Table 1 reports the performance metrics of TotalSegmentator's predicted organs-at-risk segmentations as compared to the ground truth annotations. Dice similarity coefficients are consistently better on the MidP scans than on the time-averaged scans, but the difference is minimal. The (asymmetric) 95% Hausdorff distance is marginally lower on the MidP scans for both lungs and the spinal cord, pointing towards slightly better performance for these OARs. For the lung segmentations, this a95HD is close to the voxel spacing for both scan-averaging methods. The a95HD for heart and

[1] For instance, the pulmonary artery is considered part of the heart by TotalSegmentator, whereas the dosimetrists did not include this substructure in the annotations (following the standard [10]).

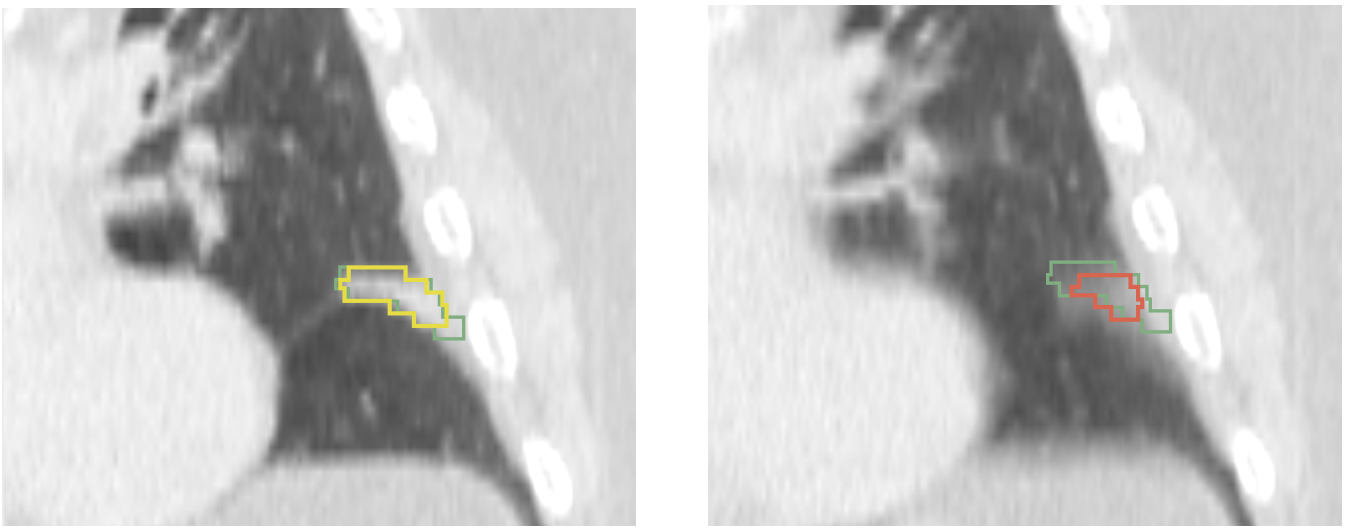

Figure 2: Example of paired MidP (left) and time-averaged (right) scan slices in the sagittal plane, shown with ground truth GTV annotation (green) and the predicted segmentation obtained from the corresponding trained nnUNet (yellow for the model trained on MidP scans, red for the model trained on time-averaged scans).

esophagus is comparable between both averaging methods, as the means overlap within one standard error.

4 Discussion and Conclusion

We have evaluated deep learning autosegmentation on MidP and time averaged CT scans of lung cancer patients and found improved performance for MidP scans for both the GTV and OARs. These results indicate that in-room motion compensated imaging techniques may be beneficial for online adaptive radiotherapy for anatomical regions subject to respiratory motion. The manual delineations in this work were performed on the MidP scans. This potentially induces a bias compared to the time average scans. However, as the MidP scans are designed to reconstruct the anatomy in the time averaged mean position, the segmentations should also represent the underlying anatomy for the time averaged scans. Manual delineations on time averaged scans will be challenging due to the respiratory motion induced blur and induced increased inter-observer variation. In the work we evaluated the auto-segmentation performance for both targets and organs at risk. It is often assumed that the segmentation of targets is more challenging than segmentation of OARs. In this work the performance of autosegmentation targets did not seem to be inferior to OARs although there were considerable differences between different OARs. This may be partly explained by the low interobserver target delineation variation in lung SBRT [11]. As our hospital doesn't use internal target volumes to obtain a GTV-to-PTV expansions, these structures were not available for evaluation. Maximum intensity projection scans may be more suitable for this task. In this work we used the DICE and 95HD for performance evaluation as these are widely used in this context. These metrics, however, do not strongly correlate with the amount of time involved in correcting auto-segmentations or the margin that is needed to correct for auto-segmentation inaccuracies. Added path length and root-mean-square error may be more suitable for these tasks. In this work, we used scans derived from 4D CT scans acquired for treatment planning to evaluate the performance of autosegmentation for which we had hundreds of annotated datasets available. Further research should be performed to confirm the impact of in-room 4D or motion compensated imaging techniques for online adaptive. In this work we approximated 3D imaging by time averaging of the 4D CT. While this approach induces respiratory induced blur, actual 3D imaging techniques may have additional artifacts such as streaks or shifts.

