPT is considered particularly beneficial for cancers of the head and neck (H&N) due to many organs at risk (OARs) involved and their proximity to the target volumes. However, IMPT is susceptible to uncertainties that arise from inter-fractional variations (e.g. patient setup) and proton range uncertainty [1].
Robust (worst-case) optimization is commonly used in IMPT treatment planning to obtain adequate Clinical Target Volume (CTV) coverage and limit high doses to OARs in a set of predefined scenarios [2–5]. However, robust optimization comes with the cost of extended planning time [6].
Deep learning (DL) models have been proposed recently to alleviate the problem of long planning times. Although DL has demonstrated to be capable of predicting realistic dose distributions in the order of seconds, published studies on using it in the context of IMPT plan robustness evaluations have limitations [7, 8].
In [7], DL is used to predict scenario dose distributions, but further dose mimicking is required to make the overall plan robust. In another study [8], DL is used to predict only the nominal scenario dose of a robust plan, and dose mimicking is employed to obtain a robust plan, considering all robustness scenarios.
In this study, we investigated three strategies that use DL for direct dose prediction in all separate scenarios for the chosen robustness settings in H&N cancer robust IMPT treatment planning: 1) a naive approach, training a separate model for each scenario individually, 2) a model for each scenario similar to strategy 1, but using transfer learning to speed-up the training, and 3) an integrated single model where labels were used to predict the dose for each specific scenario.
Scenario-specific distance maps with voxel distances to the isocenter were used as input for the prediction model(s) for all three strategies, playing a pivotal role in augmenting a model's capacity to incorporate setup error scenarios in the context of patients with various Computer Tomography (CT)-scan resolutions.

2 Materials and Methods

2.1 Data preparation

The dataset included contoured planning CT-scans of 392 H&N cancer patients with a variety of tumor locations. All patients were fully automatically robustly planned using Erasmus-iCycle for wish-list driven Multi Criteria Optimization (MCO) [9, 10], resulting in high-quality plans with consistent trade-offs. Nine scenarios were used for the robust planning: nominal scenario (no errors), 2 range errors (RE) scenarios (+3%/-3%) and 6 setup errors (SE) scenarios (+3/-3 mm) in the three directions X, Y & Z. Prescribed doses were 70 Gray equivalent (GyE) and 54.25 GyE for the high dose CTV and low dose CTV, respectively. For all patients, the clinical contours for both CTVs and OARs were used.
After the plan generation, the resulting dose distributions for all patients and all scenarios were stored as the ground truth (GT) for models training and evaluation. Before training

the models and as a preprocessing step, the Digital Imaging and Communications in Medicine (DICOM) files of the CT, Radiotherapy (RT) structure sets and the 9 scenario doses were converted into a voxelized version and downsampled to a grid size of 256 x 256 x 128 voxels. To determine the bounding box of the patients, a composite patient was constructed by overlaying all patients. This resulted in a voxel size of 1.8 x 1.3 mm^2 in XY (right-left and anterior-posterior) direction, and 2 or 2.5 mm in the Z direction, which was left unscaled to avoid large resampling artifacts. We introduced the isocentric distance map to handle patient-dependent Z resolution, see section 2.2.
Furthermore, the contoured targets, OARs and the patient external were converted into 3D binary masks, in which each patient voxel was set to 1 if the voxel was inside and 0 otherwise. The result of the data preparation process consisted of 10 binary masks for the structures (2 CTVs, 7 OARs and the patient external), 1 CT image, and the 9 scenario dose distributions. The CT and the binary masks were used as inputs for all of the prediction models.

2.2 DL strategies for scenario specific dose prediction

A naive way to predict robustness scenarios dose distributions is to train a DL model for each scenario independently (strategy 1) . The limitation of this approach is long computation times for both training of each model and for predictions.
An option to overcome this limitation, is to use transfer learning (strategy 2) in which we use the model trained to predict the nominal scenario dose distribution as a pretrained model and fine-tune it to predict the scenarios dose distributions, training again a model for each scenario. It would reduce the training times that would be required to train the models for the other scenarios from scratch.
As a third option (strategy 3), all scenarios were trained within one model, with a one-hot-vector (label) [11] added to explicitly indicate an individual scenario. The label represents the scenario index (in our case from 0-8). An embedding vector for the scenario index was produced using a learnable embedding layer. The label was used to steer the model towards the desired scenario dose distribution to be predicted.
The isocentric distance map was calculated by determining the Euclidean distance between the voxel at the isocenter and every voxel contained within the patient contour. The distance maps were provided as input to the models to introduce the isocenter information and handle different Z resolutions. For all strategies, the isocentric distance map was shifted according to the setup error scenario, i.e. the isocenter and thus the isocentric distance map was shifted +3/-3 mm in the respective directions. For the range uncertainty, the isocentric distance map was kept at the nominal scenario, but the HU of the CT is scaled with +3%/-3%. This approach mirrors the methodology employed in dose calculation engines, where simulation of SE scenarios involves deflecting beam directions and scaling the Hounsfield unit (HU) (or stopping power ratios) of the CT to compute doses for RE scenarios.

2.3 Experimental Setup

The dataset of 392 H&N patients was divided into training (283), validation (31) and test (78) sets. All models were based on the Hierarchical Dense (HD) UNet [12, 13]. Except for strategy 3, which used a label for each scenario passed to the decoding path of the HD-UNet, the inputs were the same for all strategies: the CT, the binary structure masks and the isocenter distance map for each patient.
To improve the training convergence, isocenter distance maps were normalized by 300 mm, the HU of the CT were clipped using a window of $[-1000, 1500]$ [14] and normalized by 1000, and the dose distributions were also normalized by the prescribed dose for CTV High (70 GyE).
All the experiments were done on a single NVIDIA A100 TensorCore 80 GB GPU. We used the Adam optimizer [15] with learning rate 10^{-4} with a batch size 1, and the voxelwise mean square error as a loss function. After every 10 epochs of stagnation and no improvement in the loss over the validation data, the learning rate is reduced by a factor of $\frac{3}{4}$.
For the transfer learning in strategy 2, in scenario models training we used the final state of the optimizer of the nominal model as the starting point of the optimizer for all scenario models, the last learning rate used in the last training epoch of the nominal model was used as the initial rate in the scenario models, to only allow fine-tuning of the model weights.
For training the single model (strategy 3) we randomly sampled a patient from the training set and a scenario each time.
Dose metrics for predicted target and OAR doses were computed and compared with the GT. For robustness evaluations VWmin and VWmax dose distributions were constructed from the 9 predicted dose distributions. The CTVs were evaluated on VWmin $V_{95\%}$ and VWmax near maximum $D_{0.03cc}$. Also robustly optimized OARs (brainstem and spinal cord) were evaluated on VWmax $D_{0.03cc}$. Statistical significance was tested using the Wilcoxon signed rank test with $p < 0.05$ as threshold for significance.

3 Results

Figure 1 shows for the 78 test patients, differences in predicted and GT VWmin and VWmax dose distributions. All strategies show high accuracy CTV coverage prediction, but strategy 3 clearly outperformed the other 2 (two upper panels in Fig. 1). For CTV Low, percentages of predicted plans with VWmin $V_{95\%}$ within 1%-point of the GT were 91% for strategy 3, compared to 8% and 56% for strategies 1 and 2, respectively. For CTV High, these percentages were 80%, 0% and 20%, respectively. Strategies 1 and 2 performed slightly better for VWmax $D_{0.03cc}$ of CTV High, while OAR

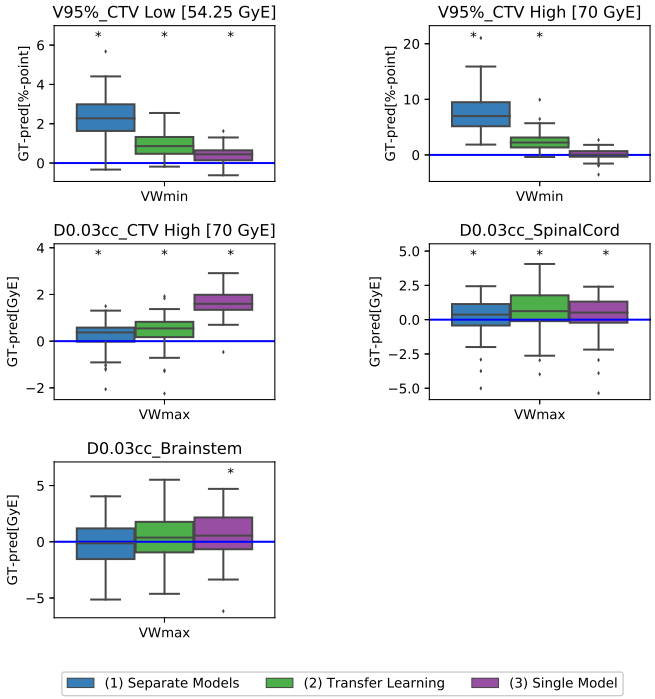

Figure 1: For the 78 test patients, pairwise differences between in dosimetric parameter values of voxelwise min or max dose distributions of predicted and GT plans. * = significantly different ($p < 0.05$).

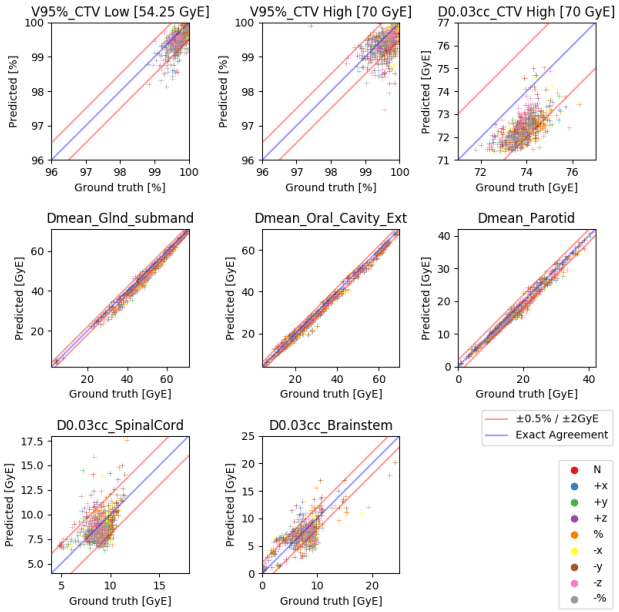

Figure 2: Predicted vs ground truth doses metrics for DL strategy 3. Each marker represents a predicted dose parameter with the corresponding ground truth value. Marker colours refer to investigated scenarios.

doses were highly similar. Figure 2 shows for the test patients excellent agreement between plan parameters of the individual scenario doses predicted with strategy 3 and GT parameters.

Strategy 3 was most efficient in terms of calculation times. Training times for strategies 1, 2 and 3 were 51, 24, and 16 hours respectively. Models loading times prior to predictions were 21.55 seconds for 1 and 2 and 3.85 seconds for loading the single model in 3. Average prediction times per scenario were 1.17 for 1 and 2 and 1.14 seconds for 3.

4 Discussion & Conclusion

Strategy 3, using a single DL model for predicting dose in all separate IMPT robustness scenarios with scenario labels as input, showed overall closest agreement between predicted doses and GT, outperforming the results of the other two investigated prediction strategies, in particular for target coverages. Only near-maximum doses were slightly underestimated. Given the complexity of the H&N treatment site and the limited training set size of 283 cases, it is expected that results will improve with increasing dataset size.

Strategy 3 was also most efficient in calculation times with training times of 16 hours (instead of 51 and 24 hours for strategies 1 and 2 respectively). For individual patients, the model loading time for the prediction of the scenario doses of a patient with strategy 3 was 3.85 seconds and prediction took on average 1.14 seconds per scenario, which results in a prediction time of 14 seconds for all scenarios. For both strategies 1 and 2, the overall prediction time is 32 seconds, as each scenario requires loading a new model to the GPU memory. Both in training time and robust prediction time, strategy 3 also has the best potential to scale up to larger numbers of scenarios, such as 21 or 29 as commonly used in IMPT. In the 21 scenario case, the overall prediction time would increase to 75 seconds for strategies 1 and 2 in contrast to 28 seconds for strategy 3.

Inverse robustness to control uncertainties in the RBE parameter in proton therapy planning

Mara Schubert[1]

[1]Department of Optimization, Fraunhofer Institute for Industrial Mathematics, Kaiserslautern, Germany

Abstract The relative biological effectiveness (RBE) of protons in comparison to photons depends on many factors. However, no highly accurate RBE model exists for varied cases that could be applied in treatment planning. Instead, in practice a constant RBE factor of 1.1 is used. Consequently, the effect of proton radiation might be over- or underestimated.

Here we introduce an inverse robustness model to maximize robustness of plans with respect to variations in the RBE parameter, without relying on a specific RBE model. Moreover, there is no need to specify a robustness measure beforehand. Importantly, our approach does not require a predefined robustness measure but instead focuses on maximizing the range of RBE values a plan can accommodate while ensuring that dose objectives remain within a predifined range.

We applied this concept to a prostate and a head and neck case. Our results show that it is possible to slightly shift the dose distribution to gain robustness against deviation from 1.1 in the RBE parameter for some structures, without significantly altering the overall treatment plan. Other structures demonstrated less robustness against variations in RBE.

Therefore, the outcomes of inverse robust optimization can be used to assess the robustness of a treatment plan against RBE variations or to identify structures that might need additional preventive measures.

1 Introduction

The biological effect of a given physical dose varies depending on the type of radiation. It is well-known that the relative biological effectiveness (RBE) of protons compared to photons is not constant but depended on factors such as dose, linear energy transfer (LET), and tissue parameters [1]. However, there are significant differences among various RBE models, and the uncertainty in tissue parameters further complicates the matter [2]. As a result, in clinical proton therapy planning, a constant RBE parameter of 1.1 is used, assuming that protons are 10% more effective than photons. Considering the uncertainties in the RBE is crucial when assessing the robustness of a treatment plan, as the actual RBE determines the effects of the radiation.

Many robustness concepts require to previously decide on the scenarios a plan should cover. The lack of a generally accepted model for the RBE parameter makes this difficult.

The concept of inverse robustness, as introduced in [3], does not require the a priori definition of an uncertainty set. Instead, it identifies the largest uncertainty set that can be accommodated when treating an uncertainty parameter as variable rather than fixed at a constant nominal value.

We applied this concept to the proton therapy planning problem with the RBE factor as uncertainty parameter. The aim is to find a treatment plan that is nearly as good as the treatment plan calculated with the nominal RBE value of 1.1, yet maximizes the measure of the set of acceptable RBE values. Hence, it enables treatment planners to find the plan that is the most robust with regards to variations in the RBE parameter and meets the dose objectives nearly as good as a conventionally chosen plan. The results then allow an evaluation whether the range of covered RBE values is sufficiently broad or if there is a need to find a different plan with better coverage or use further methods to limit the expected RBE variations to the interval covered by robustness.

2 Materials and Methods

2.1 Proton Therapy Optimization Framework

A typical proton therapy planning problem has the following structure:

$$\begin{aligned} \min_{x\in X} \quad & F_{\bar{r}}(x) = (f^1_{\bar{r}}(x), ..., f^n_{\bar{r}}(x)) \\ s.t. \quad & g^j_{\bar{r}}(x) \leq 0 \qquad \forall j \in \{1, ..., m\}. \end{aligned} \tag{PPP}$$

X denotes the set of feasible treatment plans. $F_{\bar{r}}(x)$ is vector valued. The single objective functions $f^i_{\bar{r}}(x)$ and the constraints $g^j_{\bar{r}}(x)$ depend on the beamlet intensities x. The RBE factor r determines how the dose is weighted. It is a constant parameter with nominal value $\bar{r} = 1.1$. The solutions are the best compromises between the objectives, the so called Pareto points.

2.2 The Inverse Robustness Problem

Given a solution of (PPP), the aim of inverse robustness is to maximize the volume of the set in which the uncertainty parameter can be vary, without degenerating the previously found solution. To achieve this, we fix the objectives values of the plan in the constraints of the inverse robustness problem.

Here, we treat the RBE factor as the uncertainty parameter. We allow a different value for the RBE parameter in each structure s. We measure the volume of the uncertainty set by summing the lengths of intervals, leading to the following

a) dose evaluation functions	
gEUD	$\sum_{i\in S}(r_s(D\cdot x)_i)^p$
OD	$\sum_{i\in S}(r_s(D\cdot x)_i - d_{ref})_+^p$
UD	$\sum_{i\in S}(d_{ref} - r_s(D\cdot x)_i)_+^p$
b) with relevant interval boundary	
gEUD	$\sum_{i\in S}(b_s(D\cdot x)_i)^p$
OD	$\sum_{i\in S}(b_s(D\cdot x)_i - d_{ref})_+^p$
UD	$\sum_{i\in S}(d_{ref} - a_s(D\cdot x)_i)_+^p$

Table 1: The dose evaluation functions we used for our model: gEUD: generalized equivalent uniform dose, OD: overdose, UD: underdose. D refers to the dose influence matrix. The product $D\cdot x$ is the dose in each voxel. The exponent p is a positive integer and the expression $(y)_+$ means $\max\{0,y\}$.

formulation:

$$\begin{aligned} \sup_{\substack{x\in X,\ W\subseteq U,\\ W=[a_i,b_i]^s}} \quad & \sum_{s\in S} b_s - a_s \\ s.t. \quad & f^i(x,r_s) \le f^{*i} + \varepsilon^i \qquad \forall r_s \in W,\ \forall i \in \{1,...,n\} \\ & g^j(x,r_s) \le 0 \qquad\qquad \forall r_s \in W,\ \forall j \in \{1,...,m\} \\ & \bar{r} \in W. \end{aligned} \tag{IRP}$$

U is the feasible set of the interval boundaries for the RBE parameter. We defined $U = \{[a_1,b_1]\times ... \times [a_s,b_s] : t_1^i \le a_i \le 1.1 \le b_i \le t_2^i\ \forall i \in S\}$, where S is the index set of the structures and t_1 and t_2 are the thresholds for the lower and upper interval boundaries, respectively. The objective values of the treatment plan chosen from (PPP) are f^{*i}.

The following objectives to evaluate dose were considered: generalized equivalent uniform dose, overdose and underdose (Table 1 a)). All are monotonous in r_s. Consequently, the constraints of (IRP) are satisfied for all $r_s \in W$ if they are met at the critical interval boundaries for each function. Table 1 b) shows which interval boundaries to use.

The constraints still hold if the RBE parameter is not constant in a structure, but varies within the interval $[a_s,b_s]$. This allows our approach to cover variable RBE values without the need to rely on a model for variable RBE.

Clearly, if only one dose evaluation function belongs to a structure s, the corresponding interval for r_s reaches one of the predefined threshold for the interval boundary. It is advisable to set tight limits for these structures. Otherwise they might outweigh intervals of structures where relatively little variation is possible.

2.3 Case Study

We applied the concept to two cases from the CORT dataset [4]: A prostate case with four gantry angles at (60°, 120°, 240°, 300°) and a head and neck case with four gantry angles at (45°, 90°, 270°, 315°).

For the prostate case we calculated the largest possible range of RBE values without plan degeneration and with an allowed relative deviation of 5% for maximal possible intervals of $[1,2]$ in all structures. Subsequently, we narrowed the allowed interval for some structures, and lastly we maximized the RBE interval for the rectum, both at a relative deviation of 5%.

For the head and neck case we used relative deviations of 5% and 10% from the nominal treatment plan. We used two sets of structures where the RBE range was maximized: One with several structures of the treatment site and one where the focus lay on structures whose dose was controlled by objective function in (PPP), rather than just by the constraint functions.

MatRad [5] was used to calculate the dose influence matrices and create the heat maps of the dose distribution. The optimization of (PPP) and (IRP) were conducted using python.

3 Results

When adhering strictly to the original dose objectives, the solution of the inverse robustness problem relies completely on degrees of freedom in the dose distribution to maximize the possible intervals for the RBE parameters.

In the prostate case, the right and left femoral heads demonstrated robustness against RBE values as high as 1.57 and 1.63, respectively. For the other structures (Rectum, Bladder and planning target volumes (PTV)) no deviation from 1.1 was tolerable.

When increasing the permissible deviation from the treatment plan to 5%, both femoral heads were robust against RBE variations in the whole considered interval of $[1,2]$. The upper threshold for the PTV56 increases to 1.14 and for the whole body to 1.32. However, the covered interval for the rectum, bladder, and PTV68 remained unchanged.

By reducing the upper interval boundaries to 1.2, the tolerance for the RBE in the rectum increased to 1.11, and in the PTV56 to 1.19.

To explore the largest possible interval for the rectum at 5% deviation, we optimized only the interval length for the rectum. This resulted in an RBE interval for the rectum of $[1,1.15]$. Figure 1 shows the dose volume histograms (DVHs) and a heat map for each scenario. The DVHs are similar, whereas slight shifts in the dose distribution lead to plans that are more robust to variations in the RBE factor.

In [6] a method to analyze RBE was presented and applied to clinical data of prostate cases. Depending on the case type and fractionation, they obtained 95% confidence intervals all within $[1.045, 1.213]$. Although they mentioned that their analysis did not take all aspects into account that influence RBE, it gives an orientation about the range of the RBE parameter. The absolute difference of 0.168 observed in their study aligns with the range our results also cover for some structures.

As second example we analyzed a head and neck case. Set-

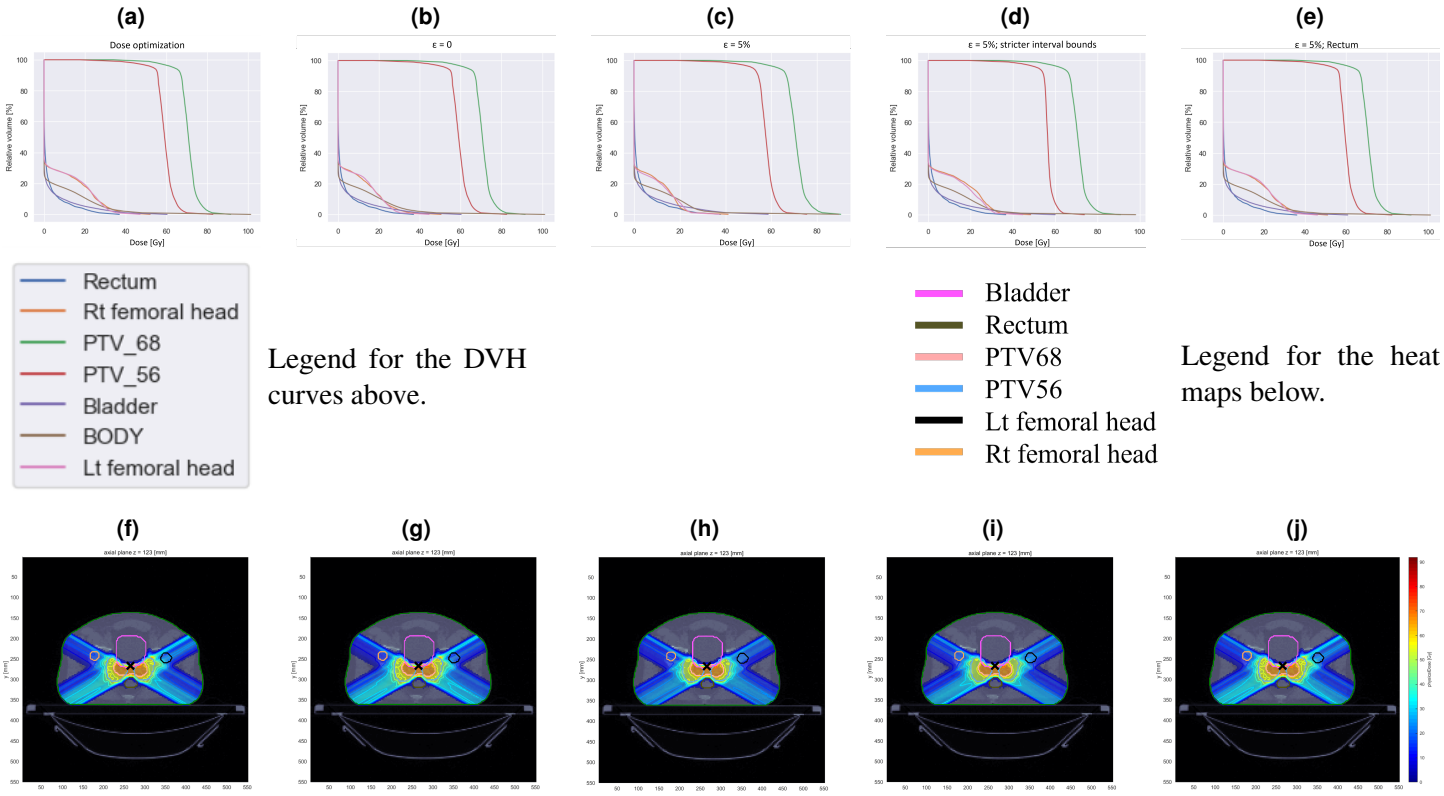

Figure 1: Prostate case. Dose is weighted with constant factor 1.1. Upper row: DVH curves, lower row: heat maps dose of an axial slice for a), f) dose optimization; inverse robustness with b), g) $\varepsilon = 0$, c), h) relative deviation of 5% and upper interval threshold of 2, d), i) relative deviation of 5% and upper interval threshold of 1.2 , e), j) relative deviation of 5% and only inverse robustness optimization for RBE parameter in the rectum.

ting the allowed relative deviation to 5% resulted in significant RBE intervals only for structures whose dose was controlled exclusively through constraints rather than minimized in (PPP).

We then focused on maximizing the RBE intervals for both parotid glands, PTV63, and PTV70, setting an upper interval threshold of 2 for the latter structures, and of 1.2 for the skin. For all other structures the interval length was not optimized. The skin was robust against RBE variations in the whole allowed interval. The resulting intervals for PTV63 and PTV70 were $[1.1, 1.136]$ and $[1.1, 1.143]$, respectively. The parotid glands were not robust against RBE variations.

Increasing the allowed deviation to 10%, while maintaining the same interval thresholds, increased the RBE intervals for PTV63 and PTV70 to 1.163 and 1.181, respectively. However, the intervals for the parotid glands could not be enlarged, reaffirming their sensitivity to RBE fluctuations. Figure 2 shows the DVH curves and heat maps for this case and the described settings for inverse robustness optimization.

4 Discussion

Robustness concepts typically necessitate trade-offs in the objective values. Unlike traditional methods where robustness levels are predetermined, inverse robustness explores achievable robustness levels for a given cost per objective. This is particularly useful for parameters where little is known about their distribution. However, it can be adapted to include additional knowledge. As observed for better results the search space, i.e. in our case the interval boundaries, should be limited to relevant values. The volume function can also be adjusted. Once it is known sufficiently well, the probability distribution of the RBE parameter could be used instead of the interval length.

Unsurprisingly, in both examples we observed structures where deviation from an RBE of 1.1 was infeasible. In our model this is especially likely to happen if the dose of a structure is tightly controlled by constraints, since we did not add slack variables to the constraints. If critical structures are affected, it could be an indicator to chose a different treatment plan or ensuring control over other RBE-influencing factors such as LET.

We are currently addressing the former issue. Furthermore, providing treatment planners with information on achievable RBE robustness during initial treatment plan selection, and, additionally considering the interval lengths for the RBE parameter of different structures as conflicting goals, leads to a hierarchical bi-level multicriteria problem. We have recently developed a method to solve this special subclass of bi-level problems as a common multicriteria optimization (MCO) problem and thus enable the use of established MCO methods [7].

Moreover, we are working on a method to focus on predefined

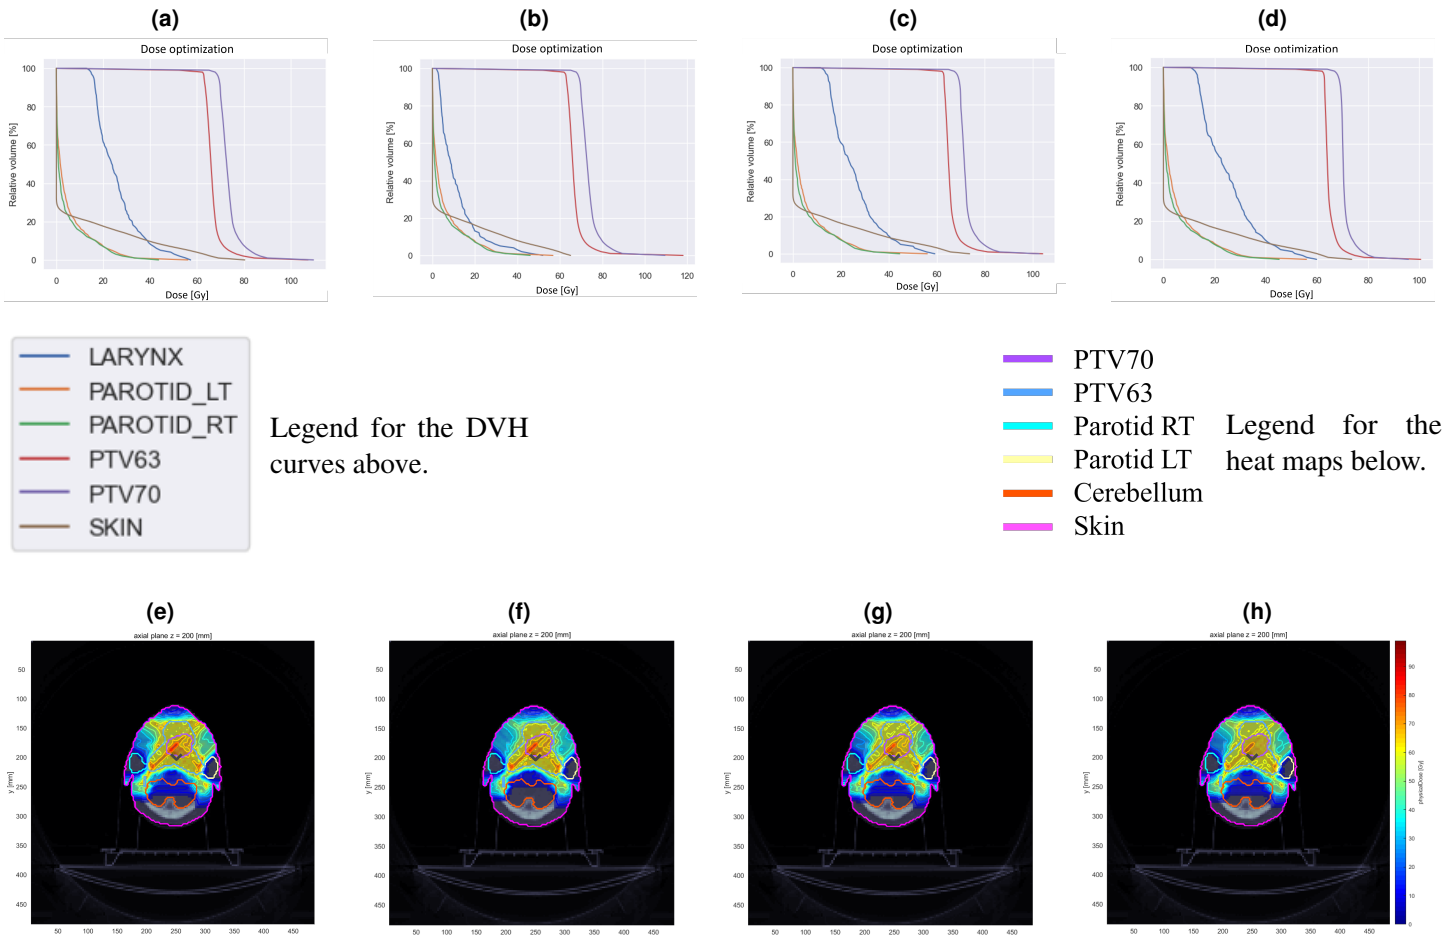

Figure 2: Head and neck case. Dose is weighted with constant factor 1.1. Upper row: DVH curves, lower row: heat maps of dose of an axial slice for a), e) dose optimization; inverse robustness with b), f) relative deviation of 5% and upper interval threshold of 2 c), g) relative deviation of 5%, only optimization for critical structures, d), h) relative deviation of 10% , only optimization for critical structures.

areas where RBE deviations are expected, such as the end of the Bragg peak [1], aiming to maximize the RBE range in these areas only. This approach should prioritize clinically relevant results and optimally utilizes the degrees of freedom in the dose distribution for more critical areas.

5 Conclusion

We introduced inverse robustness to address uncertainties in the RBE parameter for proton therapy planning. This method does not depend on RBE models or other parameters. By setting the price of robustness one is willing to pay, one obtains the largest possible intervals for variation of the RBE parameter that a plan can accommodate. If available, additional knowledge about the RBE can be included and can help to gain more degrees of freedom for the optimization. Thus, we believe that inverse robustness is a promising method for incorporating RBE into robust treatment planning for protons, even in the absence of a universal RBE model.

Abstract Fast and accurate dose prediction in carbon ion therapy is crucial for optimizing treatment efficacy and minimizing adverse effects by precisely targeting tumors while sparing healthy tissues. This study explores machine learning (ML) models for accelerated dose prediction in carbon ion therapy. While GANs and transformer models have been previously introduced for dose prediction in other therapies, this work introduces the diffusion model as a novel approach. Trained on high-quality datasets from Geant4 simulations, these models exhibit promising performance results, showing a potential for both precision and speed in prediction dose distributions in mixed radiation fields of therapeutic carbon ions.

1 Introduction

Carbon ion therapy in radiotherapy utilizes the unique physical properties of carbon ions, including their high mass and charge. This enables a precise dose distribution in the tissue with a characteristic Bragg peak. Compared to protons, the Bragg peak of carbon ions has a higher energy deposition at the end of the range, allowing for even more precise local dose application. These characteristics allow for highly precise tumor treatment by focusing the radiation dose specifically on the tumor tissue while sparing the surrounding healthy tissue.

Due to the high precision, carbon ion therapy requires a very accurate dose calculation. Monte Carlo (MC) radiation transport simulations are considered as the most accurate dose calculation approach. However, the long calculation times of MC simulations limit their usefulness in everyday clinical practice, particularly for complex forms of therapy such as carbon ion therapy. The acceleration of MC simulations is therefore the focus of current research efforts, with a decisive emphasis on the application of machine learning (ML) methods.

There are numerous studies on the use of ML to accelerate MC simulations. Particularly fast and accurate results have been shown by approaches which predict the dose distribution in the patient based on patient geometry and beam properties. Generative Adversarial Networks (GANs) and transformer models have been proposed most recently as dose prediction models [1,2]. However, to the best of our knowledge, this methodology has not yet been applied to carbon ion therapy.

This work therefore examines whether this methodology can be transferred to dose calculation in carbon ion therapy. In addition to the application of the known GAN and Transformer models, a diffusion model for dose calculation is developed and compared with the other models.

2 Materials and Methods

High-quality data sets are crucial for machine learning, as they significantly influence the accuracy and performance of the model. To train the models, a dataset was created using the simulation software Geant4 [3]. CT images from the GLIS-RT data set of the TCIA [4], which depicts the head and neck region of various patients, were used as geometry. Six patients were randomly selected from the data set. A monoenergetic carbon ion beam of varying energy between 1250 MeV and 3000MeV and a diameter of 1 mm was simulated. For higher geometric variability, the same geometry was irradiated from different positions and the calculated dose and density matrices were also rotated in steps of 90°.

The GAN approach was published in [1]. The authors used a conditional GAN for dose prediction in microbeam radiation therapy. The GAN model consists of a generator and a discriminator. The generator produces the dose matrix based on a density matrix of the geometry and a dose matrix of the corresponding beam configuration in homogeneous water. The discriminator is trained to distinguish between real and generated data. Through this continuous rivalry, the generator constantly improves to produce more authentic dose maps, while the discriminator develops its detection capability.

The transformer model for dose prediction was proposed in [2] in the context of proton therapy. Transformer models can model complex dependencies in long sequences through self-attentive layers by utilizing attention mechanisms. In this approach the density and dose matrices are divided into a sequence of 2 dimensional slices along the beam direction. The transformer architecture is combined with a Convolutional Neural Network (CNN) for extracting information from the inputted density matrix and decoding the output dose matrix. The encoded density matrix is combined before the transformer module with a vector representing the energy of the carbon ions.

The Diffusion model approach disseminates information from the simulated dose matrix through a step-by-step stochastic diffusion process. A U-Net, conditioned on the density matrix and beam information, is trained to predict the noise added in one time step. The dose matrix is reconstructed by subtracting the predicted noise from the noisy image. After training, the U-Net is able to predict the dose distribution starting with a random noisy image and the conditional information.

Training involves both training and validation datasets. For testing, a distinct dataset is uniformly reserved across all geometries and energies. Additionally, to assess generalization, a complete brain geometry not encountered during the training phase was included in the testing process.

All models were optimized with respect to their hyperparameters.

3 Results

Table 1 presents the performance measurements for the optimized GAN model, including both the validation dataset and the two test datasets. The performance metrics include the averaged MSE per voxel, along with the average 1% and 3% passing rates.

To examine the network's generalization across various geometries, Figure 1 illustrates the MSE averaged across energies for different source positions in the unseen geometry.

The time required for one dose prediction using Geant4 ranges from 1 to 3 hours, depending on the beam energy and geometry factors. For the trained GAN model, the average computational time per prediction is 0.012 seconds on a CPU and 0.009 seconds on a GPU.

The Transformer and Diffusion Models are still under development.

Table 1: Average performance metrics of the optimized GAN model for the validation- and test dataset and for the held-out geometry.

Performance Metric	Validation Dataset	Test Dataset	Unseen Geometry
MSE [10^{-5}]	1.75 ± 0.44	1.53 ± 0.26	106.90 ± 9.76
1% passing rate [%]	99.48 ± 0.06	99.47 ± 0.05	99.60 ± 0.03
3 % passing rate [%]	99.80 ± 0.03	99.81 ± 0.03	99.71 ± 0.02

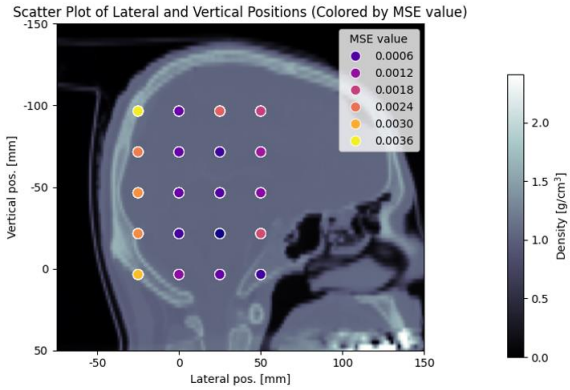

Figure 1: Average MSE at different source positions of the held-out test geometry.

4 Discussion

The GAN architecture demonstrates promising performance for fast dose prediction through machine learning. Dose prediction using a trained GAN model is five orders of magnitude faster than a Monte Carlo simulation with Geant4. In all cases, an average passing rate greater than 99% was achieved. Challenges arise in specific geometries, such as when the beam is close to the skull along most of its path. The elevated MSE values observed for the unseen geometry compared to the test dataset indicate the necessity of incorporating a broader range of diverse geometries, each characterized by its unique dimensions, into the training process.

5 Conclusion

Three different machine learning models for dose prediction in carbon ion therapy are explored and compared with each other. The available results for the GAN model showcase high passing rates exceeding 99% and an ability to generalize to the geometry. The results demonstrate that accurate and fast dose prediction through machine learning is viable even within the context of mixed radiation fields, such as in carbon ion therapy.

Abstract The aim of this study is to investigate whether there exists a correlation between radiomics features and histological expression of biomarkers in an orthotopic non-small cell lung cancer (NSCLC) mouse model. Tumours were induced in thirty-two athymic male mice by implanting a human NSCLC line in their lungs. The mice were split into four treatment groups. Radiomics features were extracted from cone-beam computed tomography images taken two to three times per week over the course of two weeks of treatment. The mice were then euthanized and their tumours are currently undergoing immunohistochemical staining to detect several biomarkers. Thus far, many extracted features show significant variations across treatment groups, even before the different treatments begin. Further, many features show strong linear correlations with other features. We describe the experimental and analysis protocol and outline our efforts to account for these findings, including normalization of features by a baseline value and using feature selection protocols.

1 Introduction

Radiomics is an expanding branch of research that concerns itself with the extraction and analysis of quantitative characteristics, or features, from medical images [1]. Radiomics lends itself well to the study of solid cancer cases for several reasons. For one, medical images are ubiquitous to modern cancer treatment, and so a radiomics analysis can serve to increase the amount of information available to a patient's treatment team without demanding additional examinations. Radiomics analyses can also augment the information found within these medical images as certain features, such as those describing the texture of a tumour, are not meaningfully appreciable by the human eye on its own [2].

Radiomics, and medical imaging in general, are usually limited to describing macroscopic tumour characteristics. Biopsies may be performed to investigate microscopic characteristics, such as the tumour's microenvironment and the expression of histological biomarkers, but biopsies are invasive and can only provide information on the section of the tumour that is excised.

The goal of this project is to investigate whether there exists a correlation between radiomics features and histological biomarker expression in an orthotopic non-small cell lung cancer mouse model. If such a correlation is established, radiomics analyses of medical images could present a non-invasive way to probe a solid tumour for microscopic biomarker information. This analysis also presents an avenue for evaluating a tumour's response to treatment if the expressions of certain biomarkers are clinically relevant tumour response parameters.

2 Materials and Methods

2.1 The Mouse Model

For this study, orthotopic implantation of tumour cells was performed on 32 male athymic mice, by injecting H1299 non-small cell lung cancer (NSCLC) cells in either the left or right lung. Tumour development was monitored via cone-beam computed tomography (CBCT) and when visible tumours developed, the mice were randomly divided into four treatment cohorts: a control (CTRL), a group to receive radiation treatment (RT), a group to receive injections of L-carnosine (CAR), and a group to receive a combination of L-carnosine and radiotherapy (CAR+RT). L-carnosine is a naturally occurring dipeptide with anti-cancer properties [3] that has been shown to exhibit a radiosensitizing effect in lung cancer cells [4]. On Day 0, the mice in the RT and CAR+RT groups were treated with a single dose of 20 Gy. The mice were followed for at least two weeks thereafter, and underwent CBCT imaging two to three times per week. Finally, the mice were euthanized. Their lungs were resected and processed for immunochemistry.

2.2 Immunohistochemistry

Tissue sections from the tumour-bearing lungs are currently undergoing immunochemistry analysis for the detection of several biomarkers. Among these are Ki-67, a protein associated with cellular proliferation [5]; HIF-1α, a protein associated with hypoxia [6]; and TNF-α, an inflammatory cytokine associated with cellular immune response [7]. These biomarkers represent clinically relevant information about how each tumour responded to its treatment.

2.3 Radiomics Features

The CBCT images for each mouse were manually segmented at three time points: Day 0 (the day of radiation treatment),

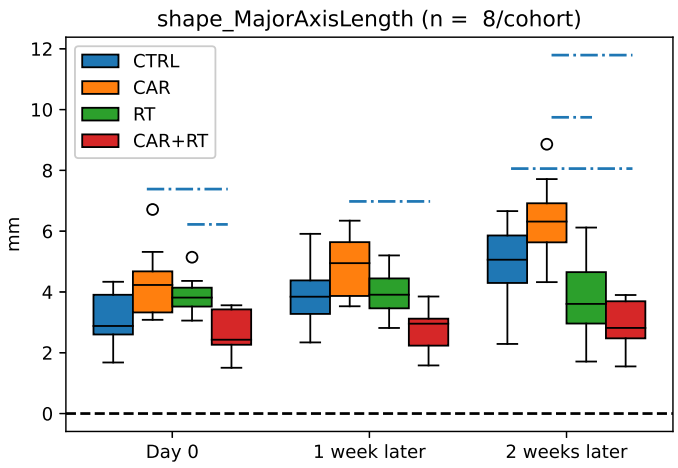

Figure 1: The major axis length is a radiomics feature in the shape family that describes the largest axis length of the smallest ellipsoid required to totally enclose the ROI.

one week thereafter, and two weeks thereafter. The segmentation consisted of defining a binary region of interest (ROI) in each image enclosing the tumour as conformally as possible. Then, using the open-source pyRadiomics package, 107 radiomics features were calculated from the pixels within each ROI and extracted [8]. The features can be categorized into three broad families: first-order features, which create a histogram of the pixel values within the ROI and then calculate statistics on the histogram; shape features, which describe the geometry of the ROI; and higher-order features, which create matrices based on the interrelationship between a pixel's values and the values of its neighbours to describe the texture of the ROI.

When comparing radiomics features across cohorts, we used a Kruskal-Wallis non-parametric test with a Dunn's post hoc test to identify statistically significant inter-cohort variation.

3 Results

3.1 Absolute Features

Many features show notable variation within and across treatment cohorts, even on Day 0. For example, Figure 1 shows the major axis length, a shape feature, of the tumours at the three contoured time points. Even on Day 0, there is large variation across the treatment cohorts, so much so that the major axis length of the tumours in the CAR+RT group deviates significantly from those of the tumours in the CAR and RT groups.

3.2 Feature Correlation

Many of the extracted features appear to be strongly linearly correlated to other features. For example, Figure 2 presents a clustermap of gray level co-occurrence matrix (glcm) features extracted from the tumours in the RT group at the 2 week time point. These are higher-order features that describe how

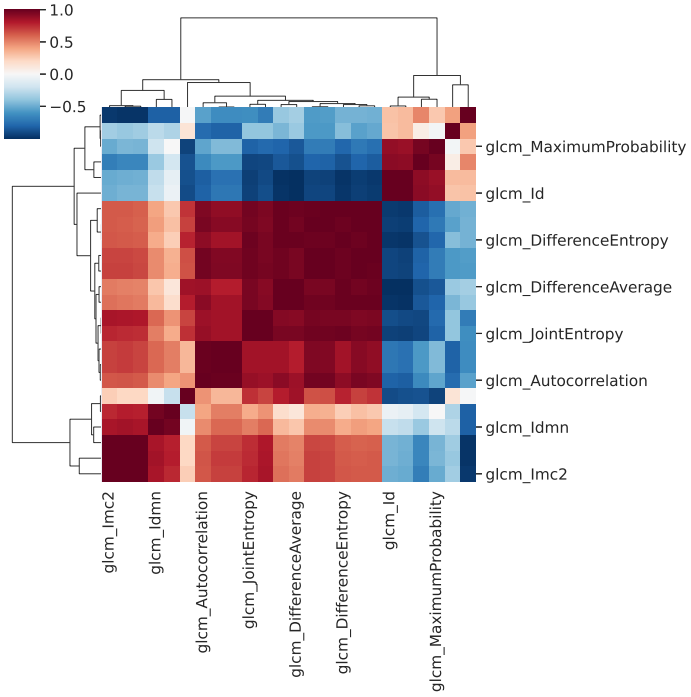

Figure 2: A clustermap representing correlations between gray level co-occurrence matrix (glcm) features in the RT group at the 2 week time point shows the linear Pearson R correlation between each pair of glcm features as a shaded box on the grid. Dark red boxes represent strongly positive correlations (R = 1), and dark blue boxes represent strongly negative correlations (R = -1). For visual clarity, every third feature is labelled by name.

often pairs of grayscale values are found near each other within the ROI. Very few boxes are light in color, indicating that the vast majority of glcm features in the RT group at the 2 week time point are strongly linearly correlated to several others.

4 Discussion

The inter- and intra-cohort variation of features at Day 0 is to be expected as there is variability both in the cell implantation process and in individual response and tumour development. However, this variation poses an obstacle when one wishes to compare the efficacy of one treatment versus another. To fairly assess the effect of each treatment on extracted features, the values of each feature will be normalized by a baseline value, such as the values on Day 0.

The strong correlation between features is also to be expected as many radiomics feature definitions are inherently sensitive to others. Further, when assessing changes to features in response to treatment, the underlying biological and physical processes are less numerous than the features extracted. For example, Figure 1 shows that after two weeks of treatment, the tumours in the CAR+RT group had significantly smaller major axis lengths than those in the CTRL and CAR groups. That radiation kills cells and thus retards growth in tumours is well known and is, in fact, the main reason radiotherapy is employed. These results are obviously linked to the cell

killing effect of radiation and one could easily predict that other shape-based features, like total tumour volume, will follow a similar trend. Indeed, an important step in employing radiomics is feature selection, whereby features that provide superfluous or redundant information are ignored from further analysis [9]. By using clustermaps, a representative feature from each cluster can be chosen to reduce the total number of features that require analysis.

5 Conclusion

We extracted over 100 features from non-small cell lung cancer tumours implanted orthotopically in an athymic mouse model and are in the process of comparing them. Thus far, we have shown that even at the beginning of the treatment period, the values of features within and across cohorts can be notably different. Further, we have shown that many features show strong linear correlations with other features, indicating that the number of features containing unique and clinically relevant information is likely quite small. We plan on comparing these extracted features to the expression of several biomarkers in the coming months.

Abstract The microvasculature plays an essential role in the microenvironment, supplying nutrients, drugs and facilitating immune cell trafficking. In previous studies, microvascular health status was predictive of radiotherapy toxicities in different cohorts of patients. In this study, we present a computational workflow that generates synthetic microvascular networks leveraging data from a sublingual microscope collected in a cohort of 63 Head and Neck Cancer patients. The workflow facilitates the development of personalized computational models to analyze the role of the microvasculature in radiation toxicity. The synthetic networks replicate the microvascular density and vessel diameter of the patients, enabling mechanistic simulations of microvascular flow and drug/nutrient delivery. The results demonstrate the capability of the computational framework to generate relevant microvascular scenarios, with blood flow parameters aligning with physiological ranges. This model will serve as a valuable tool for mechanistically evaluating how the microvasculature shapes the microenvironment, contributing to current models on RT toxicity in diverse patient cohorts.

1 Introduction

The microvasculature plays an essential role in the microenvironment, delivering nutrients to tissues and facilitating drug delivery and immune cell trafficking. For these reasons, the microvasculature significantly influences cancer treatments, including chemotherapy, immunotherapy, and even radiotherapy (RT) through oxygen delivery and the potential presence of hypoxia within the tumor. The central role of the microvasculature in cancer treatment extends beyond the tumor to include healthy tissue toxicity. Acute and late toxicity define the therapeutic window, impacting therapeutic efficacy and quality of life for cancer patients.

In the context of radiotherapy, several trials have associated an increased risk of normal tissue toxicity with conditions that negatively affect the microvascular system, such as hypertension, diabetes, smoking, alcohol abuse, and obesity [1–3]. In a previous analysis, we demonstrated the predictive role of microvasculature healthiness for acute toxicity after RT in breast, prostate, and Head and Neck Cancer (HNC) patients, using a sublingual microscope [4]. Specifically, impaired microvasculature was associated with an elevated probability of toxicity. The functional information provided by the sublingual microscope can enhance the personalization of predictive models by tailoring them to the individual patient's functional status.