Abstract Cone-beam CT (CBCT) images are commonly acquired during radiotherapy to help setup the patient and to monitor changes of their anatomy. However, standard 3D CBCT images do not estimate breathing motion and are susceptible to motion artifacts when it occurs. State-of-the-art surrogate driven motion models can estimate the motion for each CBCT projection using correspondence between the internal motion and one or more respiration surrogate signals. However, it can be challenging to measure or extract surrogate signals that are strongly related to the internal motion. Therefore this study proposes a novel surrogate-optimized respiratory motion model and investigates the feasibility of applying it on CBCT projection data. This method optimises the surrogate signal(s) as well as the correspondence model, eliminating the need for the surrogate signals to have strong relationship with the internal motion. Our method is evaluated on both simulated and real patient data and compared with a surrogate-driven motion model, showing promising improvements across all metrics for the simulated data, and improved image quality for the real data.

1 Introduction

3D Cone-beam CT (CBCT) is commonly used in radiotherapy (RT) to help setup the patients and to monitor their anatomical changes during the treatment course. However, the acquisition time of 1-2 minutes for 3D CBCT means that the standard reconstructions cannot estimate patients' breathing motion, and the blurring artifact caused by the motion [1] can make it difficult to accurately assess anatomical changes.

A common approach to address the above problem is 4D CBCT, which sorts CBCT projections into multiple phases/bins according to respiratory signals. Projections within each phase are used to reconstruct a single CBCT image with less motion artifacts than the 3D CBCT. However, this method assumes reproducible periodic respiratory motion, so cannot account for inter-cycle (i.e. breath to breath) variations in the motion [2]. Moreover, 4D CBCT acquisitions require more projections, leading to a longer acquisition times (4-6 minutes), and the uneven distribution of projection angles within each respiration phase induces streak artifacts.

Recently we proposed a surrogate-driven motion model [3] to estimate the motion for each projection of a 3D CBCT scan and reconstruct a motion-free image. It adapted the general motion modelling framework in [4], which can model inter-cycle variations, so that it can be fitted to CBCT projection data, and hence does not require phase sorting or extra acquisition time. This method models the relationship between 3D motion fields and low-dimensional respiration surrogates signals which can be measured by external devices [5] or extracted directly from projection images [6]. Since the surrogate signals are synchronised with the CBCT acquisition, the motion field for each projection can be inferred from the surrogate signals taken at the same time. However, such methods assume there is a strong relationship between the surrogate signals and the internal motion, which is not always true.

This study aims to use a data-driven approach to optimize the surrogate signals at the same time as fitting the motion model directly to the CBCT projection data, which is denoted as a surrogate-optimized motion model. Both simulated and real clinical 3D CBCT scans are used to demonstrate the advantage of the surrogate-optimized motion model over the surrogate-driven motion model.

2 Methodology

2.1 General Motion Modelling Framework

The input data consists of n measured CBCT projections $(\mathbf{P_t}, t = 1, ..., n)$. The aim is to estimate transformations for each projection that can warp the reference state image $\mathbf{I_0}$ to dynamic image $\mathbf{I_t}$ at any time t, as shown below:

$$\mathbf{I_t} = T(\mathbf{I_0}, \mathbf{M_t}) \tag{1}$$

where T is a function that uses the spatial transformation parameterised by $\mathbf{M_t}$ to resample $\mathbf{I_0}$. This study adopts the free-form-deformation transformation model, in which case $\mathbf{M_t}$ refers to control point grid displacements at time t. Using the estimated transformations, the reference state image $\mathbf{I_0}$ can be obtained by motion compensated reconstruction [7] to remove the motion artifacts.