On the other hand, computational models can describe the state of the microvascular environment based on a set of parameters, including physical quantities (e.g., red blood cell (RBC) concentration, oxygen/drug concentration, permeability of the vascular wall) and microvascular morphology [5, 6]. Through computational modeling, we can assess the impact of these data on the microenvironment, such as interstitial pressure, oxygen availability, and drug/nutrient delivery [7]. This work aims to integrate patient data with computational modeling. To achieve this, we collected data from patients using the sublingual microscope to create a set of synthetic computational domains. In this study, our primary focus was on microvascular morphology, including microvascular radius and density. Using these data, we constructed computational microvascular networks. Then we simulated blood flow, describing parameters such as blood velocity, RBC transport, and blood pressure.

2 Methods

This work was carried out in three main steps: (i) collection of patients' data; (ii) generation of synthetic microvascular networks that match radius and density data; (iii) computational simulation of blood flow in the synthetic microvasculature.

2.1 Patients' data

We enrolled 63 HNC patients who received a prescribed total tumor dose ranging from 60 to 70 Gy, with 1.7-2.12 Gy/fraction. Using the GlycoCheck system, we measured microvasculature parameters in the sublingual region, including capillary density, capillary radius distribution, and RBC velocity. These data were obtained non-invasively using a handheld sublingual camera that recorded blood flow in the capillaries prior to RT treatment (Figure 1).

2.2 Building synthetic microvascular networks

As the initial step for the patient-specific microvascular simulation, we constructed computational domains designed to replicate the dimensions of the images obtained by the sublingual microscope, utilizing a $700 \times 950, \mu m$ rectangle. Within this domain, we created synthetic microvasculature,

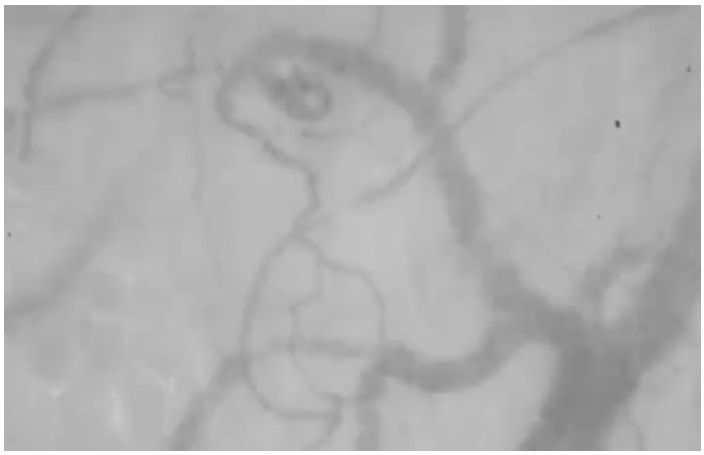

Figure 1: Frame extracted from the sublingual microscope recordings.

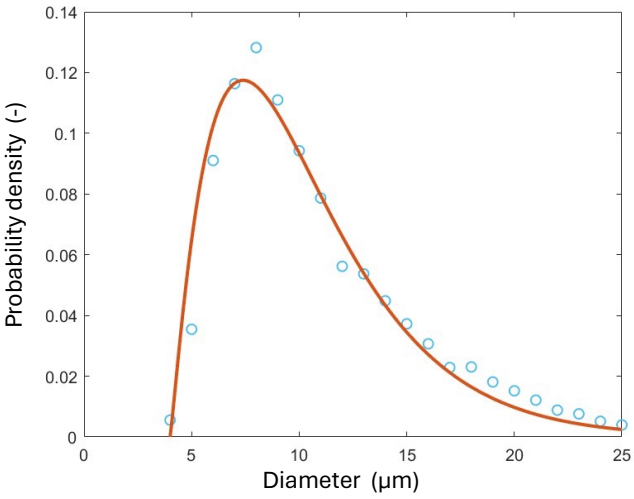

Figure 2: Microvascular diameter distribution from patients (dots) and its approximation with the γ distribution.

employing hierarchical two-level networks to mimic the data obtained from the microscope (Figure 1). The first level comprises a few larger vessels present in the images, while the second layer consists of smaller vessels originating from the first layer. Each of these layers was generated using a Voronoi-based approach, chosen for its bio-mimetic features, as described in previous works [6, 7].

In summary, we randomly generated a defined number of seeds and subsequently used them to perform Voronoi tessellation. Each edge represents a vessel, and the entire tessellation constitutes the microvascular network. The density of the vessel depends on the initial distribution of the seeds. The number of Voronoi seeds for the first layer is set to 4. On the contrary, the number of seeds for the second layer was adjusted to match the microvascular density. The sublingual microscope calculates the vascular density by considering a subset of vessels. Lee and colleagues [8] measured the total capillary density in a similar setup with a cohort of 6673 individuals, estimating it to be 43146 $\mu m/mm^2$.

We applied a correction based on this value to account for the total capillary density:

$$Total\,density = 43146\,\mu m/mm^2 \times \frac{desired\,density}{median\,density}. \quad (1)$$

Following this correction, we set the radius for each vessel to complete the morphological definition of the synthetic microvascular network. This step was performed on the second layer of the vessels, mirroring the approach taken by the sublingual microscope. Initially, we constructed a probability function based on radius data from our HNC cohort (Figure 2 - γ distribution with parameters = 2.15 and 2.95). Subsequently, for each vessel, we assigned the radius such that: (i) the resulting microvascular network mimics the length-weighted distribution obtained from patients; (ii) the diameter is strictly smaller than half the length of the considered capillary, emphasizing the length as the dominant dimension.

2.3 Simulation of microvascular flow

After the network generation, we simulated the blood flow within the synthetic microvasculature considering the presence of RBCs. Briefly, we calculate the blood pressure for each node and the flow rate for each branch. This involved solving a Poiseuille-like problem (Eq. 2), coupled with the mass conservation equation (Eq. 3):

$$p_{i,in} - p_{i,out} = R_i Q_i \qquad with\, i = 1,...,n_{branches} \quad (2)$$

$$\sum_{i \in j} Q_i = 0 \qquad with\, j = 1,...,m_{nodes}. \quad (3)$$

The resistance term is defined by including the Fahraeus-Lindqvist effect:

$$R_i = \frac{128\,\mu(H_i,d_i)\,L_i}{\pi\,d_i^4}. \quad (4)$$

RBC flow is determined considering mass conservation at each junction and neglecting potential fluid filtration through the capillary wall (Eq. 5). For bifurcations, the model accounts for the uneven partition of RBCs when flowing through them, known as the Zweifach-Fung effect (Eq. 6, 7):

$$\sum_{i \in j} Q_i H_i = 0 \qquad with\, j = 1,...,m_{nodes}; \quad (5)$$

$$H_\alpha = F_{QE\alpha}\,H_{father}\,\frac{Q_{father}}{Q_\alpha} \quad (6)$$

$$H_\beta = (1 - F_{QE\alpha})\,H_{father}\,\frac{Q_{father}}{Q_\beta} \quad (7)$$

An iterative method was used to solve the problem as a result of the interdependence of the RBC distribution on flow and vice versa (via viscosity). Further details on the model, including the definitions of $\mu(H_i,d_i)$ and $F_{QE\alpha}$, as well as the iterative solution strategy, can be found in [6]. The problem is then complemented with boundary conditions, defined as the inlet RBC concentration ($H_{in} = 0.1$, [9]), and a pressure

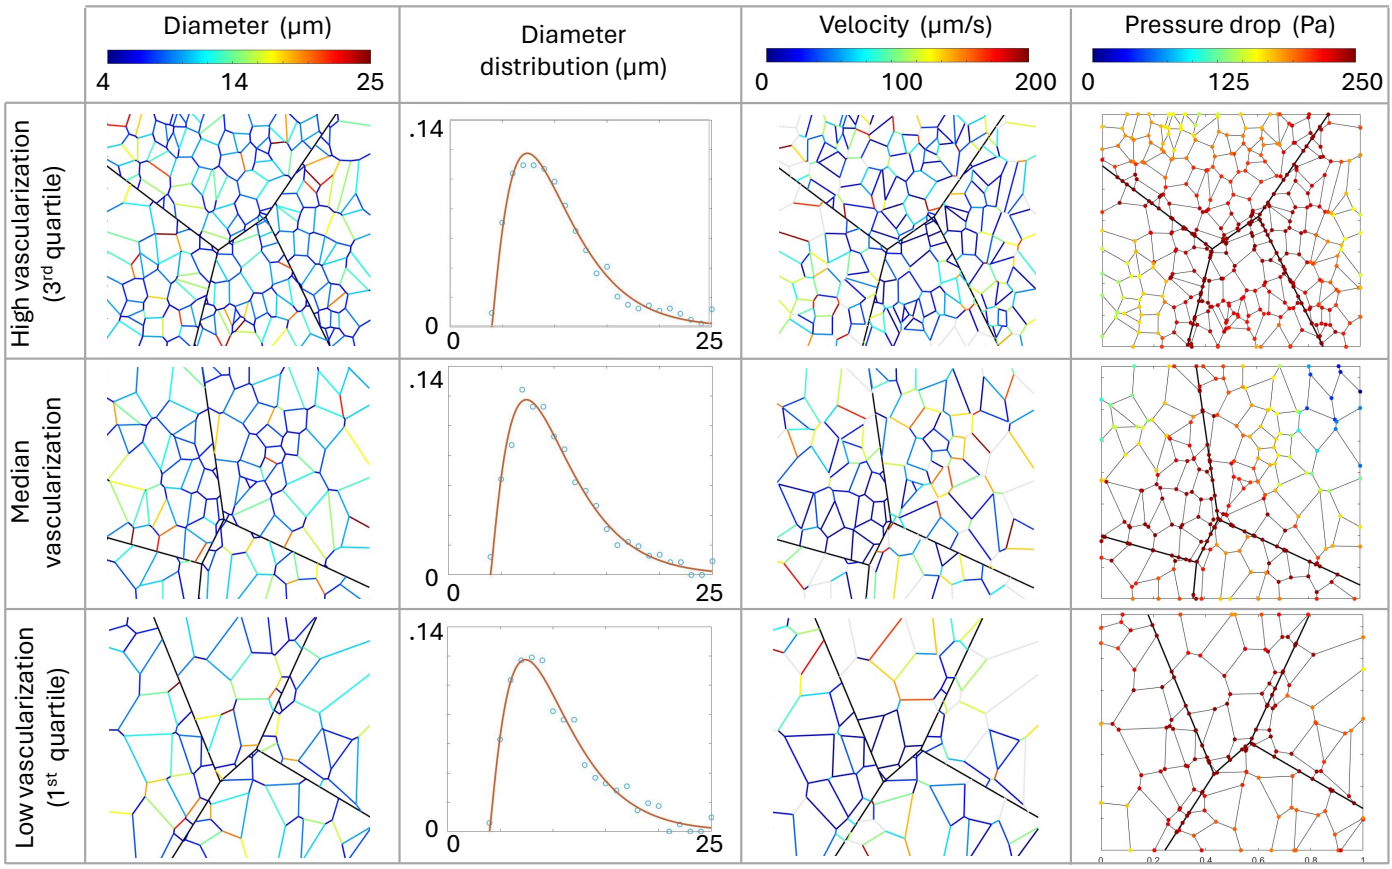

Figure 3: Synthetic microvascular networks based on the microvascular density data (Low = first quartile, Median, and High = third quartile. We report the diameter of the vessel within the network (first column), its distribution compared to the theoretical one (second column), and the computational estimation of the flow, quantified as velocity (third column) and pressure drop (fourth column). Blood velocity greater than 200 μm is indicated in grey.

drop ($\simeq$ 2 mmHg). The exact outlet pressure was defined considering the inlet-outlet distance, adjusting the pressure drop based on the shortest inlet-outlet path length. The inlet nodes are identified as the intersections of the first and second layers of the microvasculature, while outlet nodes are identified as the intersections of the second layer with the outer boundary of the domain.

3 Results

The results presented here are based on radius and density values extracted from the HNC cohort, focusing on the generation and calculation of microvascular networks. Three distinct cases are outlined, corresponding to the 1st, 2nd (median), and the 3rd quartile of capillary density in our population (Figure 3).

3.1 Microvascular networks

The morphology of the synthetic microvascular network is illustrated in the first column (Figure 3), delineating the first layer of the microvasculature (larger vessels, $d \simeq, 100\mu m$) in black and the second layer color-coded based on the diameter value ($4\mu m \leq d \leq 25\mu m$). By reducing the target density and, consequently, the number of seeds, we successfully obtained networks with lower total length and a reduced number of segments. The second column presents the diameter distribution, along with an approximated sample distribution, as a useful reference. These two types of data prove the generation of microvascular networks based on a target microvascular density and diameter distribution.

3.2 Blood velocity and pressures

Blood flow results are detailed as blood velocity (third column) and pressure (fourth column). First, these results demonstrate that the synthetic microvascular network is well-connected, and the computational workflow generates relevant scenarios. This observation is further supported by the velocity and pressure drop results, both falling within a physiological range ($v \simeq 50 - 200\,\mu m/s$) and Δp a few mmHg) [6, 10]. The velocity results also align with the same order of magnitude of the data collected using the sublingual microscope (Figure 4).

4 Discussion

In this study, we collected data acquired from a sublingual microscope in a HNC cohort consisting of 63 patients. Using

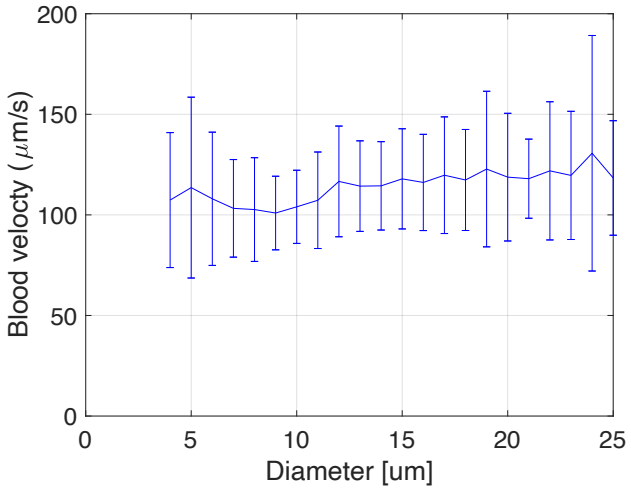

Figure 4: Blood velocity distribution obtained from patients' data showing the average values with standard deviation.

these data, we constructed a set of synthetic microvascular networks. Our results are based on population-based statistics, specifically focusing on microvascular density and vessel diameters. As a remark, our workflow is not restricted to population-based target values; rather, it can seamlessly integrate patient-specific target values. This adaptability enables the development of personalized computational models of the microenvironment, facilitating the analysis of the role of the microvasculature in radiation toxicity. In addition, pressure boundary conditions can be customized to replicate individual blood velocity measurements, which are also available for individual patients.

The flexibility of the presented workflow extends to modifications that involve employing different network generation strategies. For instance, Voronoi tessellation can be replaced or supplemented with alternative methods. Such modifications enable the creation of non-uniformly distributed networks, providing a more accurate representation of possible pathological states.

The proposed model serves as a valuable computational framework for a mechanistic evaluation of how the microvasculature shapes the microenvironment. These mechanistic insights contribute to analyses on the role of microvasculature in radiation toxicity in different cohorts of patients [4].

5 Conclusion

We introduced a computational workflow to generate synthetic microvascular networks based on a cohort of 63 HNC patients. These networks faithfully mimic the microvascular density and vessel diameter of the patients, enabling mechanistic simulations of microvascular flow and flow-mediated drug/nutrient delivery. The integration of this computational framework and patient data provides a valuable tool for unraveling the role of microvasculature in RT toxicity.

Modeling the geometric distortion and fan beam imaging of an on-rails computed tomography scanner for 2D/3D registration

Giovanni Fattori[1], Riccardo Via[1], Antony John Lomax[1,2] and Sairos Safai[1]

[1]Center for Proton Therapy, Paul Scherrer Institut, Villigen, Switzerland [2]Department of Physics, ETH Zürich, Switzerland

Abstract Intraoperative CT scanners are increasingly present in high-precision radiotherapy units, enabling the acquisition of tomographic images of the treatment geometry. While providing high quality images, geometric uncertainties most often preclude the use of on-rails scanners as imagers for patient position verification. We studied the distortion of volumetric images and topograms, while modelling the fan-beam projective geometry for the calculation of digitally reconstructed topogram (DRT) images in the context of 2D/3D registration. Distortion models parameterized by comparison with laser tracker measurements enabled image-based localization with errors below 0.3 mm on individual directions in 3D. Finally, in a phantom study we evaluated the accuracy of a new 2D/3D positioning approach from orthogonal CT topogram image pairs, reporting similar accuracy and in conformity to clinical practice guidelines.

1 Introduction

Originally developed for interventional surgery, on-rails computed tomography (CT) scanners are nowadays gaining interest in high-precision radiotherapy. Indeed, their higher image quality makes them an attractive alternative to cone beam systems in the context of adaptive radiotherapy and proton therapy in particular, where the attenuation of the CT scan is crucial for the estimation of the beam range [1]. By and large, these scanners are combined with robotic positioning systems that allow intraoperative volumetric imaging of the patient on the surgical table in the exact treatment geometry. Despite the presence of several units in proton therapy facilities around the world, typically on-rail scanner use is limited to CT simulation and acquisition of control images, rather than for actual image guidance. The repurposing of on-rails technology as a patient positioning verification imager is not common and requires careful characterization of the geometric uncertainties associated with the moving gantry and fan beam geometry.

A major issue is that the reconstructed images are distorted in the longitudinal direction caused by non-linearity in the scanner motion during imaging and inaccurate readings of the gantry position encoders. Modelling the effect of such mechanical complexity on the reconstructed image coordinates and the consequent mapping of the CT space into real-world physical units is necessary for the use of on-rail scanners as for verification imaging in high-precision radiotherapy procedures.

On the other hand, the advantages of having a conventional CT in the treatment room go beyond image quality, and include the ability to reach long scan ranges, with images one meter or more in length, that are particularly useful for verifying extremities or the whole cranio-spinal axis. This applies not only to volumetric tomography but also to topogram images, which can be acquired in pairs at orthogonal angles and, provided that the projective geometry is known, be used for patient alignment in a 2D/3D registration approach.

We present the calibration and fan beam geometry model of an in-room, on-rails CT scanner (Sensation Open, Siemens Healthineers, Erlangen, Germany) installed for proton therapy at our institute. Firstly, we address the longitudinal geometric distortion of 3DCT imaging coordinates along the direction of scanner motion. This is followed by the topogram imaging characterization, for which we also introduce and calibrate a model of the projective imaging geometry for the computation of digitally reconstructed topogram (DRT) images. Finally, in a phantom study, we evaluate the accuracy of a novel 2D/3D positioning approach that makes use of CT topogram image pairs.

2 Materials and Methods

Modeling the geometric distortion of CT volumes

Repeated 3DCT images of a geometric phantom (Figure 1) have been acquired centering the scan range longitudinally at three different distances from the scanner parking position. The phantom holds 12 ceramic spheres of 2 cm diameter, facilitating their accurate measurement with a reference laser tracker equipment (Leica AT901 LR, Leica Camera AG, Wetzlar, Germany) and automatic localization in 3DCT images at 0.98x0.98 mm in-plane resolution and 1 mm slice thickness [2]. Data of each scan range have been processed individually to optimize the root mean square error (RMSE) of a point-based registration between the centers of spheres in the room (world) coordinates with respect to their corresponding imaging positions, including a linear correction along IEC-Y with scaling (s) and bias (b) free parameters:

$$P'_{Y_{IEC}} = P_{Y_{IEC}} + (s * P_{Y_{IEC}}) + b \qquad \text{(Eq. 1)}$$

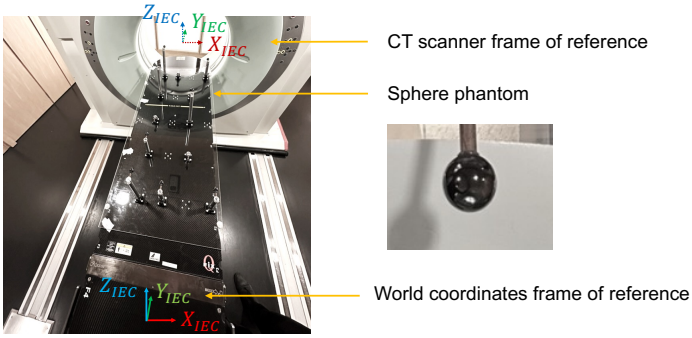

Figure 1: geometric phantom used for assessing the geometrical trueness of 3DCT imaging coordinates and reference systems involved.

A simpler version of this phantom with just two sphere points has been acquired for validation purposes, to compare the laser measurements with their undistorted image coordinates.

A model for fan beam topogram imaging

Modeling the fan beam projection geometry starts from the definition of the transform that maps the fixed CT scanner frame of reference {CT} and the digital model of the rotating (α) X-ray source {S} (Figure 2). At a source-to-image (SID) distance along the negative direction of the X-ray source reference system, we find the center of the DRT imaging plane, which in an ideal geometry is aligned to the CT gantry center of rotation. This assumption can be altered by defining the center of projection ($\boldsymbol{c}$), that offsets the digital model of source and panel.

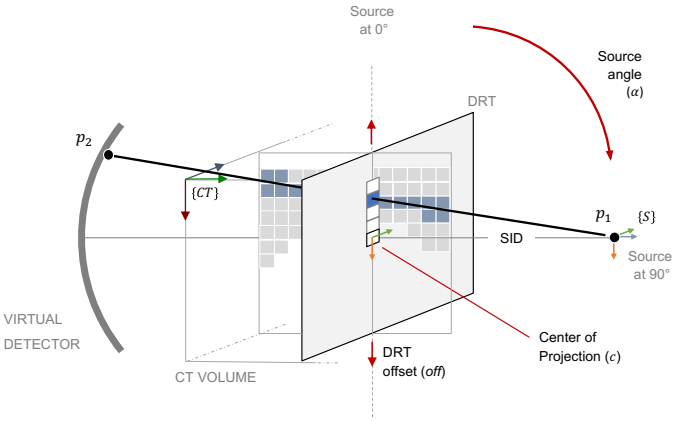

Figure 2: Projection geometry with the image volume {CT} and the X-ray model source {S} reference systems. One ray is casted from the source (p1), it crosses the whole volume and hits the detector in p2, contributing to the image intensity of one pixel of the DRT image located SID distance away from the source along the negative z-axis direction.

The mapping operator ${}^{S}_{CT}M$ is the result of composing an isocentric rotation of the source and its translations, including SID and the center of projection:

$$R_{SourceIso} = \begin{bmatrix} R_{Gantry} & R_{Gantry} \cdot \boldsymbol{c} - \boldsymbol{c} \\ 0 & 1 \end{bmatrix} \text{ and}$$

$$T_{SourceShift} = \begin{bmatrix} -c_x \\ SID - c_y \\ -c_z \end{bmatrix},$$

$$\text{With } R_{Gantry} = \begin{bmatrix} \cos(-\alpha) & -\sin(-\alpha) & 0 \\ \sin(-\alpha) & \cos(-\alpha) & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

From ${}^{S}_{CT}M$ it is possible to calculate the position of any arbitrary location (${}^{CT}_{\square}P$) in the CT field of view as it were seen from the local reference system mounted on the source (${}^{S}_{\square}P$). Afterwards, ${}^{S}_{\square}P$ is projected onto the DRT image plane, whilst correcting for the fan beam dispersion and using the intercept theorem as per equation 2.

$$ {}^{DRT}_{\square}P = \begin{bmatrix} {}^{S}_{\square}P_x * SID \,/\, abs({}^{S}_{\square}P_z) \\ {}^{S}_{\square}P_y \\ -SID \end{bmatrix} \qquad \text{(Eq. 2)}$$

Based on empirical evidence, an additional free parameter introducing a transversal shift of the DRT image plane is required to best replicate the actual topogram images. Such an offset (*off*) is applied only to the *x*-component of the DRT coordinates after projection, i.e. ${}^{DRT}_{\square}P'_x = {}^{DRT}_{\square}P_x + off$.

Modeling the geometric distortion of CT topogram images

Thirteen CT-dots (Beekley 119) of 2 mm diameter have been placed on blocks of light foam to sample pseudo-randomly the CT field of view. Both 3DCT and topogram images for lateral (LAT, $\alpha = 90°$) and posterior-anterior (PA, $\alpha = 180°$) projections have been acquired twice over the period of a year (dataset I and II). Topograms were acquired at two resolutions, using small and large field of view (FoV) for 1 mm and 2 mm in-plane pixel spacing images respectively. Fiducial positions have been localized manually in all datasets and the 3DCT positions were corrected for the longitudinal geometric distortion as per Eq. 1. Such undistorted fiducial positions have been then compared with the corresponding ones from topogram images to evaluate the longitudinal image distortion.

Calibration of fan beam projection geometry

The CT-dots dataset introduced before has been used for calibrating the fan beam projection geometry model by optimizing the projection error on the DRT plane of 3DCT points against the corresponding ones on topogram images acquired for the same setup. The dataset has then been extended by including 24 ceramic fiducials embedded on the two sides of the treatment couch top.
For the purpose of calibrating the fan beam projection geometry, the longitudinal direction is irrelevant, and therefore all locations have been collapsed as if they were lying onto a single axial image plane. The calibration routine is setup as a constrained optimization function using L-BFGS-B optimizer with 1e-13 tolerance for termination. Each projection angle and FoV has been calibrated individually.