The transformation parameters over time can be arranged into a $N_m \times n$ matrix $\mathbf{M} = [\mathbf{M_1}, ..., \mathbf{M_n}]$, where N_m is number of parameters that define the transformation $\mathbf{M_t}$ at a single timepoint t. Assuming the low-rankness of the respiration motion [8], $\mathbf{M}$ can be approximated to

$$\mathbf{M} = \mathbf{C} \cdot \mathbf{S} = \sum_{i=1}^{r} \mathbf{C}^{(i)} \cdot \mathbf{S}^{(i)} \tag{2}$$

where r is the rank number, $\mathbf{C}$ and $\mathbf{S}$ are $N_m \times r$ and $r \times n$ matrices denoting r spatial bases and r temporal bases respectively. For surrogate driven models, $\mathbf{C}$ is the motion model which is optimised during the fitting, but $\mathbf{S}$ are the measured surrogate signals which are fixed during fitting. In this work we **extend the surrogate-driven method by also optimising the surrogate signals**.

To determine the model parameters, we minimize the following loss function

$$f = -\sum_{t=1}^{n} L(\mathbf{P}'_\mathbf{t}, \mathbf{P}_\mathbf{t}) \tag{3}$$

where L represents local normalized cross correlation [9], $\mathbf{P}'_\mathbf{t}$ is the estimated projection at time t and is given by:

$$\mathbf{P}'_\mathbf{t} = \mathbf{A}_\mathbf{t} \cdot \mathbf{I}_\mathbf{t} = \mathbf{A}_\mathbf{t} \cdot T(\mathbf{I_0}, \mathbf{M_t}) \tag{4}$$

in which $\mathbf{A_t}$ is the CBCT projection acquisition matrix at time t.

2.2 Optimization Algorithm

How many temporal basis functions are needed is an open question, although it has been shown that two principal components are sufficient to approximate intra-fraction lung motion [10]. In this study, one spatial and temporal basis were optimized first and more degrees of freedom were included and optimized sequentially to account for more complicated motion. More specifically, we started with optimizing just one spatial and temporal basis until objective function value did not improve, after which another pair of spatial and temporal basis was incorporated and optimized with the previous bases frozen. The same process could continue until no improvement of image quality was observed by manual check. The first temporal basis was initialised with a surrogate signal extracted from the CBCT projections using the Intensity Analysis method [6] and the other temporal bases were initialised with the derivative of the previous optimized temporal basis.

Stochastic gradient descent is used to optimize $\mathbf{C}^{(i)} (i = 1, ..., r)$. More specifically, ten subsets of evenly spaced projections are created and one of them is randomly selected with uniform probability to update the gradient at each iteration:

$$\begin{aligned} \frac{\partial f_s}{\partial \mathbf{C}^{(i)}} &= \sum_{t \in \Omega_s} \frac{\partial \mathbf{M_t}}{\partial \mathbf{C}^{(i)}} \cdot \frac{\partial \mathbf{I_t}}{\partial \mathbf{M_t}} \cdot \frac{\partial \mathbf{P}'_\mathbf{t}}{\partial \mathbf{I_t}} \cdot \frac{f}{\partial \mathbf{P}'_\mathbf{t}} \\ &= -\sum_{t \in \Omega_s} \mathbf{S}_t^{(i)} \cdot \frac{\partial T(\mathbf{I_0}, \mathbf{M_t})}{\partial \mathbf{M_t}} \cdot \mathbf{A_t}^* \cdot \frac{L(\mathbf{P}'_\mathbf{t}, \mathbf{P_t})}{\partial \mathbf{P}'_\mathbf{t}} \end{aligned} \tag{5}$$

where f_s is the loss function as in Eq. 3 but now summed over the selected projection subset, $\mathbf{A}^*$ is the back-projection matrix and Ω_s is the set of indices in the selected subset.