Fast computation of DRT images

Digital image reconstruction is based on Siddon-Jacobs algorithm for incremental ray tracing [3]. Once the transformation that maps CT imaging coordinates into the source reference system (${}^{S}_{CT}M$) is known, its inverse can be used to map every pixel of the DRT image into the CT volume frame of reference. The same applies to the position of the source, and thus a ray direction can be defined from these two points in the {CT} reference system. The voxels of the 3DCT crossed by the ray are identified using Siddon's algorithm to compute the DRT pixel intensity value. In fan beam imaging, the lateral dispersion of the cone beam was

replaced with a sliding source model, with the ray calculation being adapted to reflect the geometry of topogram imaging with the virtual detector at the projection isocenter, rather than ray endpoint as it is for conventional radiograph imagers. Of note, the actual detector characteristic is not relevant to this parametrization as pixels of the DRT image represent rays going from the source *p1* to a point *p2* on the detector which is not linked to the physical elements of the CT array (Figure 2). Our implementation is a new interpolator filter for the Insight Toolkit (ITK) library.

Patient alignment with 2D/3D topogram registration

Clinical positioning using pairs of orthogonal topogram images has been simulated using a phantom patient head (CIRS, Norfolk, Virginia, United States). A ceramic sphere placed cranially to the phantom has been set as treatment isocenter and its laser tracker measurement used as a control point. After acquiring a planning 3DCT image (0.98 mm in-plane and 1 mm slice thickness), an arbitrary translational offset has been applied to the phantom before taking positioning topogram images. From these data, 2D/3D image-based correction has been computed in the CT scanner frame of reference and corrected for topogram-specific distortions before comparison with laser tracker reference measurements in world coordinates (Figure 1). The setup correction was obtained iteratively minimizing Mattes mutual information (50 bins) between two pairs of DRT and topogram images (Figure 3) with the Nelder-Mead optimizer (simplex delta=2, convergence tolerance = 0.1). The registration is based on the multi-threaded framework of ITK and makes use of the DRT model from the previous section. The procedure is DICOM compliant and supports standard radiotherapy formats.

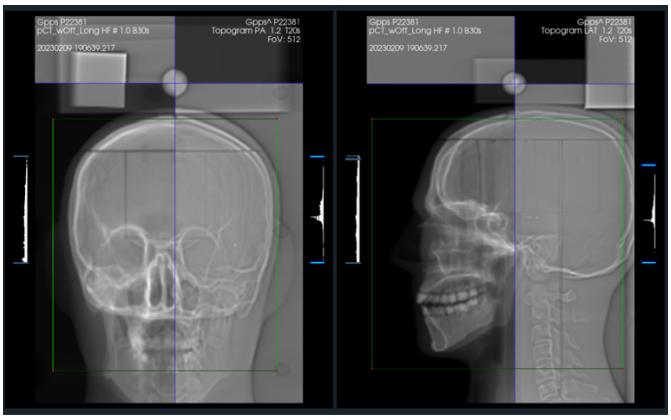

Figure 3: CT topogram (1st and 3nd quadrants) and DRT (2nd and 4th quadrants) images of the phantom head at two orthogonal projections. Above the head is the 2 cm sphere used as target control point.

3 Results

Geometric distortion of CT volumes

Optimal bias and scaling parameters (Eq. 1) have been computed from the dataset for the three scan ranges and assigned to the center-of-volume (CoV) of the respective images. These distortion parameters, scaling in particular, are not a linear function of the volume center – the further the scanner moves away from the parking position the larger the distortion (Figure 4). As such, the three experimental data points were fit with a second order polynomial curve (RMSE << 1e-5) to allow extrapolation of distortion parameters for any realistically possible CoV. The RMSE of the registration, based on the points corrected for longitudinal distortion was 0.27 mm on the calibration dataset and similarly less than 0.2 mm on two different validation datasets acquired with a CoV at 984 mm and 1015.5 mm distance from the CT parking position.

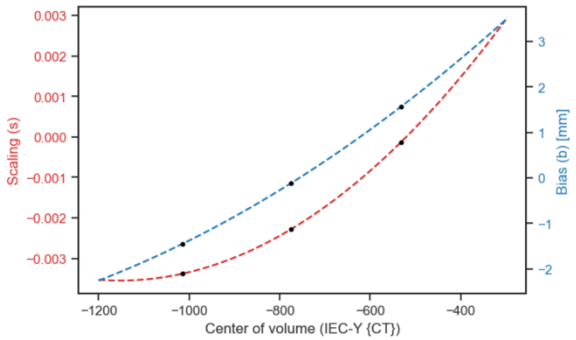

Figure 4: Scaling and bias experimental data as a function of the CT image center of volume and second order fit for paramters extrapolation.

Geometric distortion of CT topogram images

The geometric distortion model presented above has been used to compute the reference dot positions in the longitudinal direction from 3DCT images before comparison with corresponding topogram points. All data was fitted with Huber L2-regularized linear regression (RMSE: 0.33 mm) whose parameters describe the distortion correction of the topogram image coordinates relative to the scanner frame of reference (Figure 5). Residual errors (distance from fit line) on the calibration dataset were within ±0.25 mm of the corresponding (undistorted) reference 3DCT for 50% of the points; all data were within ±1 mm of such a reference.

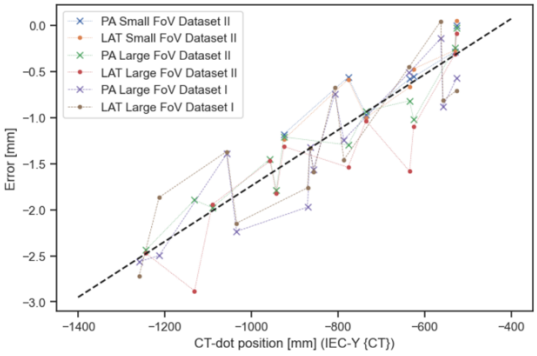

Figure 5: point error in longitudal direction as a function of the distance from the scanner frame of reference in parking position for PA and LAT images at two FoV sizes. Points connected with dotted lines belong to the same acquisition and imaging settings. Fit line is dashed.

Fan beam calibration

Lateral and posterior-anterior projections, each with small and large FoV, were calibrated individually. The patient position relative to the imaging equipment, e.g. head-first-supine / feet-first-supine, was also found to play a role in the topogram image representation, and therefore required specific calibration.
Overall, the RMSE of the corresponding point distances on the calibration dataset were below 0.1 and 0.3 mm for topograms acquired with small or large FoV respectively. A complete end-to-end validation is presented in the following section.

2D/3D registration of head phantom

Multiple registrations have been performed in sequence using topogram images at different resolutions. An initial manual registration that focused on the isocenter sphere has been followed by two automatic runs using topogram image pairs with small and large FoV. Only the phantom head region, excluding the control point sphere, has been considered for automatic registration. Sub-millimeter residual registration errors on the target sphere center with respect to laser tracker have been measured, with discrepancies below 0.3 mm using higher resolution topogram images.

Registration	FoV	x [mm]	y [mm]	z [mm]
Manual	Small	-0.18	-0.01	0.12
Automatic	Small	-0.27	-0.01	-0.05
Automatic	Large	-0.36	0.55	0.13

Table 1: residual errors following manual and automatic 2D-3D registration with CT topogram images with respect to the laser tracker measurement. Directions in IEC-world frame of reference (Figure 1).

4 Discussion

We present the geometrical characterization of a clinical on-rails CT scanner installed in a proton therapy treatment room for patient positioning verification. The procedures and methods for deriving a geometry model to correct the non-linearity in the longitudinal direction have been described for both 3DCT and topogram images, together with the computation of digitally reconstructed images for 2D/3D registration.
Although the concept is the same, i.e. linear scaling of the longitudinal axis coordinates, for 3DCT, the parameters for correcting distortion have a dependency on the center of volume position, whereas for topogram imaging a unique scaling was used. To a large extent, this is due to the difference in the mechanical operation of the scanner between the two imaging modalities. With its internal components spinning at high speed during 3D tomographic imaging, the CT scanner has a strong angular momentum opposing its longitudinal motion. Topogram imaging is different from the mechanical point of view of the scanner, as the source-detector ring is fixed to the angle of projection and this changes the dynamics of the movement. Second-order effects on topogram image geometry may have been masked by the use of manually identified reference positions, which suffer from significant geometric distortions despite using fiducials of small dimension. Higher quality topogram calibration data could allow for more refined models, although their necessity must be evaluated in the context of the overall accuracy of the system for the purpose of patient positioning, which has been shown to be already well within clinical tolerances.
The DRT projection geometry has been studied before in the context of Hi·Art TomoTherapy [4]. Unlike such physics-based models, we have here taken a computer graphics oriented approach, that although may compromise a little on absolute accuracy of DRT image intensity, on the other hand is detector agnostic and allows for implementation as a fast rendering routine. To the best of our knowledge, this is the first report of 2D/3D registration using topograms for clinical application.
The mechanical characterization of the robotic treatment couch, and its sag between imaging and treatment position, is a mandatory requirement to profit from intraoperative CT as a verification imager. However, this aspect is extremely specific to the design of the manipulator and the treatment room, and is beyond the scope of this contribution.

5 Conclusion

We introduced a model of the geometric distortion and fan-beam projection geometry of a CT on-rails. The model was further integrated into a 2D/3D registration framework with orthogonal topogram image pairs.
Once fitted to experimental data from our scanner, we report positioning errors of less than 0.3 mm in single directions for most common clinical settings, supporting the use of this intraoperative scanner as an imaging system for patient positioning in high-precision radiotherapy based on topogram imaging.

Abstract

Introduction: Hypoxic bladder patients benefit from hypoxia modification added to radiotherapy, but no biomarkers are used clinically for patient stratification. We aimed to investigate the potential of OE-MRI to identify hypoxia in xenografts derived from MIBC.

Methods: MIBC cells were inoculated into nude mice. Mice were imaged 1h after receiving a pimonidazole injection with an Agilant 7T 16cm bore magnet interfaced to a Bruker Avance III console and a T2-TurboRARE sequence using a dynamic MPRAGE acquisition. Dynamic Spoiled Gradient Recalled Echo images were acquired with 0.1mmol/kg Gd-DOTA injection. Tumours were harvested, sectioned, RNA extracted for transcriptomic analysis.

Results: Hypoxia scores were higher for pimo-high vs pimo-low samples (p=0.0002). Expression of known hypoxia-inducible genes were higher: *CA9* (p=0.012) and *SLC2A1* (p =0.012).

Conclusion: Hypoxic regions determined using OE-MRI were greater in the larger tumour. OE-MRI reflects other measures of successfully implemented in MIBC derived xenografts and differences in their transcriptomic profiles.

Introduction

The development of cancer is a multi-step process driven by both genetic and environmental factors [1]. Hypoxia is a feature of most solid tumours associated with genomic instability and treatment resistance particularly to radiotherapy [2]. Improved responses can be achieved by hypoxia modification during radiotherapy [3]. To date, there are no biomarkers in clinical use that identify patients with hypoxic tumours. Hypoxia scores derived from the collective expression of multiple genes have been shown to predict benefit of hypoxia modification [4-6]. Advanced functional imaging modalities have the ability to identify hypoxia and study genomic instability and heterogeneity of tumors associated with tumors [7]. Medical imaging techniques can identify regions within tumours for additional treatment dose and are suitable for serial measurements [8]. Combining two magnetic resonance imaging (MRI) techniques, oxygen-enhanced MRI (OE-MRI) and Dynamic Contrast Enhanced (DCE-MRI), enables the non-invasive mapping of hypoxia in tumours. [9]. DCE-MRI identifies regions within tumours that are perfused whilst OE-MRI show regions that utilise oxygen.
Imaging genomics links medical imaging with molecular profiling for biomarkers discovery. Radiogenomics offers a promising avenue for personalised medicine, enabling non-invasive characterization of tumours, prediction of treatment response, and improved patient outcomes [7, 10]. The aim of this study was to implement OE-MRI/DEC-MRI in a xenograft model of bladder cancer for future hypoxia biomarker target discovery to enhance the radiotherapy outcomes.

2 Materials and Methods

HT1367 MIBC cells were inoculated subcutaneously into the flanks of female CD nude mice with (1×10^6 cells in 100µl saline) (0.1ml vol). The injection was done under isoflurane anaesthesia. All experiments were carried out under UK Animals (Scientific Procedures) Act 1986, UK Home Office regulations. When the tumors reach 300 mm^3 (small) or 700 mm^3 (large) in diameter, mice were injected (ip) with the hypoxia marker pimonidazole (pimo) 1h before imaging. The Mice were then placed in an Agilant 7T 16cm bore magnet MRI interfaced to a Bruker Avance III console. The mice were first imaged with OE-MRI to obtain the oxygen signal following by DCE-MRI to identify the regions of hypoxia based on the diffusion. Animals were scanned using T2-TurboRARE, oxygen-enhanced MRI (OE-MRI), and dynamic-contrast enhanced MRI (DCE-MRI). OE-MRI scans were acquired using a dynamic MPRAGE acquisition: TR/TE=6000/3.10 ms, TI=2000 ms, voxel size=0.234 x 0.234 x 0.5 mm, 30 slices with total duration of 32 minutes. The anaesthetic carrier gas was switched from medical air to 100% O_2 midway through the OE-MRI scan, and kept at 100% O_2 for the remainder of the scanning session. Following OE-MRI, DCE-MRI was performed to determine perfused volume pixel (voxels). Dynamic Spoiled Gradient-Recalled (SPGR) images were acquired for 5 minutes 52 seconds (flip angle=30°, TR/TE=10.2/1.9 ms), with 0.1mmol/kg Gd-DOTA (Dotarem, Guerbet) injected after 60 seconds at 1mL/min with a tail vein cannular to intravenous (i/v), under anaesthesia, during the scan as a contrast enrichment.
Voxel size and field of view (FOV)of DCE-MRI and OE-MRI scans matched. The voxels with significant post-contrast enhancement ($p<0.05$) in DCE-MRI scans were classified as perfused and tissue was split into pOxyE and pOxyR regions. The tumours were harvested in liquid N_2, sectioned and RNA extracted from two 10um sections for transcriptomic analysis using Clariom S microarrays.

3 Results

1. Identification of oxygen-rich and perfused regions

Figure 1 illustrates regions of enhancement oxygen in tumours using OE-MRI (i) and prefusion using DCE-MRI (ii). The regions of oxygen enhancement and perfusion in were identified white (iii) in small and large xenograft bladder tumours.
Figure 1B shows montage plots of the oxygen-enhancement (OE-MRI) maps and perfusion (DCE-MRI) in slices from left to middle and from right to middle of the small and large tumour. Regions that are perfused normoxic (pOxy-E) are shown in yellow and regions that are perfused hypoxic (pOxy-R) are shown in blue.

Table 1 shows the overall measurement of normoxia (P-OxyE) and hypoxia (P-OxyR) and the proportion of tumours that are necrotic in the small and large tumour. Both hypoxia and necrosis are higher in the larger compared with the smaller tumour.

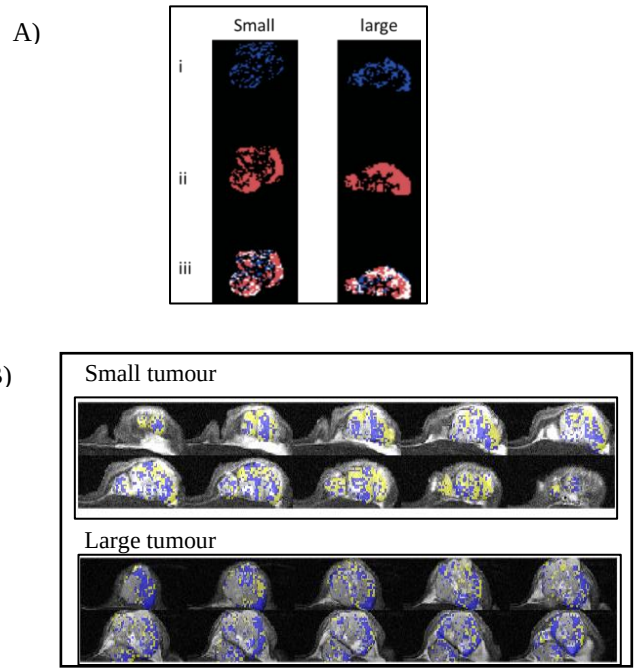

Figure 1: (A) Regions of oxygen enhancement (i) in blue, perfusion (ii) in red and a Montage (iii) of (i) and (ii) illustrating regions of perfusion and oxygen enhancement in white. (B) Montage of images derived by OE-MRI and DCE- MRI for the small tumour and large tumour. Top image in each panel reflects the right side of the tumour and bottom image reflects the left side of the tumour. Perfused normoxic areas (pOxyE) (yellow), perfused hypoxic areas (pOxyR) (blue) and not perfused areas identified (grey).

	Small tumour	Large tumour
Perfused	73%	48%
Perfused OxyE (normoxic)	49%	24%
Perfused OxyR (hypoxic)	51%	76%
Non-perfused (necrotic)	27%	52%

Table 1: Percentage of small and large tumour that is perfused, perfused with O_2-enhancement (normoxic), perfused without O_2-enhancement (hypoxic) and not-perfused (necrotic).

2. Identification of hypoxic, non-hypoxic and necrotic regions

Figure 2 shows regions stained with the pimo-antibody in sections immediately adjacent to the upper and lower sections micro-dissected for RNA extraction. The locality of both pimo-staining is similar in both indicating that the regions of hypoxia will be consistent though the micro-dissected.

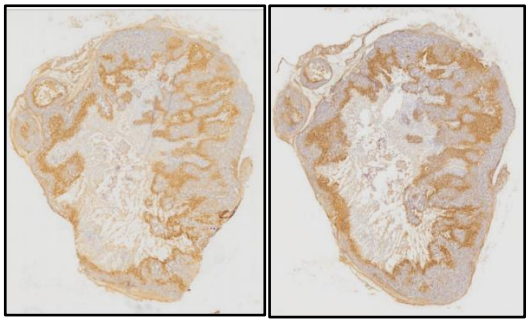

Figure 2: Sections above and below micro-dissected series of sections. RNA extraction from xenografted tumours.

3. Expression of genes associated with hypoxia

Figure 3 shows the increase in the expression of known hypoxia associated genes, *CA9* (p=0.012), *SLC2A1* (Glut-1) (p =0.012) and *VEGFA* (p=0.0152) in pimo-positive (red) compared with pimo-negative regions (blue).

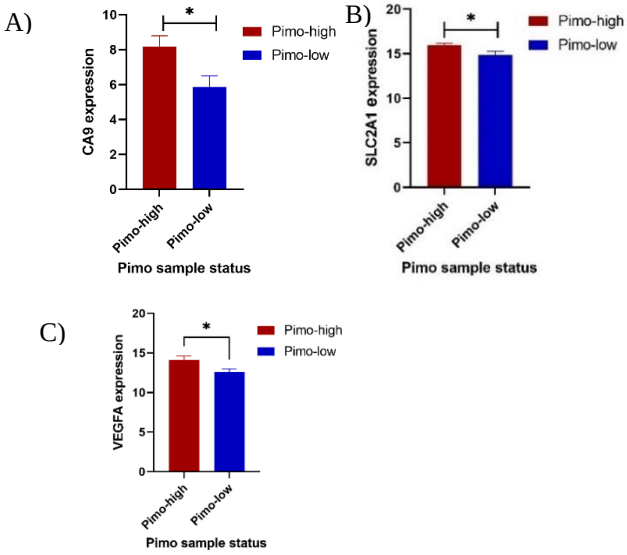

Figure 3: Expression of genes associated with hypoxia. Expression of (A) *CA9*, (B) *SLC2A1* and (C) *VEGFA* in pimo-positive and pimo-negative regions. *p<0.05, ***p<0.001.

4. Hypoxia Score (HS) generated using the West 24 gene hypoxia signature

Hypoxia scores (HS) were generated from both tumours using a 24-gene expression bladder cancer hypoxia signature (Yang et al 2017). Figure 4 shows the HS of each (A) individual sample and (B) mean of the pimo-positive

(n=3) and pimo-negative (n=3) samples. HS was higher (p=0.0052) in the pimo-positive (red circle) than in pimo-negative (blue circle) samples.

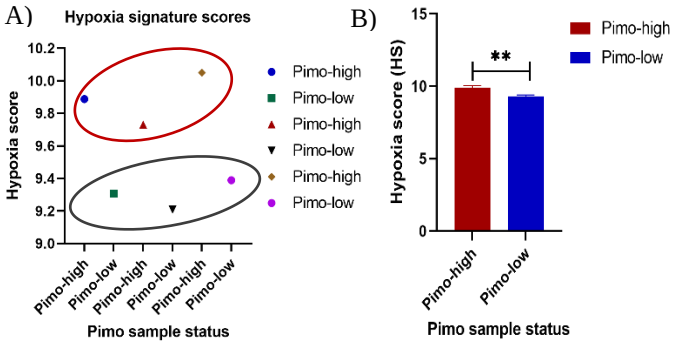

Figure 4: Hypoxia Scores (HS) generated from RNA extracted from pimo-positive and pimo-negative samples. (A) The HS in samples from each pimo-positive and pimo-negative sample. (B) Mean and SD of HS differences (** P.Value<0.0052) between Pimo-positive and Pimo-negative.

4 Discussion

Hypoxia is an important prognostic factor in solid tumors mediating resistance to radiotherapy. The need for hypoxia biomarkers is exemplified by Spiegelberg et al. who found that the failure of phase III trials can be fully explained by lack of patient classification based on tumour hypoxia status [11]. Combined DCE-MRI and OE-MRI for the identification of hypoxia has been validated in clinical [12] as well as pre-clinical [13] work, and is therefore a reliable tool to combine with genomics for hypoxia biomarker discovery [9]. The higher proportion of hypoxia in the larger tumour compared with the smaller tumour demonstrated using OE-MRI/DCE-MRI agrees with other studies [11, 14, 15]. Hypoxic tumours and necrosis pose significant challenges for radiotherapy [16]. Here, necrosis was also higher in the large tumour and was evident in over half the volume in agreement with previous studies reporting on size association with necrotic fraction [11, 17]. Several studies have shown that the presence of the necrotic regions in tumours associated with hypoxia [18, 19] and that patients with high necrosis benefit with carbogen-nicotinamide (CON) modified therapy [18]. Identifying the relationship between hypoxia and its role in promoting cancer progression and resistance to radiotherapy were performed. Tumour hypoxia induces angiogenesis through up-regulation of *VEGF* expression. Other mechanisms that enable cancer cells to thrive in hypoxic conditions include up regulation of cell surface expression of Glut-1 thus increasing glucose uptake to fuel glycolysis and *CA9* to reduce the consequent intracellular acidification. Genes encoding the cell surface proteins CAIX, GLUT-1 and *VEGF3* (*CA9*, *SLC2A1* and *VEGF3*), associated with hypoxia [20, 21], had increased expression in pimo-positive regions. Clinical work has shown that both *CA9* and Glut-1 co-localise with pimondazole (GLUT1: P<0.0001) and (*CA9*: P<0.0001) in patients with MIBC [20]. Studies have demonstrated that overexpression of CAIX and GLUT-1 protein in squamous cell Head and Neck Cancer and MIBC is associated with poor response to chemotherapy [22]. Genomic analysis helps to better understand the biology of bladder cancer leading to the identification of disease at early stages, facilitates patient stratification and predicts patent outcome. Combining hypoxia imaging techniques with gene expression signatures are likely to provide robust biomarkers of tumour hypoxia leading to improved patient treatment selection and develop personalised radiotherapy [23]. DCE-MRI parameters, like the pharmacokinetic marker ABrix, can pinpoint tumour hypoxia, a key factor in treatment resistance, while gene expression profiles reveal the underlying molecular landscape.

This approach allows for the construction of personalised gene signatures that predict response to radiotherapy, enabling tailored treatment strategies. This personalised approach, informed by both functional imaging and molecular fingerprints, has the potential to improve tumuor control, reduce side effects, and ultimately enhance radiotherapy outcomes for cancer patients.

5 Conclusion

Hypoxic regions determined using OE-MRI were greater in the larger tumour. OE-MRI reflects other measures of successfully implemented in MIBC derived xenografts and differences in their transcriptomic profiles determined in

same tumours. OE-MRI should be further investigated in bladder cancer.

Abstract Treatment of non-small cell lung cancer with proton therapy allows for delivery of high radiation dose while sparing critical normal tissue structures compared to conventional photon therapy. However, there are currently no established clinical endpoints to study the biological effect between these radiation modalities. Computed tomography (CT) imaging allows for extraction of ventilation through deformable image registration of 4DCTs and may provide information on imaging-based functional changes in the lung. We hypothesize that patients treated with protons exhibit different changes in ventilation compared to those treated with photons. For 20 photon and 20 proton cases, ventilation was extracted using 4DCT Jacobian-based methods and correlated with dose and radiation-induced pneumonitis development. Ventilation was tracked over the course of treatment on a voxel-wise basis and stratified into high and low function. Ventilation differences across modalities were compared by function and pneumonitis development. Patients treated with protons exhibited statistically significant improvements in ventilation change of low functioning voxels compared to photon patients. Future work will evaluate ventilation change specifically in the lung regions that developed pneumonitis.

1 Introduction

Lung cancer is the leading cause of cancer death and the second most common form of cancer in the U.S [1]. 80-85% of lung cancer is non-small cell lung cancer (NSCLC) [1], and while surgical resection provides the best outcomes, radiotherapy (RT) is a more feasible option for many patients, especially those advanced in age. However, the lungs are particularly radiosensitive, and RT often leads to toxicities such as radiation-induced pneumonitis (RP) which reduce patient quality of life after treatment [2], [3].

Proton RT is a promising option to reduce normal tissue toxicity, but research to date has failed to demonstrate a clear difference in toxicity development between patients treated with photon or proton RT [4], [5]. Current clinical practice for toxicity modeling and outcome prediction in proton RT relies solely on regional dosimetric factors, such as dose volume histograms (DVHs) and does not incorporate patient-specific biological factors. However, since proton RT is known to produce a different biological effect compared to photon RT [6], [7], [8], biological factors should be considered when designing toxicity models.

Computed tomography ventilation imaging (CTVI) uses deformable image registration (DIR) of 4DCT images to calculate ventilation and has emerged as an efficient alternative to typical ventilation imaging such as single-photon emission computed tomography (SPECT) or positron emission tomography (PET). It has been validated in both animal and human studies [9], [10], and clinical trials have begun to show the potential of using CTVI to design treatment plans that reduce dose to highly functional areas of the lung for toxicity reduction [11], [12]. In particular, it has been shown that pre-treatment ventilation is correlated with dose and pneumonitis development for photon patients [13], [14]. While research has shown that CTVI can be feasibly incorporated into functional avoidance plans for proton therapy [15] and can improve toxicity models for photon patients [16], [17], [18], toxicity models for proton RT have not yet incorporated such functional changes to predict outcomes at a voxel level.

In this study, we extracted ventilation from 4DCTs using Jacobian-based ventilation for both photon- and proton-treated patients. We evaluated how each patient's ventilation changes on a voxel-wise basis over the course of treatment across treatment modality, RP development, and dose. We hypothesize that there will be significant differences in ventilation change over treatment across radiation modalities. In particular, since proton RT is known to reduce normal tissue toxicity, we hypothesize that proton-treated patients will have a greater capacity for ventilation improvement due to greater sparing of normal lung tissue.

2 Materials and Methods

40 patients treated for NSCLC were chosen retrospectively from a randomized clinical trial [4]. 20 patients were treated with photon RT, 12 of which developed RP, and 20 patients were treated with proton RT, 10 of which developed RP. Photon patients were treated with intensity modulated radiation therapy (IMRT) and proton patients were treated with passive scattering proton therapy (PSPT), each for 37 fractions at a prescription dose of 74 Gy. All patients received concurrent chemotherapy. Each patient had 4DCTs acquired for planning and weekly up to the final week of treatment, as well as a PET/CT scan acquired 3-12 months after treatment, which was used to diagnose RP. Dose plans for each patient were calculated on the exhale (T5) scan of the planning week.

The Jacobian determinant, shown below, is a representation of local volume change and can be calculated using DIR [9].

$$J(x,y,z) = \begin{vmatrix} 1+\frac{\partial u_x(x,y,z)}{\partial x} & \frac{\partial u_x(x,y,z)}{\partial y} & \frac{\partial u_x(x,y,z)}{\partial z} \\ \frac{\partial u_y(x,y,z)}{\partial x} & 1+\frac{\partial u_y(x,y,z)}{\partial y} & \frac{\partial u_y(x,y,z)}{\partial z} \\ \frac{\partial u_z(x,y,z)}{\partial x} & \frac{\partial u_z(x,y,z)}{\partial y} & 1+\frac{\partial u_z(x,y,z)}{\partial z} \end{vmatrix}$$

The Jacobian determinant of the displacement vector field (DVF) from each registration was used to determine each voxel's differential expansion or contraction, enabling the calculation of the specific volume change of the voxel, *J(x,y,z) – 1*. An additional scaling factor using the Hounsfield Unit (HU) values of the associated T5 scan of the 4DCT was incorporated to provide a more physiologically accurate measurement of ventilation and converted specific volume change to specific ventilation [19], denoted by *V*:

$$V = \left(\frac{-HU}{1000}\right)^{-1} * (J(x,y,z) - 1)$$

Figure 1 shows the workflow for determining voxel-wise correlation of the Jacobian over treatment. First, intra-fraction DIR using a hybrid intensity-based algorithm was performed between the T0 and T5 scans of the 4DCTs for the planning week and final week of treatment separately. Focus ROIs were used to align the lung contours during the registration process. The resulting intra-fraction DIRs were used to calculate the Jacobian determinant. Next, an inter-fraction DIR was performed between the T5 scans of the planning and final weeks of treatment. This step allowed for voxel-wise correspondence across timepoints. For photon patients, a biomechanical-based algorithm was used to perform the inter-fraction DIR, and a hybrid intensity-based algorithm was used for the proton patients. The DVF from the inter-fraction DIR was applied to the Jacobian map from the final week to map it to the planning week coordinate space. The resulting Jacobian maps were then scaled using the HU correction factor to calculate ventilation. Since the planned doses were also done on the T5 scan of the planning week, the dose maps match the Jacobian maps on a voxel level. Lastly, the gross tumor volume (GTV) was segmented using an in-house segmentation model and removed from the evaluation to avoid erroneous ventilation calculations. Grills et al. found that GTV contours underestimate composite pathologic tumor size by 1.2 mm [20], so all GTV contours were expanded by 3 mm to ensure consistency before removal from the lung contour.

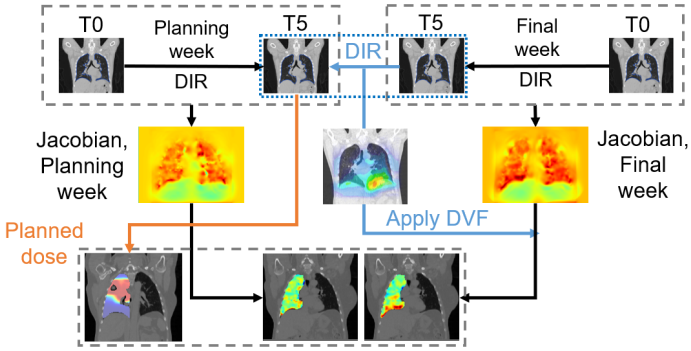

Figure 1: Workflow figure to extract voxel-wise change in ventilation over the course of treatment and accumulated dose using deformable image registration (DIR) and deformation vector fields (DVFs).

The change in ventilation between beginning and end of treatment for each voxel was calculated for each patient. Voxels were then stratified by function, toxicity, and treatment modality. To stratify voxels by function, the median Jacobian value was determined from the planning week ventilation map for each patient. A high functioning voxel was defined as a voxel that had a ventilation value above the median value in the planning week, and a low functioning voxel was defined to have a ventilation value below the median value in the planning week. After stratifying by function, voxels were binned by dose in 5 Gy increments and the ventilation differences were averaged in each bin. The averaged differences were plotted against dose for proton and photon patients, split into RP vs. non-RP patients for all voxels, then split again into high vs. low functioning voxels. T-tests were conducted on the ventilation differences between photon and proton patients, within each dose bin as well as across all dose bins.

3 Results

Boxplots of the average differences in ventilation for photon and proton patients are shown in Figure 2. Average differences further split into high and low functioning voxels are shown in Figure 3.

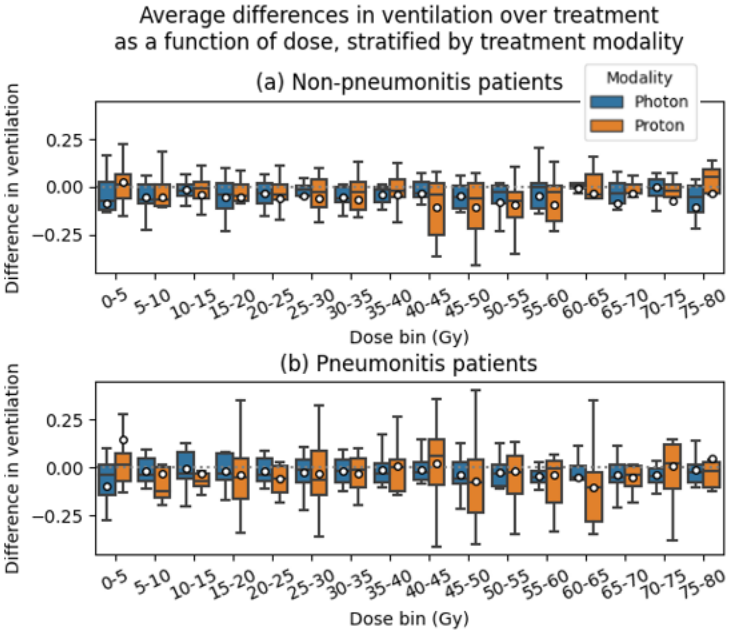

Figure 2: Boxplots of average differences in ventilation for patients that did not develop pneumonitis (a) and patients that did (b). Patients were split into photon and proton cohorts, shown in blue and orange respectively. Dose bins are 5 Gy in width and range from 0 to 80 Gy. Ventilation function is determined by the median of the ventilation values from the planning week.

High functioning voxels decreased in ventilation over the course of treatment while low functioning voxels increased in ventilation, with relatively small changes in overall ventilation averaged across function. In the high functioning voxels, ventilation tended to decrease by a greater magnitude for proton treated patients compared to photon treated patients. In contrast, proton patients

demonstrated an increase in ventilation in low functioning voxels where photon treated patients did not.

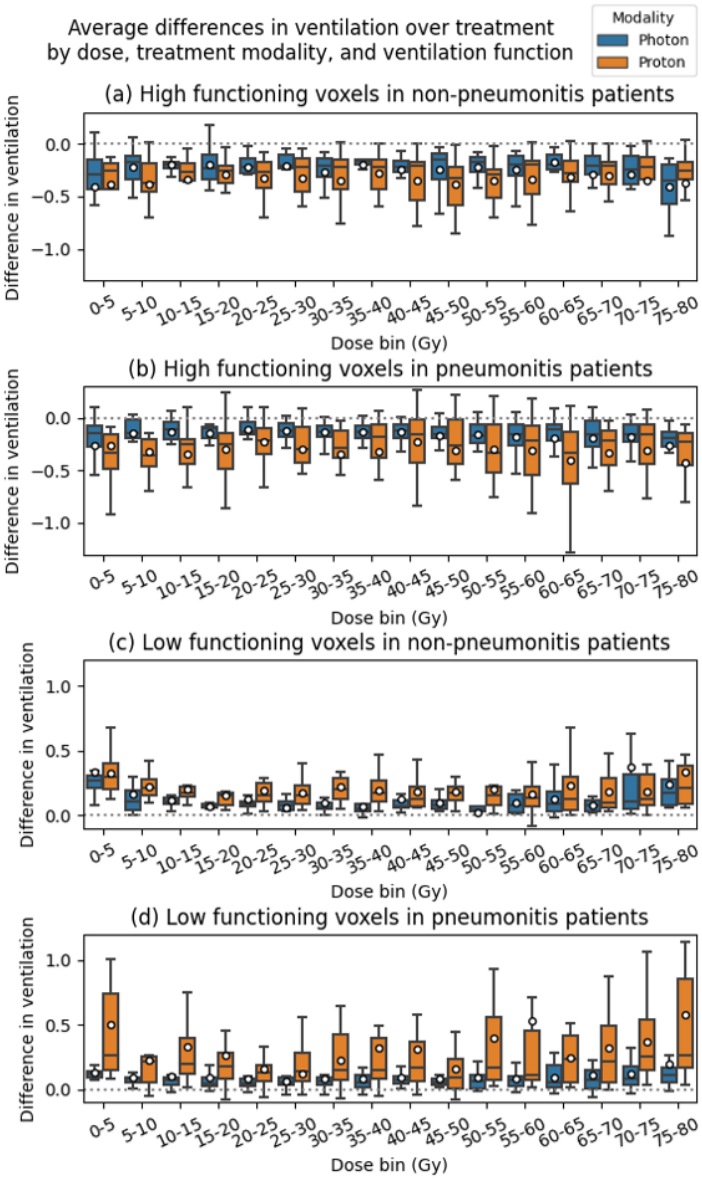

Figure 3: Boxplots of average differences in ventilation for pneumonitis (RP) and non-RP patients, split by toxicity and ventilation function. (a) and (b) show high functioning voxels in patients that did not and did develop RP respectively. (c) and (d) show low functioning voxels in patients that did not and did develop RP. Patients were split into photon and proton cohorts, shown in blue and orange respectively. Dose bins are 5 Gy in width and range from 0 to 80 Gy. Ventilation function is determined by the median of the ventilation values from the planning week.

Ventilation differences for all voxels prior to stratification by function were not found to be significant. T-test p-values for the high and low functioning voxels corresponding to Figure 2 are shown in Table 1. Ventilation differences were found to be statistically significant ($p < 0.05$) when considering all dose bins. Within each dose bin, statistical significance was found only in the low functioning voxels. In particular, the 15-20 Gy, 25-30 Gy, and 30-35 Gy dose bins were found to be statistically significant when comparing patients that did not develop RP, and the 70-75 Gy dose bin was significant when comparing patients that developed RP.

Table 1: P-values for t-tests conducted across treatment modalities. T-tests were performed for each cohort within each dose bin and over all dose bins combined. Statistically significant p-values are shown in bold.

Dose bin (Gy)	Low function, non-RP, photon vs. proton	Low function, RP, photon vs. proton	High function, non-RP, photon vs. proton	High function, RP, photon vs. proton

4 Discussion

Statistical significance was found when comparing all dose bins, indicating that there is a significant difference in ventilation overall when comparing modalities. High functioning voxels exhibited a decrease in ventilation over the course of treatment for all patients while low functioning voxels increased over the course of treatment. These findings were similarly demonstrated in Patton et al. [13], who showed that higher functioning voxels decreased by 4.8% per 10 Gy compared to lower functioning voxels, which decreased by 2.4%. Additionally, statistical significance within dose bins was found mostly above 20 Gy, which has also been shown to be a significant threshold for toxicity development by King et al. [21] and Graham et al. [22].

Proton patients tended to have more extreme changes in ventilation overall as demonstrated by the t-tests. In the low functioning voxels, the increase in ventilation was significantly higher for proton patients, supporting the hypothesis that the higher sparing of normal tissue in proton RT allows for greater increase in function, due to sparing of normal tissue.

Some limitations of this study include the lack of spatial information for each voxel and the large amounts of averaging for each patient. Future work will include a more in-depth analysis of the voxels within the regions of the lung that developed RP for patients that were diagnosed with RP. Since different DIR strategies were employed across time points for photon patients compared to proton patients, we will also be comparing results achieved with the same inter-fraction DIR. The photon patients in our dataset also have accumulated dose plans, and a future study will compare how ventilation changes for planned and accumulated doses. Lastly, additional patients will be incorporated for further analysis.

5 Conclusion

We developed a workflow to calculate voxel-wise change in lung ventilation and dose using Jacobian-based methods. Proton patients exhibited more extreme changes in ventilation in comparison to photon patients. Future work will incorporate more patients and work towards establishing CT based lung ventilation as a functional endpoint when evaluating differences between photon and proton therapy.

Abstract In vivo dosimetry (IVD) using the electronic portal imaging device (EPID) can increase accuracy of radiotherapy treatment (RT)by catching treatment errors, monitoring dose delivery, and assist in treatment adaptations. As manual assessment of information generated by the EPID is labor intensive work, artificial intelligence (AI) has been proposed to catch treatment errors. To foster the translation from research to clinical implementation, a human-centric design process consisting of a five-day design sprint was taken, yielding a prototype of an interface to interact with the AI, including AI certainty metric, explainable AI (XAI), and a decision-aid tool. The prototype was well received by end-users. Further work will focus on the AI certainty metric, and development of appropriate XAI.

1 Introduction

In vivo dosimetry (IVD) aims to catch treatment errors, assist in treatment adaptation, and monitor the actual dose delivered to the patient [1]. For external beam radiotherapy, the electronic portal imaging device (EPID) lends itself well for IVD. In practice, IVD using EPID is rarely performed, as assessing the complex and multitude of EPID-generated information is too time consuming to act upon treatment errors in time as required for dose-guided radiotherapy (DGRT). Recently, developments using artificial intelligence (AI) allow for rapid processing of these large quantities of complex EPID generated data to extract relevant information for further decision making [2].

In practice, only few AI systems developed for supporting the radiotherapy (RT) workflow reach the clinic. To ensure maximum utility of the AI and foster human-AI collaboration, the development of clinical AI systems interacting with humans requires a human-centric approach [3]. To promote IVD for clinical practice, we designed an AI-based system to evaluate treatment accuracy and detect treatment errors by automatically analyzing EPID images, while presenting human-interpretable information to users.

2 Materials and Methods

Design thinking is a systematic innovation process that prioritizes needs and challenges of the end user [4], instead of first progressing through a lengthy development process before presenting a finished product to the end users. A team of experts with expertise in user experience design, AI and medical physics participated in a five-day design sprint using the principles of design thinking to develop a prototype of the proposed system. In total, eight people actively participated in the design process which was a mix of researchers and experts from industry. An additional six experts, four user experts and two industry experts, were consulted during the exploration and testing phase. The co-creation design methodology covers the phases of empathize, define, ideate, prototype and test (Figure 1).

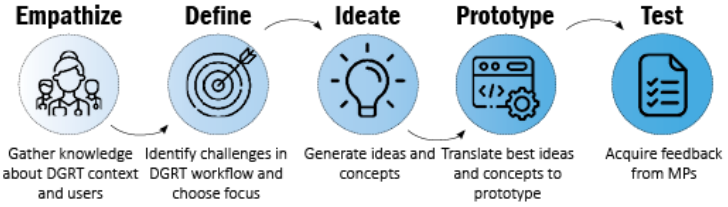

Figure 1 Steps of the co-creation design process.

The goal of the interface development was collectively drawn up and reads as follows: *"With DGRT.AI based on EPID & AI in 5 years, the medical physicist will be able to confidently detect and verify treatment errors, including root cause analysis, quickly enough to support decision-making, and taking actions when needed, always before the next fraction, to achieve safer treatment for every patient."*

In the empathize phase, three medical physicists (MPs) and three experts on radiotherapy quality assurance were interviewed. During the interviews, the goal of the interface and workflow mapping was validated, and challenges or bottlenecks in the DGRT workflow were identified.

2.1 Materials

A rapid prototype was developed using Figma inc [5]. The prototype allows for interaction with users. Synthetic images of the projected errors were generated using an in-house tool to introduce errors into the CT image, allowing for realistic synthetic images [6].

2.2 Evaluation

Finally, the prototype was tested with the end-users. The users were asked to provide feedback and to rate the system on a 7-Likert scale based on the technology acceptance model [7].

3 Results

Resulting from the design process, some novel features to interact with the AI were drawn up. These feature take into account information overload by providing a compact view of the fractions that need assessment. An in depth investigation is possible by clicking through the fraction, presenting all the information the MP needs to assess the fraction for errors.

3.1 AI-based treatment error detection

To detect the treatment error, a convolutional neural network is employed trained on time-integrated 2D gamma maps [2]. With the current performance, the AI is able to detect ten different error classes with 86.6% accuracy on synthetic data. Ongoing work aims to translate these results to real-world data. In case of an error, the error type is shown in the general overview of the developed prototype.

3.2 Overview fractions

After logging into the system, the user is provided with a list of all fractions that were flagged by the software. General information about the patient is provided, such as name, patient ID, and how far along the patient is in their treatment. The latter is important information for the user to judge how urgent the patient's fraction needs to be assessed, e.g., the last fraction of a treatment will be less urgent than a fraction in the middle of a treatment. The view is automatically ordered on error status so that the fractions containing an error are on top of the list. On the start page, the MP can see in a blink of an eye which fractions have the highest priority for further investigation as the AI-detected error is shown, including status and AI certainty score. If the AI certainty score is low (threshold to be determined), the fraction requires manual assessment by the MP (Figure 2). The information provided in the first view is kept at a minimum to prevent information overload. This was confirmed during the evaluation phase, where the MPs noted the simplicity of the system and highlighted the ease of use as their first reaction.

Error	Status	AI Certainty
Tumor regression	Failed	99.0%
Tumor shift	To be investigated	44.3%

Figure 3 Snippet of the AI information given in the first overview. The system shows which error was detected. In case of an error with high certainty, the system will tell the MP that the fraction failed. In case of low AI certainty, manual investigation by the MP is required.

3.3 Detailed fraction information

By clicking on the fraction, information relevant to the AI-classified treatment error is provided. In the example of tumor regression, the most relevant information needed to confirm the AI error classification is anatomical information, so the planning CT and CBCT images are shown (Figure 3). If desired, the user can find additional information in the left panel, such as dose information, PDIs including gamma analysis, dose recalculation based on log files, or a 3D rendering of the CT and dose.

Figure 2 Detailed view of the prototype showing the anatomical information of the patient. The MP can choose another view in the left panel. Upper red dashed area shows the AI-classified error, including the certainty score, and the options the MP has (review AI or Make decision).

3.4 AI certainty

An important property of the system is the AI certainty. By providing the AI certainty, the user may get an idea which fractions need to be manually assessed. As one of the expert users pointed out, the combination between the error status and the AI certainty gives an idea of the case complexity. While this feature was generally well received by the end-users, one of the users pointed out that the certainty score can cause some confusion. To prevent this, a detailed explanation should be available which describes how the AI certainty metric was established and how the metric should be interpreted.

3.5 Decision making aid

In practice, it is not always clear what the best decision is after detecting a certain treatment error. In our design, we propose to follow up based on protocols embedded in the system. We envision the embedded protocols to be developed based on predefined guidelines by the radiotherapy community (e.g., by ESTRO or AAPM), however, clinics can adjust the protocol to match their own protocol. Another option for the MP is to view the hospital's most used decisions for the detected treatment error to evaluate which actions have been taken in similar cases. This is a process to establish the human-AI shared decision making.

3.6 Explainable AI and feedback

If the user is skeptical about the AI decision (e.g., in case of low AI certainty), they can choose to evaluate the AI by looking at the AI explanation. In our prototype, a heatmap is overlaid over the gamma map highlighting the areas of the image that the AI considered most important for the error detection, as an explainable AI (XAI) method. The heatmap in the prototype was artificially developed. To avoid information overload to the user, the XAI information is available upon request. If the user agrees with the AI prediction, they can accept. The end-users expressed to appreciate the XAI feature to gain trust in the AI decisions.

4 Discussion

Using a co-creation strategy we were able to, within a week, prototype a novel human-interpretable system to detect RT treatment errors and aid the DGRT decision making process. Where practitioners typically choose to focus on IGRT or DGRT, our prototype allows for a combination of both to exploit their advantages, as well as AI-powered error detection which can substantially aid in streamlining these workflows. The prototype sparked enthusiastic responses from end-users. Regardless, some considerations for future work should be kept in mind.

The AI certainty metric played an important role in the MP's trust in the AI system. Computing a trustworthy AI certainty metric has not been the focus of our prototype development, but presents a challenge for the development of the presented system. To account for an accurate AI certainty metric, we endeavor to develop an AI verification framework that is able to output a certainty estimate that is accurate enough to be used in clinical practice. Additionally, in a follow up study, we aim to investigate how the explainable AI feature should be designed to best fit the user needs. XAI is a novel line of research that aims to explain why the AI makes a certain prediction. The XAI requirements are very dependent on the user's knowledge and needs. The MPs liked the XAI feature, but the current solution was difficult to interpret. Designing an optimal AI explanation was outside of scope for the presented prototype, but will be incorporated in future work.

One of the challenges identified during the exploration phase was the trend analysis of errors. The current design does not include this feature. In the evaluation phase, however, it was mentioned that trend analysis would be an interesting feature to add. In future work, we endeavor to study how AI can detect systematic and random inter-fraction treatment errors.

5 Conclusion

By undertaking a novel approach in the design of an interface for automatizing AI for radiotherapy, we developed a prototype to aid IVD. The system is designed to provide the user with enough information to evaluate each fraction in a first glance, but allows for further exploration of the data collected each fraction and AI tool. To empathize, define, ideate, prototype and test the system, the users participate the whole design cycle to leverage both human intelligence and artificial intelligence to make clinical process with more informed, efficient and effective decisions. Novel components of the system include an AI certainty estimation, XAI and feedback component, and an AI-driven decision aid.

Abstract
This study introduces a novel approach to ocular proton therapy treatment planning of ocular tumours. The aim is to autonomously equip planners with information derived from recent normal tissue complication probability (NTCP) models and predictive factors for radiation induced side effects, to assist the planners in sparing of healthy tissue. This is accomplished by utilizing our in-house dose engine OptisTPS, where we integrate machine learning (ML) and a tailored cost function to streamline computations for identifying an attainable eye orientation for treatment. The ML predictions efficiently reduce the search area for attainable eye orientations which has been demonstrated for a cohort of 190 patients. Results from the integration of the cost function and NTCP models are displayed for sampled gaze fixation points, where color represents either cost of arbitrary unit or the probability of radiation-induced toxicity, across 12 investigated patients.

1 Introduction

Ocular proton therapy (OPT) planning, established with Eyeplan [1] over four decades ago, aims to ensure target coverage while preserving delicate eye structures' functionality. Planners select gaze fixation points to determine suitable eye orientations for isocentric treatment. This study aim to identify a close to optimum eye orientation for treatment, prioritizing the sparing of healthy tissue, whilst also preserving target coverage. This is accomplished by applying penalties to dose points linked to elevated risks of radiation-induced toxicity, as outlined in [2], through dose calculations performed by our in-house developed dose engine which is a part of the OptisTPS framework. ML is used to minimize the required computational time by initially predicting a starting point for the optimization algorithm. Dose calculations are subsequently analyzed for the probability of radiation-induced side effects.

2 Materials and Methods

We integrate dose calculations from our in-house treatment planning system, OptisTPS, with a patient 3D point cloud model (Figure 1) exported from Eyeplan. This integration involves incorporating an ML algorithm to reduce the search area for determining a favourable eye orientation. All data used in this study originates from patients previously treated at our facility, the Centre for Proton Therapy (CPT), located at the Paul Scherrer Institute (PSI) in Switzerland. OptisTPS calculates 3D dose distributions based on proton range and modulation length, derived from target and patient surface models. The dedicated dose engine in OptisTPS follows the principles outlined in equation 5 of [3], integrated into an object-oriented framework with design decisions drawing inspiration from the matRad system [4]. Recently, OptisTPS was validated against Eyeplan and compared to measured patient specific depth dose profiles for 50 patients [5].

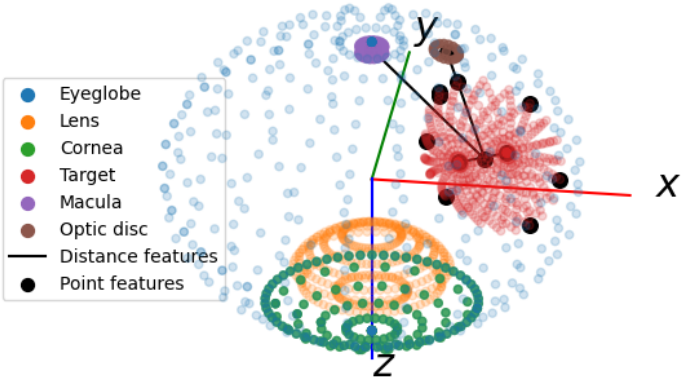

Figure 1: Point cloud patient model exported from Eyeplan in the gaze centered reference frame with highlighted features for gaze point prediction.

The 3D point cloud model of the patient is characterized by a spatial arrangement of points that represent the target and eye structures at risk, including the lens, cornea, macula, optic disc, and the entire eye globe from which the target is subtracted. Its orientation is determined by its rotation point and the direction of its gaze vector. We define a cost function that incentivizes the minimization of specific dose points associated with an increased risk of inducing secondary toxicities in eye structures at risk. The primary objective of including the ML algorithm is to predict an initial attainable gaze fixation point thus narrowing the search area for determining a favourable eye orientation for treatment. In this investigation, we examine a grid comprising 60x60x60 voxels, each with a resolution of approximately 0.59 mm/voxel, similar to the grid parameters in the corresponding clinical treatment plan defined in Eyeplan.

2.1 Optimization

In the realm of OPT, optimization is the pursuit of identifying the gaze fixation point corresponding to the eye orientation with optimal sparing of healthy eye structures for the patient. This is because nozzle setting is defined in such a way that target coverage is ensured. The objective of the optimization can therefore be formulated with equation 1 as:

$$\underset{O}{\text{minimize}}, \mathscr{C}(O) \tag{1}$$

where O represents an attainable eye orientation for treatment, and $\mathscr{C}(O)$ is the cost calculated from the dose simulated by our dose engine for eye orientation O.

2.1.1 Cost Function for healthy tissue sparing

The cost function, as illustrated in equation 2, attempts to emulate the decision-making process of the planner. It calculates $\mathscr{C}$ by applying penalties to the dose deposition attributed to healthy structures of the eye.

$$\begin{aligned}\mathscr{C} = &\sum_{i=1}^{N} \frac{w_i}{M} \sum_{j=1}^{M} Dose_{ij} + \\ &w_{macula} \cdot D_{2\%_{macula}} + \\ &w_{opticdisc} \cdot D_{20\%_{opticdisc}} + \\ &w_{cornea} \cdot D_{20\%_{cornea}} + \\ &w_{lens} \cdot \max(V_{5\%_{\text{lens}}} - 10GyE, 0)\end{aligned} \tag{2}$$

Where:

$Dose_{ij}$ represents the dose-volume points for the i-th structure and j-th volume point,
N is the total number of considered eye structures,
M is the number of dose-volume points considered for each structure (e.g., V5, V10, ..., V100),
w_i is the tunable weight assigned to the i-th structure.

In formulating the cost function, a deliberate strategy has been employed to preserve healthy tissue by leveraging the ocular structures present in the clinical model. This strategy is informed by recent findings on dose-response to healthy tissue [2, 6, 7]. The first term of the cost function penalizes the area beneath the dose-volume histogram curves for the considered eye structures. Though the area itself does not correspond to a clinical outcome, it imposes penalties on dose attributed to those eye structures that are known contributors to neovascular glaucoma (NVG) [6], as well as the dose to the optic disc and macula. The second, third, and fourth terms penalize $D_{2\%_{\text{macula}}}$, $D_{20\%_{\text{optic disc}}}$, and $D_{20\%_{\text{cornea}}}$, respectively. These are based on the findings of Espensen et al. (2021), which demonstrated the predictive capability of these parameters for visual acuity deterioration, optic neuropathy, and NVG respectively [2]. The fifth term is formulated to impose a penalty on the V5 of the lens when exceeding the threshold of 10 GyRBE, as this elevation in dose is associated with an elevated risk of vision-impairing cataracts (VIC) [7]. Furthermore, the cost function imposes an indirect penalty on the dose administered to the ciliary body due to its anatomical proximity to the lens and cornea. This intentional measure is grounded in the demonstrated association between dose to the ciliary body and the onset of cataract [2].

2.1.2 Optimization procedure

This optimization procedure involves generating a randomized set of eye orientations with the target aligned to the beam axis which together define a diverse set of gaze directions to populate the gaze fixation plane. The set of orientations are then filtered by polar limit of 25 degrees and proximity to the ML prediction. The remaining orientations are subsequently assessed for treatment suitability by computing the corresponding dose to the eye structures, cost and NTCP value. The orientations under consideration form 2D maps in the fixation point plane, represented spatially by their polar and azimuth angles and color-coded to the particular costs or NTCP model under investigation.

2.2 Gaze Prediction

Calculating the dose for each eye orientation is a computationally expensive endeavor. Therefore, an ML algorithm is first employed to reduce the necessary search area in which to densely sample the space of attainable fixation points. This gaze fixation prediction function is comprised of a set of random forest regression algorithms, which have been trained on a dataset of 1730 patients previously treated at PSI. This function predicts gaze fixation points by extracting geometric features from the patient's anatomy as represented by the patient model. These features include characteristics such as target boundaries, the center of mass of the target, and the proximity of the target to critical eye structures. Visual representation of a subset of selected features, along with the patient model, are depicted in Figure 1.

3 Results

The outcomes for 12 patients are first presented, with two patient cases studied in more detail in subsection 3.1. All results for the investigated patient cases were examined by a licensed medical physicist in OPT. This analysis concluded that all identified gaze fixation spots are acceptable. The cost function can identify a region with similar costs and comparable NTCP values to the clinical fixation point selected by the planner for all examined patients. Differences in NTPC between the clinical fixation point of the fixation point of least cost position are better or within 0.13, 0.14 and 2.81 % of for all investigated patients for optic neuropathy, neovascular glaucoma and visual acuity respectively, based on the findings of Espensen et al [2]. While the examined

fixation space is not exhaustive, the limited ML-assisted cost evaluated sampling was able to identify significant findings in terms of reduced probability of radiation induced toxicities for some patients. Specifically, for optic neuropathy, two patient cases exhibited a decrease in probability of 2 %, and one case showed a reduction of 9 %. In the context of neovascular glaucoma, two patient cases demonstrated a reduction in probability of 5 and 6 %, respectively. Regarding visual acuity, one case showed a 3 % decline.

3.1 Optimization examples

Examples for two patients are shown in figures 2 and 3. In each subplot, explored fixation points are colour coded depending on their cost or probability of radiation-induced toxicity [2]. Both figures show gradients which slope towards favourable healthy tissue sparing, suggesting gaze angle modifications for reducing radiation exposure to health tissue. Specifically figure 2 showcases a potential to reduce the risk of neovascular glaucoma by approximately 5% units with a polar angle increase of 6 degrees. In Figure 3, a case is presented where a gradient of reduced probability of neovascular glaucoma is evident manifested by reduced levels of $D_{20\%}$ to the cornea, however the same change risks increasing the likelihood of visual acuity deterioration.

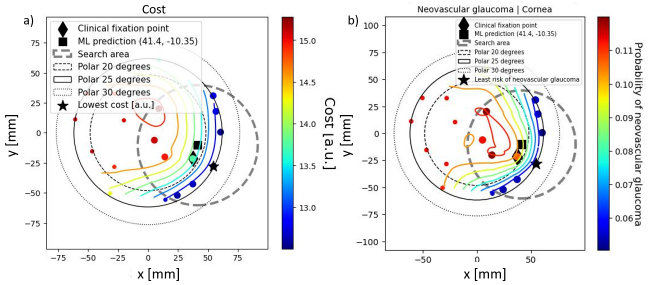

Figure 2: Investigated fixation points for the first patient example are color-coded based on their respective costs (a) or probability of neovascular glaucoma (b) [2].

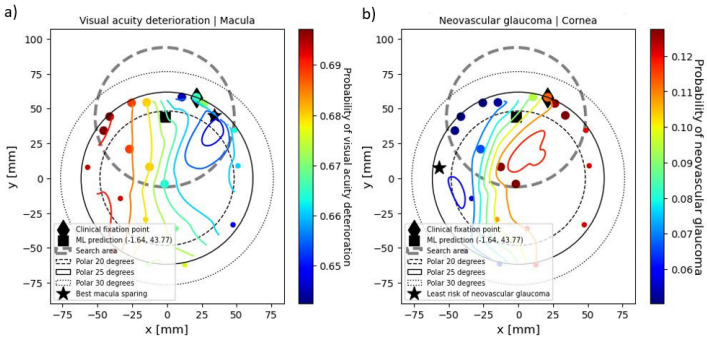

Figure 3: Investigated fixation points for the first patient example are color-coded based on their respective probability of visual acuity deterioration (a) and probability of neovascular glaucoma (b) [2].

3.2 Gaze prediction

The ML predictions closely align with the clinical orientation as shown in Figure 4, deviating by no more than 5 degrees in three quartiles of predictions for 190 patients. The black lines in the figure illustrates the proximity between the predicted fixation point and the clinical fixation point, which often display a slight underestimation of the polar angle. The observed feature importance in our ML algorithm is primary driven by the centre of mass of the target in relation to the centre and rotation point of the model in the gaze centered reference frame.

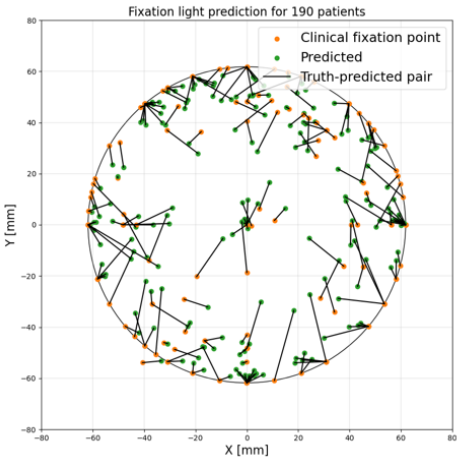

Figure 4: ML predictions for 190 patients and their corresponding clinical fixation point connected with a black line indicating correspondence.

4 Discussion

We have demonstrated that our algorithm can optimize healthy tissue sparing for ocular proton therapy patients by expressing specific penalties associated with the onset of radiation induced toxicities to healthy tissue using a cost function and NTCP models. Identified fixation points of the optimization algorithm represent a theoretical close to optimal orientation expressed in terms of cost or NTCP value. However, its clinical attainability may be hindered by clinical constraints such as avoiding to treat through an eyelid or the patient's ability to gaze according to the treatment plan. The continuous gradients given by the cost function or parameterized NTCP dose-response curves, allow the planner to track iso-lines of similar healthy tissue sparing in order to to strike a balance between sparing healthy tissue and ensuring clinical feasibility.

Additionally we have demonstrated capacity to consistently predict a fixation point near to the clinically defined point, signifying a reduction in the computational time necessary for the optimization algorithm to identify a suitable fixation point. The required optimization time can vary, typically taking a few minutes, depending on the user's choice for terminating the simulation script. However, it's important to note that the

prediction, while informed by historical patient data at PSI, does not guarantee optimality from an NTCP perspective. The ML predictions, nevertheless, efficiently constrain the search area, eliminating the need to explore all potential gaze fixation points, a methodology employed in previous studies by [8]. Figure 4 illustrates the ML algorithm's capacity to learn from the dataset. The feature importance indicates that the predominant information influencing the predictions is the spatial data concerning the horizontal and vertical aspects of the target center of mass in relation to the centre of the model. The observed learning reflects an understanding of the planner's intent to choose a gaze that minimizes dose exposure to the anterior segments of the eye by rotating them out of the treatment beam. Additionally, the learning captures the planner's intention to rotate distal targets closer to the surface, thereby reducing the proton range. It also seems to recognize that certain superficial targets in proximity to the cornea are treated with a gaze directly aligned with the axis of the treatment beam.

Our methodology refines the previous work by [8] by introducing a tunable cost function and mapping of NTCP curves. Both elements contribute to providing gradients of healthy tissue sparing. This approach preserves a more nuanced understanding of the patient positioning compared to the binary choices for each structure suggested by Henning et al. Additionally, our approach features a more accurate dose calculation engine, and achieves faster results despite employing a finer voxel grid by incorporating ML predictions based on patient anatomy.

Among the examined patient cases, NTCP value gradients of diminishing risks of radiation induced toxicities have been identified for 4 out of 12 patient cases next to the clinical fixation point, suggesting potential strategies for mitigating side effects of the treatment. One identified gradient suggests that adjusting the polar angle by 6 degrees could reduce the probability of neovascular glaucoma by 5% due to reduced exposure to the cornea. It should however be considered that small reductions in probability of radiation-induced toxicities fall within the uncertainty of the NTCP models. For half of the examined patients, no discernible benefits, NTCP changes, or cost gradients in proximity to the clinical orientation were identified. However, the cost function identifies an iso-area of similar cost in proximity to the clinical fixation point, with potential utilization for adapting treatment plans.

5 Conclusion

This work suggests that the next-generation OPT treatment planning systems could be equipped with NTCP models and adjustable expressions of cost functions to provide guidance for the treatment planner to optimize OPT treatment plans.

Abstract

Intra-fraction motion in radiotherapy is commonly modeled using deformable image registration (DIR). However, existing methods often struggle to balance speed and accuracy, limiting their applicability in clinical scenarios. This study introduces a novel approach that harnesses Neural Graphics Primitives (NGP) to optimize the displacement vector field (DVF). Our method leverages learned primitives, processed as splats, and interpolates within space using a shallow neural network. Uniquely, it enables self-supervised optimization at an ultra-fast speed, negating the need for pre-training on extensive datasets and allowing seamless adaptation to new cases. We validated this approach on the 4D-CT lung dataset DIR-lab, achieving a target registration error (TRE) of 1.15 ± 1.15 mm within a remarkable time of 1.77 seconds. Notably, our method also addresses the sliding boundary problem, a common challenge in conventional DIR methods.

1 Introduction

Deformable image registration (DIR) is a critical technique in radiotherapy, essential for accurate motion modeling, dose accumulation [1], and image alignments. The complexity of modeling the displacement vector field (DVF) and the absence of a definitive ground truth make DIR a challenging endeavor. The evolution of DIR methodologies has transitioned from foundational techniques such as optical flow and elastic models [2] to more sophisticated approaches like the demon algorithm [3] and B-spline-based methods [4]. These advancements, including the adoption of map-based approaches, have significantly enhanced precision in capturing complex image deformations. However, they are limited by their computational time demands and the need for precise initial alignment and parameter settings.

The introduction of deep learning (DL) into DIR has been a game-changer. Notable studies like VoxelMorph [5] have pioneered the use of unsupervised learning frameworks employing convolutional neural networks (CNNs). Despite their advances, DL-based methods still suffer from the need for extensive training datasets and face challenges in generalizing to diverse clinical scenarios. Besides, CNNs are sensitive to the input resolution (physical spacing). More recently, Implicit Neural Representations (INR) [6] have emerged, combining the benefits of case-specific optimization with neural network efficiency. Innovations such as IDIR [7], and ccIDIR [8] have collectively pushed the boundaries in DIR, improving processing speed and accuracy. However, they still fall short of achieving real-time performance, using at least 15 seconds for one case.

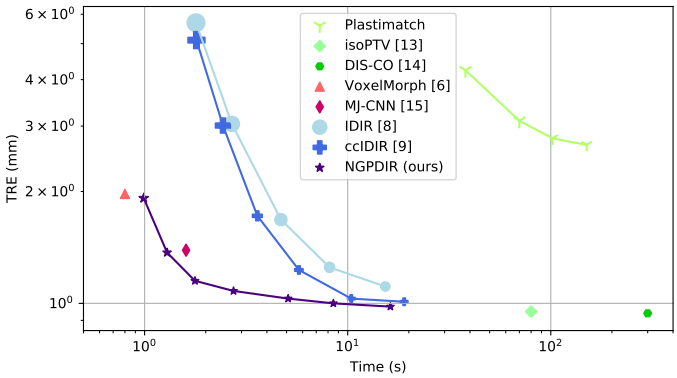

Figure 1: Landmark error, averaged over all cases, for different DIR methods. Conventional and DL-based methods are denoted in green and red, respectively, with reported values from the literature. INR/NGP based (blue) have been implemented by us and exclusively trained on the lung region for comparison.

In our work, we introduce the application of Neural Graphics Primitives (NGP) [9] for DIR, specifically adapted for 4D-CT scans in the DIR-lab dataset. By leveraging NGP for optimizing DVF, our approach combines efficiency and accuracy, utilizing learned primitives and a shallow neural network for rapid deformation field estimations. This method not only represents a significant advancement in DIR by offering quick estimations and maintaining high accuracy but also shows substantial promise for real-time clinical applications. Our preliminary findings demonstrate notable improvements in landmark accuracy, image warp accuracy, and alignment of organs-at-risk (OARs) masks, addressing challenges such as sliding boundaries. In this work, the capabilities of NGP for DIR have been assessed by applying it to the deformation of exhalation to inhalation CT data, extracted from 4DCT studies in the DIR-lab dataset [10].

2 Materials and Methods

2.1 Dataset

In this study, we employed DIR-lab that comprises 4D-CT images for the radiotherapy of thoracic malignancies. This

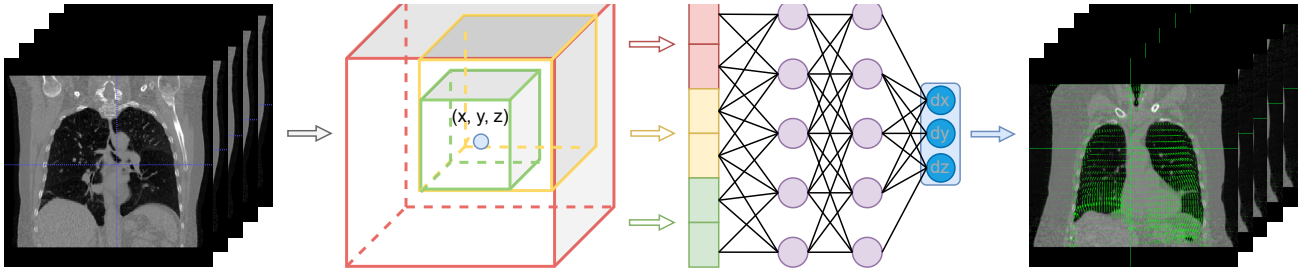

Figure 2: Schematic of the NGPDIR framework. A random point (x, y, z) is represented as the interpolations of multi-level primitives, then mapped to the displacement vector by a small network. The primitives and the network are optimized with respect to each image.

dataset includes 10 cases, from which the exhalation and inhalation phases have been extracted for this study, with the inhalation images as the fixed images. We preserved the original resolution of these 4D-CT scans, which varies across cases, and refrained from normalizing intensity values, as our proposed method is resolution-agnostic and value-agnostic.

2.2 Method

2.2.1 INR for DIR

The preliminary approach of our method is IDIR [7], which adopts INR for DIR. INR fundamentally functions by mapping 3D coordinates to corresponding values or intensities by a learnable neural network, which is a crucial aspect of reconstructing and manipulating complex spatial data. In the context of DIR, INR is adapted to map these 3D coordinates to displacement vectors $(\delta x, \delta y, \delta z)$, constituting the DVF to warp the moving image (exhale phase) towards the fixed image (inhale phase). The training process of INR within DIR involves random sampling of points within the 3D space, followed by the computation of the Normalized Cross-Correlation (NCC) loss between the warped image and the fixed image, together with a Jacobian regularization. Unlike DL-based methods that require training on large-scale datasets, INR-based DIR only needs to fit one network per case, so it combines the advantages of instance optimization with neural representation.

2.2.2 NGP for DIR

The multi-resolution encoding in NGP employs a hierarchical hash table mechanism to represent 3D coordinates at varying levels of detail, which can be formulated as follows:
Given a 3D coordinate $\mathbf{x} = (x, y, z)$, the encoding process is defined by a set of hashing functions $\{h_1, h_2, ..., h_L\}$, where each h_i corresponds to a different resolution level i. These functions map $\mathbf{x}$ to a series of indices that reference feature vectors within the respective hash tables:

$$\mathbf{f}_i = \text{HashTable}_i[h_i(\mathbf{x})], \tag{1}$$

where $\mathbf{f}_i$ is the feature vector retrieved from the i-th hash table. The final feature representation $\mathbf{F}(\mathbf{x})$ for the coordinate $\mathbf{x}$ is then obtained by concatenating the feature vectors across all resolution levels:

$$\mathbf{F}(\mathbf{x}) = \bigoplus_{i=1}^{L} \mathbf{f}_i, \tag{2}$$

where $\bigoplus$ denotes the concatenation operation. The feature representation $\mathbf{F}(\mathbf{x})$ is then passed through the neural network to predict the displacement vector $\mathbf{v}$:

$$g_\phi(\mathbf{F}(\mathbf{x})) \rightarrow \mathbf{v} = (\delta x, \delta y, \delta z). \tag{3}$$

Through this multi-level representation, NGP can manage different scales of spatial features, which is particularly beneficial for DIR where capturing both global anatomical structure and local tissue details is crucial.

2.2.3 Implementation details

For fair comparisons, we have re-implemented both IDIR and ccIDIR in a shared code base with NGPDIR, which will be made public. For training, our batch size was set at $10,000$ points, randomly sampled for each iteration. Specifically, we only used points within the lung for landmark evaluation and the body for MAE calculation. For IDIR and ccIDIR, we keep their original learning rate (LR) as $1e-4$, while for our method, we employed a higher LR of $1e-2$. Our training regimen included a warmup phase for the learning rate, followed by a cosine schedule that gradually reduced it to zero towards the end of training. To analyze the relationship between training time and accuracy, we trained each method for a range of steps: [60, 125, 250, 500, 1000, 2000, 4000]. All experiments were conducted on an RTX 4090 GPU.

2.3 Evaluation

Within the DIR-Lab dataset, the physician's labeled landmarks were provided as the ground truth. We further adopted Totalsegmentor [1] to get masks for sliding boundary regions like vertebras and ribs. Evaluations were done upon landmarks using the target registration error (TRE), and also on image difference between the fixed image and the warped one using mean absolute error (MAE). Sliding boundary areas are evaluated by Dice Coefficients and MAE. Furthermore, we visually compared the predicted motion, DVF as well as warped images from different methods.

[1] https://totalsegmentator.com/

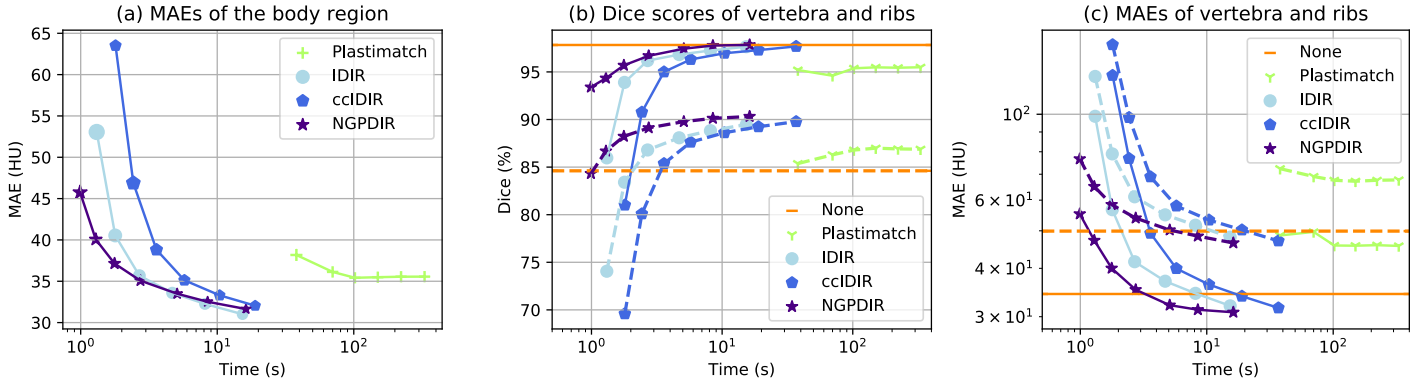

Figure 3: MAE and Dice scores for the different DIR methods averaged over all cases. Orange lines in sub-figures (b-c) represent the absence of registration as a baseline. Solid lines indicate results for the vertebra, while dashed lines correspond to ribs.

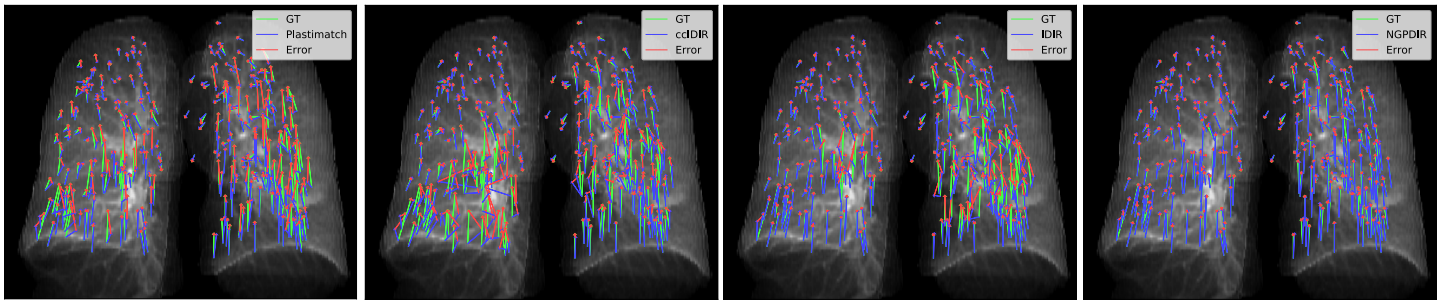

(a) Motion from Plastimatch (b) Motion from ccIDIR (c) Motion from IDIR (d) Motion from NGPDIR

Figure 4: Visualization of landmark movement for case 8. Ground-truth motions are denoted by green arrows, predictions by blue, and errors by red. The magnitude of errors corresponds to the length of the red arrows. These projections are in the coronal plane for clarity.

3 Results

Landmark prediction errors averaged over all 10 cases of DIR-Lab are depicted in Figure 1. Both IDIR, ccIDIR, NGPDIR, and Plastimatch [11] trained on the lung region with different steps are plotted as curves. Besides, we also incorporate conventional methods (isoPTV [12] and DIS-CO [13]) and DL-based methods (VoxelMorph [5] and MJ-CNN [14]) for comparisons. From the figure, conventional methods have the lowest landmark errors, while DL-based methods exceed in speed. Our NGPDIR achieved the best trade-off by far between speed and accuracy.

Other metrics are plotted in Figure 3, where the same trend can be observed. Notably, the conventional B-spline-based method (Plastimatch) cannot handle the sliding boundary regions well, achieving even worse results than the baseline (no registration), while NGPDIR quickly exceeds the baseline after training for only 1.2 seconds. Besides, ccIDIR displayed slower convergence compared to IDIR when trained on the entire body, contravening the trend in Figure 1.

The landmark motion visualizations in Figure 4 further depict NGPDIR's precision, with the shortest error vectors. Moreover, NGPDIR's DVF is notably smoother and more accurate, particularly in the most challenging case (Case No. 8), highlighted in Figure 5. Meanwhile, it surpasses all the others in the error map, outperforming Plastimatch significantly around the ribs (pointed by green arrows).

4 Discussion

In our pursuit of advancing DIR, we draw inspiration from the dynamic realm of 3D reconstruction techniques. Notably, IDIR has leveraged the foundational principles of INR and we harness the computational efficiency derived from Instant-NGP. Given that both INR and NGP are per-point query methodologies, their natural extension into DIR estimation involves querying all voxels within a volume. Further, this can be extended volume grids, bestowing our approach with the valuable property of resolution independence. This unique trait empowers our approach with consistent performance across images of varying sizes, distinguishing it from conventional DL-based methods, which can be sensitive to input resolution and size.

Our comparative analysis reveals the remarkable versatility and efficiency of this approach when compared against both Deep Learning (DL)-based and conventional DIR methods. By effectively eliminating the need for extensive datasets while excelling in per-case optimization, our approach distinguishes itself from DL-based methods. Furthermore, our utilization of neural networks and hash encoding techniques expedites convergence, presenting an appealing alternative to conventional DIR methods.

Turning our attention to the broader implications of our work, we recognize that the current limitation of implementing INR/NGP for DIR lies in their need for case-by-case fitting. As we look forward, there is exciting potential for further

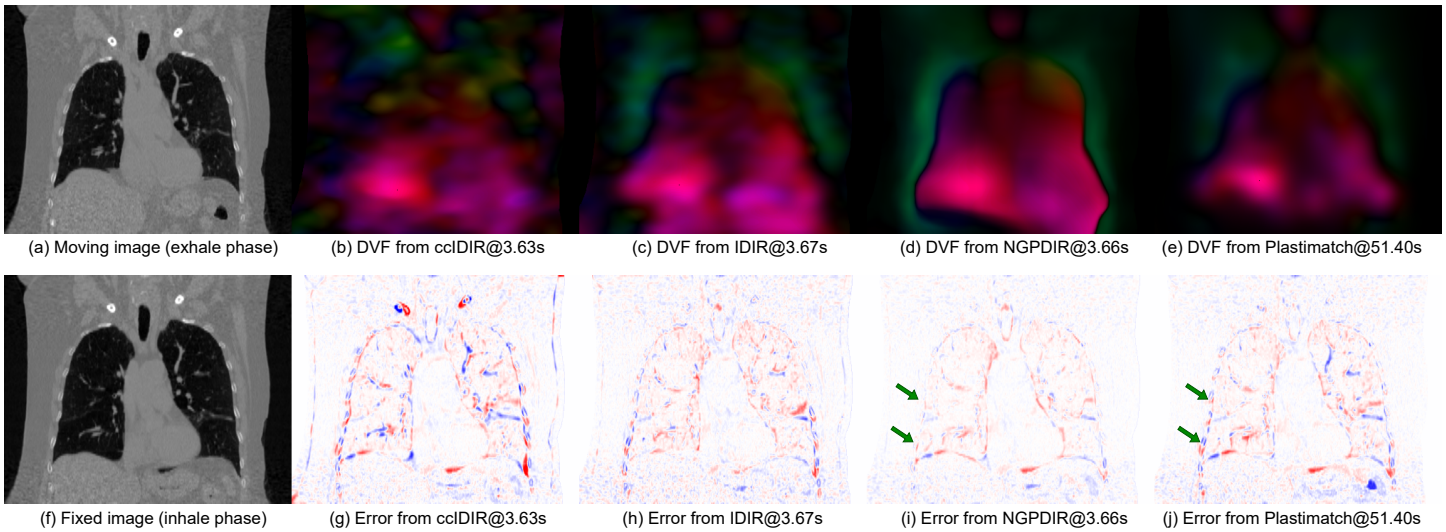

Figure 5: Example DVFs and error maps for case 8. ccIDIR, IDIR, and NGPDIR are compared with similar training times (around 3.65s). DVFs are color-coded for directionality, with the intensity reflecting the magnitude. Green arrows point to ribs (sliding boundaries).

generalization through meta-learning. This approach has the capacity to learn a general prior for specific human regions, followed by case-specific information fitting.

While we propose a fast and efficient DIR approach, it's important to acknowledge the potential bottlenecks that may hinder its real-time application. Challenges persist in the realms of image acquisition hardware and image reconstruction algorithms. Improved acquisition hardware and faster reconstruction algorithms are needed to fully realize the potential of our accelerated DIR method. Additionally, the evolving landscape of 3D reconstruction technologies holds promise, offering solutions to address the later challenges. Beyond real-time image guidance, the rapid speed of our DIR approach opens the door to a range of applications in radiotherapy, including adaptive treatment planning, organ motion tracking, and dose optimization to name a few.

5 Conclusion

In this study, we have successfully integrated NGP into DIR, a novel contribution that significantly enhances the accuracy and efficiency of medical image alignment as demonstrated on the DIR-lab dataset. The NGPDIR framework exhibits robust performance across various metrics, particularly in landmark alignment precision and the accommodation of anatomical sliding boundaries. This advancement not only propels the DIR field forward but also opens new avenues for real-time clinical applications, potentially transforming patient care with its rapid, reliable imaging capabilities.

Abstract Online adaptive radiation therapy requires fast and automated contouring of daily scans for treatment plan re-optimization. However, automated contouring is imperfect and introduces contour uncertainties. This work aims at developing and comparing robust optimization strategies accounting for such uncertainties. A deep-learning method was used to predict the uncertainty of deformable image registration, and to generate a finite set of daily contour samples. Eight optimization strategies were compared: two baseline methods, three methods that convert contour samples into voxel-wise probabilities, and three methods accounting explicitly for contour samples as scenarios in robust optimization. Target coverage and organ-at-risk (OAR) sparing were evaluated robustly for simplified proton therapy plans for five head-and-neck cancer patients. We found that the probability-based methods covered the target with better OAR sparing than the baseline methods, without increasing the optimization time. The scenario-based methods spared the OARs even more, but increased integral dose and required more computation time.

1 Introduction

Radiation therapy has progressively evolved toward greater dose conformality with the tumor, resulting in better healthy tissue sparing. However, uncertainties arising from daily setup variations and anatomical changes limit further conformality improvements as they could lead to substantial target underdosage. Online adaptive radiation therapy aims to reduce such uncertainties by the acquisition of new image data shortly before delivery and adaptation of the treatment to the current anatomy [1, 2]. Adaptation requires acquisition of up-to-date contours of the *clinical target volumes* (CTVs) and the *organs at risk* (OARs) on the new image, as well as re-optimization of the treatment plan. Both processes need to be fast, to maximize the correspondence between the new image and the treated anatomy. This time limitation makes manual contouring infeasible and automated techniques necessary.
One promising technique is *deformable image registration* (DIR) [3], which can be used to propagate the contours from the planning CT to the daily image. However, DIR is inherently uncertain, which results in uncertainty in the propagated contours. To use DIR, it is therefore necessary to quantify and account for its uncertainty. Recent research has introduced a model to predict the uncertainty associated with a DIR algorithm [4], which can efficiently generate samples of propagated contours.

[*]These authors contributed equally to this work

The resulting contour uncertainty may be explicitly included in the re-optimization. Planning using uncertain target volumes has recently gained interest, and several optimization techniques have been proposed for use with a *clinical target distribution* (CTD) rather than with a CTV [5–7]. In the context of adaptive therapy, managing uncertainties by considering contours propagated by multiple DIRs was recently proposed [8]. However, increased target robustness comes at a price. Efficient mitigation of contour uncertainty therefore requires optimization algorithms that favorably navigate the trade-offs between target coverage and healthy tissue sparing. In this work, we develop and compare different strategies for robust optimization against contour uncertainty, in a statistically consistent framework. Specifically, we consider online adaptive re-optimization for head-and-neck proton therapy and employ the DIR uncertainty prediction model from [4].

2 Materials and methodology

2.1 Contour uncertainty model

In this work, DIR is used to propagate the contours from the planning CT to daily CTs. Contour uncertainty is modeled with a previously developed deep-learning DIR uncertainty model [4]. The model predicts uncertainty based on image similarity and contrast. Specifically, it predicts the standard deviation of a Gaussian *deformable vector field* (DVF), with mean given by the output of a known DIR algorithm. The resulting Gaussian DVF can be sampled, and each sample can warp contours to the daily image, yielding a finite set of daily contours. It was shown in [4] that the resulting contour distribution represents well the contouring uncertainty for head and neck patients by comparison with manual contours.

2.2 Robust optimization techniques

In clinical practice, plans are made robust by use of margins or by optimization of the worst case from a variety of range and set-up scenarios. This implicitly mitigates some of the contour uncertainty and we therefore employ two commonly used techniques to benchmark our results. Range uncertainty is treated consistently in all methods by including three range scenarios $(0\%, \pm 3\%)$ in the robust optimization.

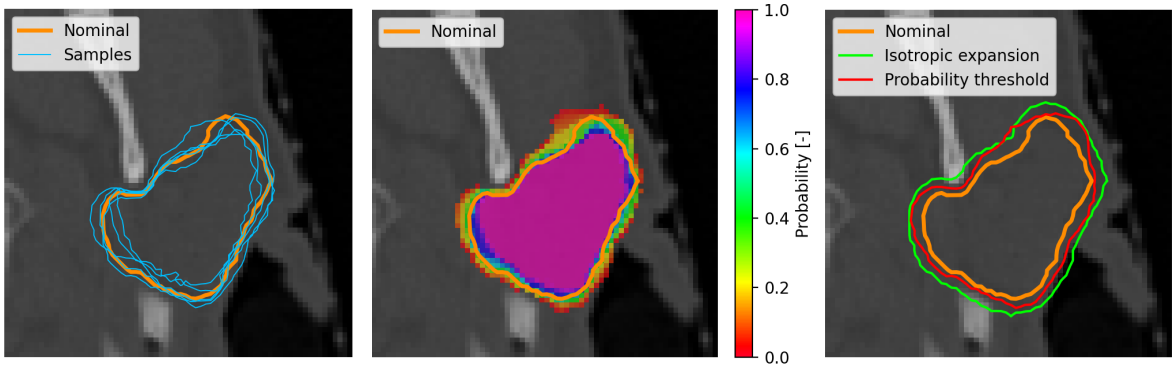

Figure 1: Visualization of contour samples with related marginal probabilities and derived non-isotropic margins. (Left) Nominal contour together with 5 contour samples; (middle) nominal contour overlayed on the voxel-wise marginal probabilties derived from the 5 contour samples; (right) nominal contour together with a 3 mm isotropic expansion and the contour related to the 20% probability threshold.

1. *Set-up robust*: These plans are optimized with isotropic set-up uncertainty (1, 3, or 5 mm) on the nominal contours, i.e., the contours warped with the mean DVF.

2. *Isotropic margin*: These plans are optimized on isotropically expanded (1, 2, or 3 mm) nominal contours.

The next set of methods all rely on converting the contour samples into voxel-wise marginal probabilities, by counting for each voxel the frequency with which it belongs to the contour (Fig. 1). No set-up uncertainty is considered explicitly by any of the following methods.

3. *Probability weighted*: These plans are optimized by scaling the objective weights with the voxel-wise probabilities, resulting in a higher importance for voxels that are more likely to be part of the contour. Additionally, we define the *expected volume* of a structure as the sum of its voxels' marginal probabilities, and use it when imposing dose-volume objectives, e.g., a D30 objective neglects 30% of the expected contour volume. This allows the optimizer to either neglect many voxels with low probability, or fewer with higher probability.

4. *Probability threshold*: These plans are optimized by only including voxels in the contour that have a probability above a certain threshold (1%, 5%, 15%, or 25%). This is similar to adding a margin around the nominal contour, but this margin is not isotropic and depends on where the contour is uncertain (Fig. 1).

5. *Expected volume objectives*: These plans replace any total-volume objectives – such as the minimum-dose objective on the target – with dose-volume objectives considering the expected volume. This allows the optimizer to neglect part of structures (99.4%, 99.6% or 99.8 %) corresponding to the replaced objectives based on their expected volumes.

Our final set of methods extends the scenario definition to also include the contours, by considering each contour sample as a plausible realization of the contour set. Each combination of a contour sample and a range error then constitutes a scenario that can be used in optimization.

6. *Worst-case scenario*: These plans are optimized by minimizing the maximum value of the objective function over the set of scenarios.

7. *Expected scenario*: These plans are optimized by minimizing the expected value of the objective function over the set of scenarios.

8. *Near-worst-case scenario*: These plans are optimized by, at every iteration, ignoring the fraction of scenarios (5%, 15%, or 25%) with the worst objective values. The maximum is then taken over the remaining scenarios.

2.3 Data

The dataset used in this work contains 5 patients with head and neck cancer. It was previously described in [3] and has also been used to validate the DIR uncertainty model [4]. Each patient had one planning CT and 4–7 repeated CTs, considered as samples of daily CTs for an adaptive treatment. Each repeated CT was registered to their respective planning CT using RayStation Anaconda [9] (RaySearch Laboratories, Stockholm, Sweden) and the DIR uncertainty model was used to predict the standard deviations of these DVFs. The resulting Gaussian DVFs were subsequently sampled 200 times yielding 200 contour samples. Of those, 100 were used in the optimization, and 100 for evaluation.
We created a simple planning template with a robust objective on the CTV and non-robust objectives on six OARs: optic nerves, brainstem, parotids and thyroid. These OARs were chosen because of their proximity to the CTV, to cover serial and parallel OAR types, and to cover both regions with high and low image contrast. All treatment plans used IMPT with the same 3 beams at gantry angles $\pm$65 and 180 with 1 cm range shifter. The plans aimed to deliver 54 GyRBE to the CTV in 33 fractions. Maximum dose objectives were used

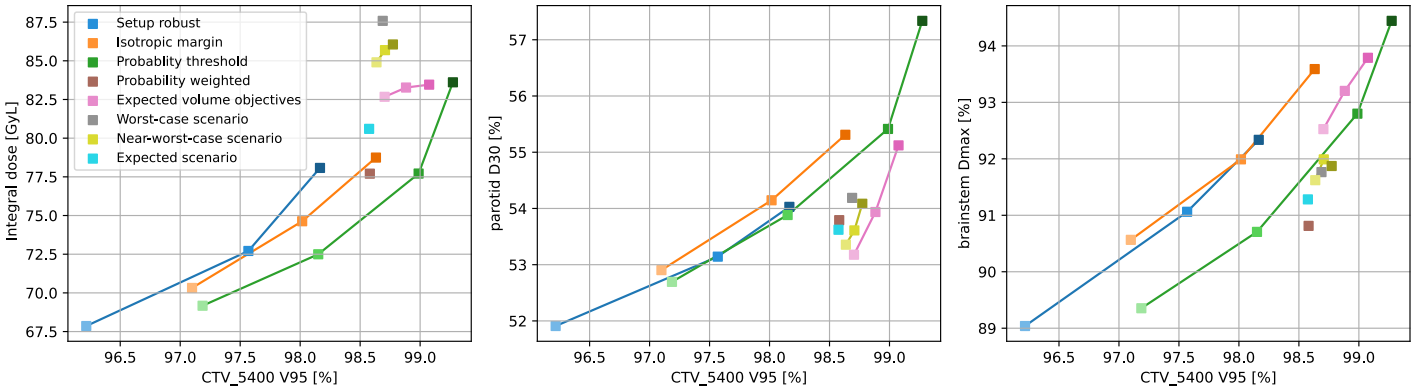

Figure 2: Mean nominal integral dose, parotid D30 and brainstem Dmax as a function of mean near-worst-case CTV coverage for the different robust optimization strategies. For each method, the markers are more transparent for the lower robustness settings (e.g. 1 mm margin) and more opaque for higher robustness (e.g. 3 mm margin).

for the optic nerves and the brainstem, whilst D30 objectives were used for the parotids and the thyroid. The dose limit in each objective function was chosen in such a way that it competed with the target objective, to highlight the effect in the optimization. In addition, a dose-fall-off objective was used to limit the dose anywhere outside the target. All plans were optimized for 50 iterations using a research version of RayStation.

2.4 Robust plan evaluation

To compare the methods, we evaluate the *near-worst-case* target coverage, *on average*: we take for each patient-scan pair the 5th percentile worst-case CTV V95% over the contour and range scenarios and compute the mean of these values over the patients and scans. Instead, the OAR metrics and integral dose were evaluated in the nominal scenario, since their objectives were not treated robustly in the optimization.

3 Results

To compare the methods, we inspect the trade-off between target coverage and three of the dose-limiting metrics (Fig. 2). Increasing the robustness parameter for any method always improved the near-worst-case target coverage. However, this robustness came at the cost of increased integral and OAR dose. In any of the plots, a position toward the lower right indicates efficient target coverage in relation to the shown dose-limiting metric. In this regard, the probability threshold method accounts for most of the efficient set of plans regarding integral dose. In addition, it also more efficiently spares the brainstem when compared with the isotropic expansion method and the setup-uncertainty method. These results suggest that an informed selection of the margin based on the probabilities outperforms the benchmark methods.

The probability-weighted method resulted in a slight increase in integral dose but less dose to OARs, when compared to the frontier formed by the probability-threshold method. This observation, that the use of probability weights prioritizes OAR-sparing over limiting integral dose when compared to the use of a margin, is consistent with previous results [6, 7]. In comparison, the plans using expected volume objectives further improved the trade-off between target coverage and parotid sparing, at the expense of brainstem sparing and integral dose.

The (near-) worst-case scenario methods spared the OARs more efficiently than the probability-threshold method but led to substantially higher integral doses. This is presumably because scenarios that conflict with OARs are likely the worst in terms of the objective value, and that trade-offs with the target coverage in affected regions will be prioritized during optimization. Although this leads to better OAR sparing, it also results in lower importance elsewhere leading to a higher integral dose. The effect is illustrated by considering dose differences between instances of the probability-threshold plan and the near-worst-case plan (Fig. 3). In contrast, the same reasoning does not apply when optimizing the expected scenario, as each scenario is consistently prioritized equally. Rather, it is theoretically similar to probability weights, which is reflected in the dosimetrically similar trade-offs between the methods.

Notably, whilst the other methods require approximately the same computation time ($\sim$100 s for 50 iterations), scenario-based methods require substantially more. The increase from 3 range scenarios to 300 composite scenarios resulted in an increase of a factor 10 in computation time.

4 Discussion

We integrated DIR-induced contour uncertainty with robust optimization in an adaptive re-planning framework for radiation therapy. It is evident from the results that accounting for the uncertainty even in simple ways, such as basing margin thresholds or voxel-wise weights on the probabilities, improves the trade-offs between robust target coverage and nominal dose-limiting objectives. Further, the trade-offs

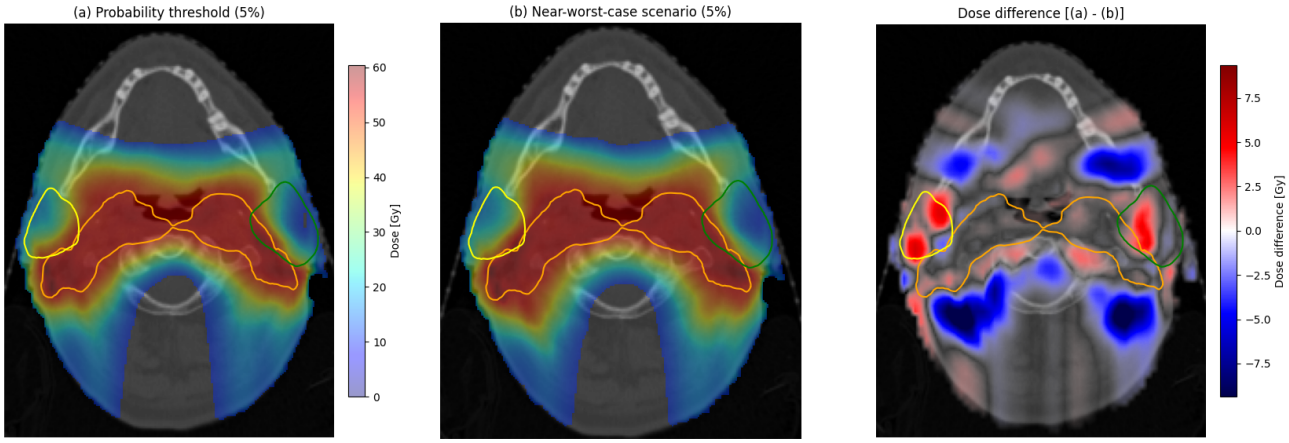

Figure 3: Doses for CT 2 of patient 3. Left: Probability threshold (5%). Center: Near-worst-case scenario (5%). Right: Dose difference. The 5% probability-threshold contours are shown for the CTV (orange), left parotid (green), and right parotid (yellow).

with OARs can be made efficient by employing scenario- or expected volume-based methods, that implicitly prioritize certain subvolumes of the target. Neglecting a fraction corresponding to the worst scenarios is much different from ignoring the same fraction of least probable voxels.
Similarly to as in [6, 7], the methods were evaluated with samples drawn from the same distribution as those used in optimization, rather than evaluating on a set of ground-truth manual contours. This was chosen because the main goal of this work is to compare the optimization algorithms, rather than to test the accuracy of the DIR uncertainty model.
Lastly, target robustness comes at the cost of increased integral and OAR dose. In this work, we have not accounted for the uncertainty in the propagated OAR contours. With the DIR uncertainty model, it is straightforward to generate the corresponding uncertainty of the OARs. It is then possible to address whether the methods can simultaneously increase the robustness of both the target and the OARs, which is the focus of an ongoing investigation.

5 Conclusion

Robust optimization using the contour uncertainty information more efficiently provides target coverage robustness compared to benchmark methods. In addition, different methods prioritize OAR sparing and limiting integral dose differently. Given the increased computational effort required for scenario-based methods, methods using thresholds or objective weights based on voxel-wise probabilities are a practical alternative in online adaptive therapy.

Short-term mortality prediction in SIII NSCLC: What do clinicians want and can models provide it?

Matthew Craddock[1,2], Azadeh Abravan[1,2], Alan McWilliam[1,2], Corinne Faivre-Finn[1,2] and Gareth Price[1,2]

Abstract Selecting the "right" treatment in the diverse SIII NSCLC patient cohort is a challenging process which is poorly supported by evidence. Currently, ~20% of SIII NSCLC patients receiving curative intent radiotherapy in Manchester die within 6 months, a timescale in which arguably they may derive no benefit from the treatment and which, we consider could be reduced by model informed clinical decision making.

We present a clinician informed modelling study in which we survey oncologists to determine their views of the utility and specification of a short term survival model in SIII NSCLC. Conventional time to event modelling, modern machine learning based methods and discrete time modelling are applied to demonstrate the inherent difficulties of deriving clinically useful predictions from low event datasets with significant class overlap.

1 Introduction

Stage III disease accounts for ~20% of all non-small cell lung cancer (NSCLC) cases and presents in a highly diverse cohort including both the young and fit, as well as the elderly, frail and co-morbid [1]. As such, a wide range of treatment options are available to SIII patients ranging from simple, single fraction palliative radiotherapy to combined curative intent chemoradiotherapy and immunotherapy.

Choosing the "right" treatment regimen from several plausible options is a challenging multi-factorial process shared between clinicians and patients. Currently, there is a dearth of evidence to support optimal treatment selection and this has led to diversity in practice as well as the potential over use of intensive radical radiotherapy treatments [1,2].

Currently, ~20% of SIII NSCLC patients receiving curative intent radiotherapy in Manchester die within 6 months, a timescale in which arguably they may derive no benefit from the treatment. While there will always be a number of patients with unexpectedly short survival, we consider 20% to be a figure which could be reduced by model informed clinical decision making.

We present a clinician informed modelling study in which we conduct a survey of oncologists to determine clinicians' views of the utility and specification of a short term survival model in SIII NSCLC. Conventional time to event modelling, modern machine learning based methods and discrete time modelling are applied to demonstrate the inherent difficulties of deriving clinically useful predictions from low event datasets with significant class overlap.

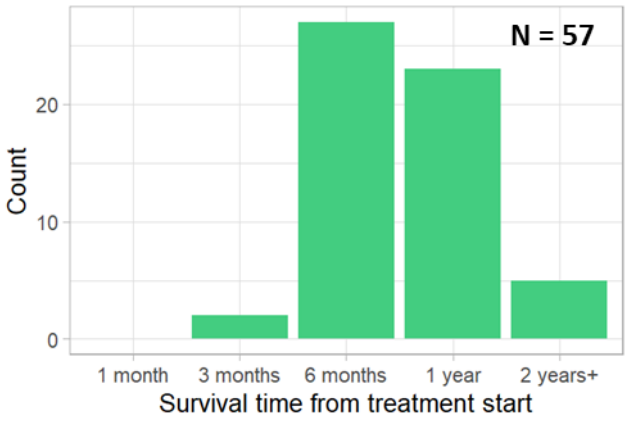

Figure 1. Responses from the survey of oncologists to: "What is the minimum meaningful survival time from the first fraction which in your opinion justifies a radical treatment?".

2 Materials and Methods

Oncologists specialising in lung cancer from multiple institutions were invited to participate in the short survey (14 questions) by email. The survey was hosted on the Qualtrics platform and 60 responses were recorded between August and October 2023 [3].

Models were developed using a dataset of 783 SIII NSCLC patients receiving a radical treatment of either 50-55 Gy in 20 fractions or 60-66 Gy in 30-33 fractions between 2012 and 2022 at The Christie Hospital, Manchester. Bloods data acquired within 30 days of the first fraction were available for a subset of 481 patients, including measurements of albumin, alkaline phosphate, calcium, glucose, lactate dehydrogenase, potassium, sodium, bilirubin, protein and urea. The publicly available dataset from Oberije et al was used for external validation of the models [4].

Variable selection was performed based on domain expert knowledge and using the analytical approach of random forest based variable importance measures with bootstrapping [5].

Three distinct modelling methods were applied: time to event, machine learning classification algorithms and discrete time modelling. For time to event modelling, the semi-parametric Cox model was used, and classification algorithms were built using the random forest method [6,7]. Discrete time modelling (DTM) is effectively a hybrid of the time to event and classification approaches in that it permits the use of classification algorithms whilst dealing with censoring [8]. It splits survival time into discrete boxes

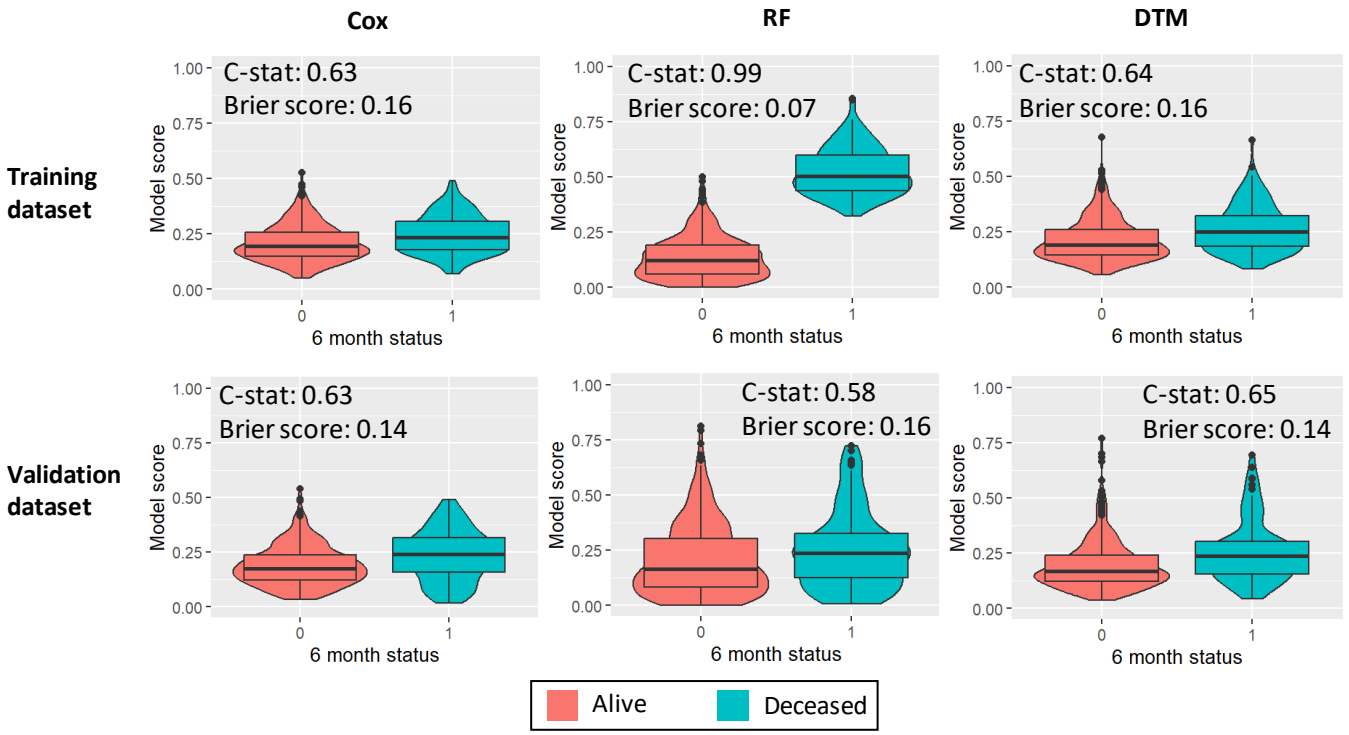

Figure 2. Prediction distributions of the Cox, random forest and neural net based discrete time model with base clinical variables (age, gender, performance status, log PTV) in the training and validation datasets.

and fits a different model in each box. The R package autoSurv (V0.1.0) was used to perform discrete time modelling using random survival forests, generalized linear models (GLMs), regularized GLMs, support vector machines, and neural network algorithms [9].

Model performance was assessed graphically by plotting the distribution of predictions by patient survival status at 6 months and quantitatively, with calculation of the discrimination C-statistic and Brier score. The Brier score is a measure of predictive accuracy which takes values between 0, representing perfect accuracy, and 1, representing inverted predictions.

Decision curve analysis (DCA) is a method of contextualising model performance with clinical decision thresholds[10]. Decision thresholds here refer to the probability values at which clinicians opt to change their treatment decision; in this work this refers to the decision to opt for a radical treatment based on the patients 6 month survival probability. As the aim of this study is to reduce the futile use of radical radiotherapy, DCA curves of interventions avoided were constructed to understand the potential impact of model predictions on current decision making.

3 Results

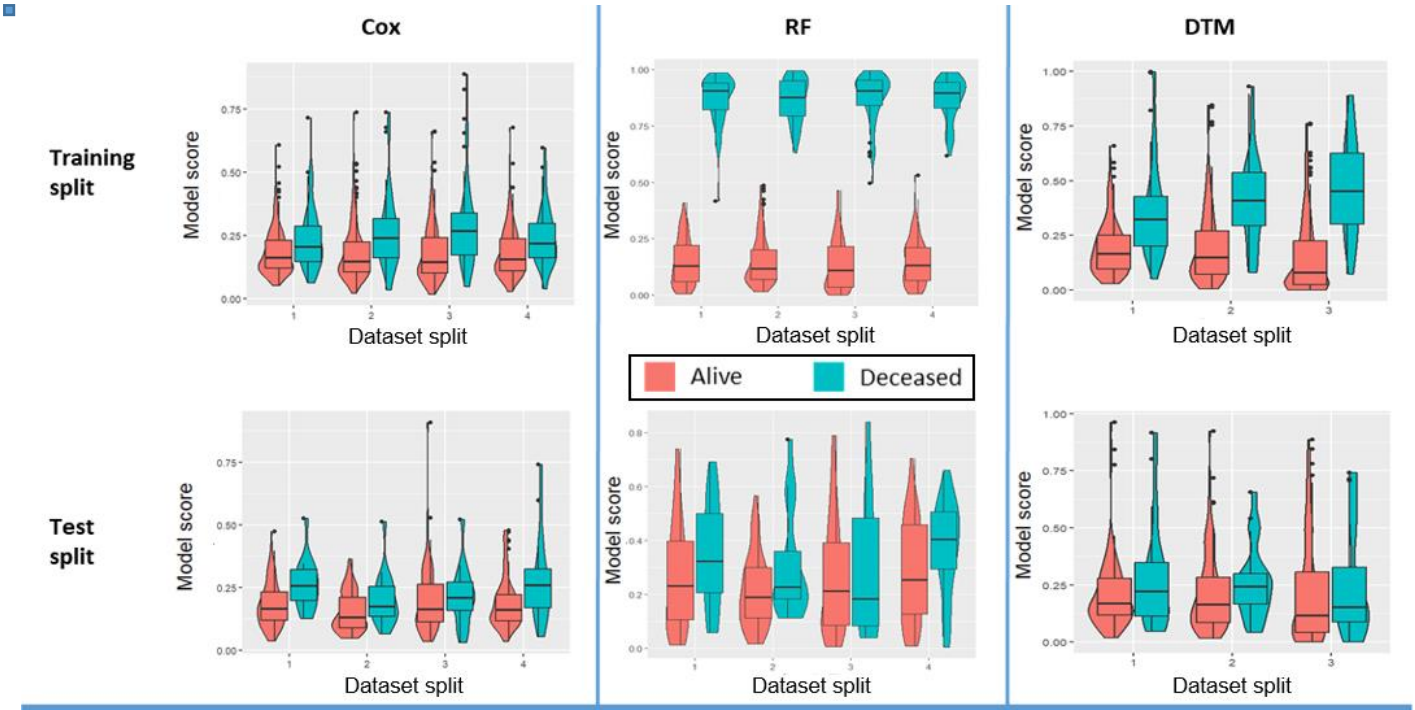
3.1 Survey

89% of respondents selected either 6 months (49%) or 1 year (40%) as the minimum meaningful survival time which they felt justified a radical treatment, with 6 months the most common response and the weighted mean over all responses equating to ~9.5 months. A short term mortality model was deemed likely to change clinical decision making by 41 out of 54 respondents and a strong preference was expressed for model output in the form of risk groupings rather than a continuous outcome or binary classification. Respondents were also asked at what threshold of probability of a patient surviving for 6 months or more would their treatment selection change from palliative to radical. The response to this question was the most mixed of all, potentially indicative of the diversity of clinical decision making in this area. The majority vote was for 50%, with an overall mean of 49%.

3.2 Modelling

Inspection of the pre-existing survival models for SIII NSCLC reveals that performance status is common to all of them, with age, gender and a tumour related volume (GTV/PTV etc) selected in 3 out of 4 models. Accordingly, these 4 variables were selected as a base set of clinical variables with which to train models to provide a performance baseline to assess the added value of any other predictors. Analytical variable reduction supported the selection of this base variable set and in the subset of patients with bloods data, lactate dehydrogenase, albumin and urea were also highly selected. As a result, models were trained with the base clinical variables alone and with the addition of the bloods metrics.

Figure 2 shows the distribution of model predictions by patient survival status at 6 months in the Christie training dataset and the MAASTRO validation dataset with base clinical variables. The random forest model is the only approach which produces meaningful separation in the training dataset, however, this performance does not translate to the validation dataset, with the model's



Performance metrics				
C-stat	Training	0.69 (0.03)	0.99 (0.00)	0.77 (0.07)
	Test	0.66 (0.08)	0.60 (0.07)	0.55 (0.08)
Brier score	Training	0.14 (0.00)	0.03 (0.00)	0.13 (0.02)
	Test	0.15 (0.01)	0.18 (0.02)	0.18 (0.03)

Figure 3. Prediction distributions of the Cox, random forest and neural net based discrete time model with base variables and blood metrics in 4-fold cross validation of the Christie dataset.

discrimination (C-statistic) falling from 0.99 to 0.58. Due to the lack of an external validation dataset for the bloods data, the generalizability of model performance with blood metrics was tested by 4-fold cross validation. As shown in Figure 3, the inclusion of blood metrics leads to higher discrimination and Brier score values in the training folds of the Christie dataset. In the test folds, the models again exhibit marked degradation in performance. The Cox model exhibits the most stable performance with discrimination (C-statistic) of 0.66 and a brier score of 0.15, but with a very meagre prediction range with an average difference in the median prediction in the dead and alive groups across all test folds of less than 10%.

3.3 Clinical Utility

Figure 4 depicts the impact of model predictions on the number of futile radical treatments avoided for a survival endpoint of 6 months, using the Cox model with base variables and blood metrics. Here, futility is defined as a radically treated patient dying within 6 months of treatment initiation. The DCA plot shows that the model only offers benefit at thresholds of between 10% and 25% which falls well below the mean decision threshold of 50% that was established by our survey of clinicians. As such the information provided by the model would offer negligible benefit to clinical decision making.

4 Discussion

In this study, we demonstrate the principle of clinician-informed modelling. By surveying the intended end user group prior to model development, we ensure selection of an end point of clinical relevance and avoid contributing to the preponderance of models which predict events of no clinical relevance [11]. Clinician informed model design also permits model evaluation which goes beyond the conventional metrics of calibration and discrimination, which are not linked to clinical utility [12]. By establishing clinical decision thresholds, we can begin to contextualize model performance. Although simplistic, methods such as decision curve analysis allow us to gain some understanding of whether the models offer benefit over current decision making practices.

The paucity of models for short term survival in SIII NSCLC may be reflective of the difficulty of achieving adequate performance at endpoints of less than 12 months. A fundamental cause of this is the lack of events – reported rates of early mortality at time points of 3-6 months range from 6% to 20%, meaning that even large datasets suffer from a relative lack of information in the patient group of most interest [13,14]. A nationwide analysis of risk factors for early mortality in lung cancer patients in France by Gossault highlighted emergency presentation and hospitalisation lasting for more than 30 days as key drivers, potentially suggesting broader datasets encompassing primary care

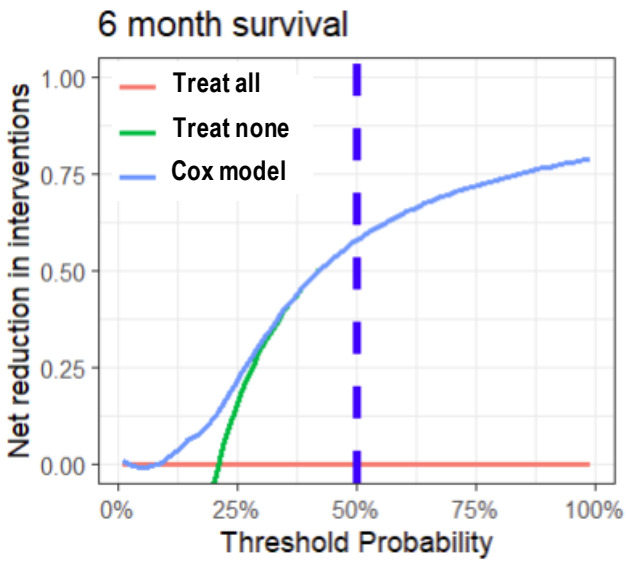


Figure 4. Decision curve analysis plot showing the net reduction in futile radical treatments as a function of decision threshold probability. The blue line indicates decisions made in concordance with the Cox model predictions and the green/red lines indicates the scenarios of none/all of the patients receiving a radical treatment.

information may be required to achieve adequate performance[14].

Our survey of oncologists indicated a strong preference for model output in the form of risk groupings. Quantitative definition of these groups is vital in correctly interpreting the meaning of a model and indeed is a requirement of the TRIPOD statement (item 11)[15]. Despite this, 47% of existing modelling studies fail to appropriately define their risk groupings and there is no consensus on the methodology used to do this [16]. This poses a risk as poor model performance can be obfuscated by misleading group names [13]. For survival models a simple approach would be to present the median survival in each group as a proportion of that in the whole cohort, such that values close to 1 represent poor group separation and values further away represent more meaningful separation.

While this study represents a rare example of clinician informed model design, it is important to recognize that decision making is a process shared between oncologists and patients. Patients may well have different requirements for model output as well as different variables driving their decision making, with treatment experience and side effects potentially being considered as important as survival [17,18]. As such a survey of patients would be a useful extension of this work and a necessity to understand model suitability and performance for all parties involved in clinical decision making.

5 Conclusion

Clinicians recognise that short term (6-12 months) survival prediction in SIII NSCLC is likely to change their decision making. Current methods are unable to generate performative models with clinically relevant endpoints in low event datasets with significant class overlap. New methods and/or novel variables are required to achieve meaningful separation of patients by their survival status at 6 months in the cohort of SIII NSCLC.

Deep learning autosegmentation performance on Mid-Position and time-averaged lung CT scans

Joren Brunekreef[1] and Jan-Jakob Sonke[1]

[1]Department of Radiotherapy, Netherlands Cancer Institute, Amsterdam, the Netherlands

Abstract 4D CT scans are routinely used in the treatment preparation process of radiation therapy (for targets in the upper abdomen and thorax to reduce geometric uncertainties. Online adaptive RT (OART) is an emerging technique to increase the accuracy in radiation therapy but in room 4D imaging techniques are currently scarce. To increase the efficiency of OART, deep learning auto-segmentation is an active field of research. In this work, we investigate the difference in auto-segmentation quality in motion averaged and motion compensated scans. We found that MidP scans led to increased segmentation performance for GTVs and organs-at-risk compared to mean-intensity projections. These results indicate that future workflows for online adaptive radiotherapy may benefit from integrating motion-compensation techniques when using deep learning auto-segmentation algorithms for delineating anatomical structures.

1 Introduction

The thoracic and upper-abdominal region are subject to respiratory motion which induces geometric uncertainties during radiation therapy. A widely adopted strategy to reduce such geometric uncertainties is to acquire 4D CTs for treatment planning [1]. Delineations of targets and organs at risk and treatment plan optimization are then typically performed on individual phases, mean/maximum intensity projections [2] or the time averaged mean position (mid-Position (MidP)) [3]. An emerging technology to reduce geometric uncertainties in radiation therapy is online adaptive radiotherapy (OART) [4]. In OART, the plan is adapted daily using in room imaging modalities such as CT, CBCT or MRI. Currently, OART is time consuming with segmentation of the target and organs at risk (OAR) being one of the bottlenecks. Therefore, deep-learning based auto-segmentation is being studied to increase the efficiency of OART [5–7]. In-room 4D imaging modalities are currently scarce. Consequently, 3D imaging techniques are being used as an alternative which are subject to artifacts such as blur. It is unknown whether such artifacts impact the performance of auto-segmentation algorithms. The aim of this study was therefore to investigate the difference in auto-segmentation quality in motion averaged and motion compensated scans.

2 Materials and Methods

Following IRB approval, we collected the 4D planning CT (pCT) scans and corresponding structure sets of 466 early stage lung cancer patients treated with stereotactic body radiotherapy (SBRT). From the 4D scan sequences, both the midPosition (MidP) and mean-intensity projection 3D scans were computed. The gross target volume (GTV) were manually delineated by the treating radiation oncologists and the organs at risk (OARs) by the dosimetrist on the 3D MidP scans. Voxel sizes ranged from 0.98x0.98x3.00mm^3 to 1.17x1.17x3.00mm^3.

The potential difference in utility between MidP and time-averaged scans for autosegmentation was analysed from two distinct perspectives. On the one hand, we investigated the effectiveness of the datasets resulting from both post-processing methods for training a neural network to segment GTVs (**Task 1**). On the other hand, we evaluated the performance of an existing state-of-the-art deep learning segmentation algorithm for anatomical structures by comparing the results to the OAR-annotations provided by the dosimetrist (**Task 2**).

More specifically, in **Task 1** we split the dataset into 400 patients for training/validation and 66 patients for testing. We subsequently train an nnUNet [8] to segment GTVs, based on the manual delineations. We distinguish two subtasks in this context: for **Task 1a** the model is given the full chest scan as input, and for **Task 1b** we simplify the objective by cropping a 15x15x15cm^3 box around the tumor's center of mass and providing the cropped scan as input to the model.

The best model is obtained through a five-fold crossvalidation procedure, and we subsequently evaluate it on the test split. We perform this process twice: once for the MidP scans, and once for the time-averaged 3D scans. Note that the dataset split into training/validation and test data happens only once, and on the patient level — as a result, both models are evaluated on the same set of patients in order to make an unbiased comparison.

In order to evaluate the autosegmentation performance, we compute the Dice similarity coefficient (DSC) and the symmetric 95% Hausdorff distance (s95HD) between the trained nnUNet's predictions and the ground truth delineations provided by the radiation oncologists. Subsequently, we compare these performance metrics between the models trained and evaluated on MidP scans on the one hand, and time-averaged scans on the other hand.

For **Task 2**, we use TotalSegmentator [9] to segment five organs-at-risk on all 466 patients in our dataset, for both the MidP and time-averaged 3D scans. The chosen OARs are the heart, spinal cord, esophagus, and left and right lungs. We

then compare these autosegmentations to the dosimetrists' ground truth annotations by again computing the Dice similarity coefficient and the 95% Hausdorff distance. However, since the dosimetrists' annotations are sometimes incomplete in regions far removed from the GTV area in the craniocaudal direction, we restrict computation of these metrics to only the axial slices where the relevant OAR annotations are not everywhere zero. Also, since the annotation conventions of the dosimetrist and TotalSegmentator are not identical,[1] we report the *asymmetric* 95% Hausdorff distance (a95HD) from the ground truth dosimetrist delineation to TotalSegmentator's predicted segmentations (as opposed to the s95HD).

3 Results

3.1 Task 1

The results of the GTV segmentation task are shown in Figure 1 and Table 1, where "GTV (full)" refers to Task 1a and "GTV (crop)" to Task 1b. When the objective is to segment the tumor in the full scan (Task 1a), many tumors are missed completely in both the midposition- and time-averaged scans. For the simpler Task 1b of segmenting the GTV in a smaller cube-shaped region centered on the tumor, all GTVs are at least partially found for both scan post-processing methods. The models trained (and evaluated) on MidP scans attain the best performance in both scenarios, reaching a mean Dice similarity coefficient of 0.85 and a (symmetric) 95% Hausdorff distance of 4.2mm in the second subtask.
We present an example slice of a test patient's scan for both the midposition- and time-averaging methods in Figure 2. This Figure demonstrates the blurring effect of the breathing cycle motion, and the mitigation of this effect due to the midposition-averaging. The ground truth GTV delineation is shown in green in both of the images. In the leftmost image, we show the predicted segmentation of the model trained on MidP scans, whereas the rightmost image shows in red the prediction of the model trained on time-averaged scans.

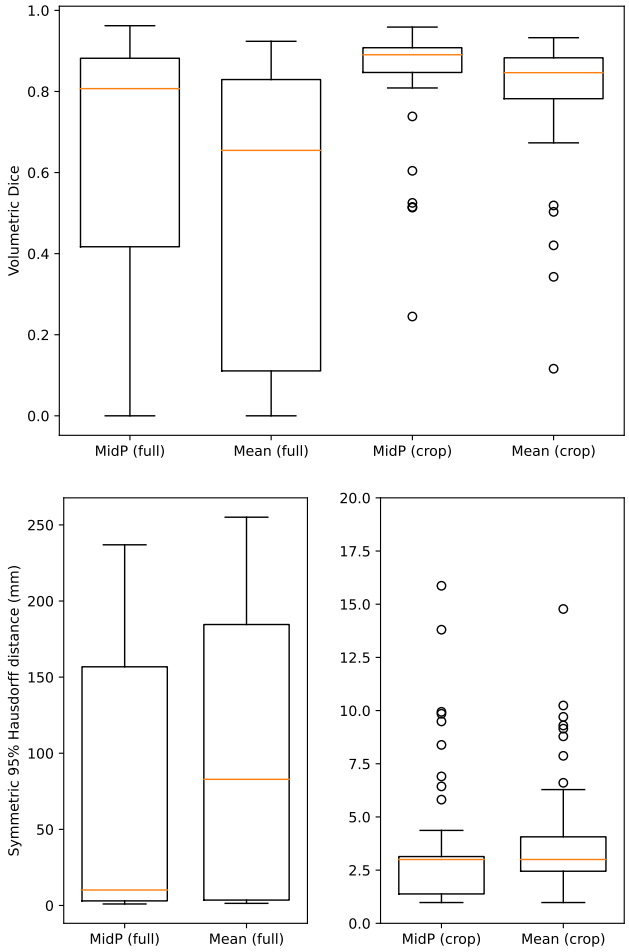

Figure 1: Performance metrics for GTV segmentations on MidP and time-averaged 3D scans, as evaluated on the test set consisting of 66 patients (Tasks 1a, 1b. Three outliers (one for MidP-averaged, two for time-averaged) are not shown in the 95% Hausdorff distance plot so that the bulk of the results can be inspected in more detail.

3.2 Task 2