$\mathbf{S}^{(i)}$ is optimized with gradient descent for each time point separately. For time t, the gradient is similar to Eq. 5:

$$\frac{\partial f}{\partial \mathbf{S}_t^{(i)}} = -\sum_{v=1}^{N_m} \mathbf{C}_v^{(i)} \cdot \frac{\partial T(\mathbf{I_0}, \mathbf{M_t})}{\partial \mathbf{M}_{\mathbf{t},v}} \cdot \mathbf{A_t}^* \cdot \frac{L(\mathbf{P}'_\mathbf{t}, \mathbf{P_t})}{\partial \mathbf{P}'_\mathbf{t}} \tag{6}$$

Note that the outermost summation is over space rather than over time.

For the ith basis function, we performed 5 iterations of optimising $\mathbf{C}^{(i)}$ and then 5 iterations of optimising $\mathbf{S}^{(i)}$. Then $\mathbf{S}^{(i)}$ was normalized to have mean of 0 and standard deviation of 1, and the corresponding spatial basis was scaled accordingly. Then motion compensated FDK reconstruction [7] was used to update $\mathbf{I_0}$, which should match the mid respiration position since the surrogate signals have been normalized. All the steps were repeated up to a maximum of 5 times or until no more improvement.

This study adopted a multi-resolution approach with three spatial resolution levels. The optimisation was only performed at the first two levels as it was found that optimising at the final (original) resolution level only provided marginal improvement but greatly increased the computation time. Our method has been implemented by extending an open source software SuPReMo, and will itself be released in the future.

2.3 Test Data

Phantom simulation and clinical 3D CBCT scans from eight patients were used to evaluate and compare the surrogate-optimized and surrogate-driven motion model.

The 4DXCAT software [11] was used to generate a reference state image and the motion fields for each projection of a 3D CBCT scan, according to breathing signals measured from cine sagittal MR images of real patients. A python library for motion field post-processing [12] was utilized to make the simulated motion fields more physically plausible. The OpenRTK library [13] was then used to generate the CBCT projection images from the dynamic phantom images according to projection acquisition geometry of a 1-minute CBCT scan on Elekta Synergy (Elekta AB, Stockholm, Sweden). The number, dimension size and resolution of the projection images were 310, 512×512 and 0.8×0.8 mm. For the phantom simulation, the repspiration was driven by two input breathing signals. Therefore, two surrogate signals / temporal basis were used. For the surrogate-driven motion model, we extracted the first surrogate signal from projections using Intensity Analysis and used its derivative as the second surrogate signal.

The Clinical 3D CBCT scans were from the ROSS-LC clinical trial (REC ref. 14/NW/0037). The data were acquired using an Elekta XVI system under standard 3D CBCT settings, i.e. ∼600 projections during a 2-minute scan over a full rotation. The SID and SDD were 1000 mm and 1536 mm respectively. Resolution and dimensional size of the projection images were 0.8×0.8 mm and 504×504 respectively. Eight patients with medium or large field-of-view scans were used.

For the phantom simulation data, the ground-truth motion fields for each projection were known, which could be used to generate tumor masks for each projection and a gold standard

motion compensated reconstruction. Four evaluation metrics were calculated: the dice score between estimated and true tumor masks (DSC), the euclidean distance between estimated and true tumor centroid positions (E_{center}), the magnitude of motion field differences (E_D), and the Peak-Signal-To-Noise-Ratio between the motion compensated reconstructions using estimated and true motion fields (PSNR). All the metrics above refer to the average value over all projections.

3 Results

Table 1 displays the evaluation metrics for the phantom simulation experiment. By applying a motion model all the metrics were substantially improved. Compared with the surrogate-driven method, the proposed surrogate-optimized motion model further improved all the metrics, although the improvements were relatively small except for DSC and E_{center}.

Scenarios	DSC	E_{center}	E_D	PSNR
no motion model	0.627	4.188	1.701	24.806
surrogate driven	0.835	1.728	1.300	25.88
surrogate optimized	0.883	1.181	1.260	26.00

Table 1: Evaluation metrics on phantom experiments under three scenarios: no motion model, surrogate-driven motion model, or surrogate-optimized motion model. Definition of metrics are in section 2.3.

Figure 1 shows the surrogate signal extracted by Intensity Analysis and the optimized temporal basis for patient 1 from the ROSS-LC clinical trial, respectively. For this patient, manual check found that the reconstructions out of one and two bases looked almost the same, so only one temporal basis was used. It can be seen that the surrogate-optimized approach produces an optimised temporal basis that is different to the input surrogate signal extracted by Intensity Analysis, but whether the optimised temporal basis can better estimate the patients' internal motion is impossible to determine without knowing the ground-truth motion.

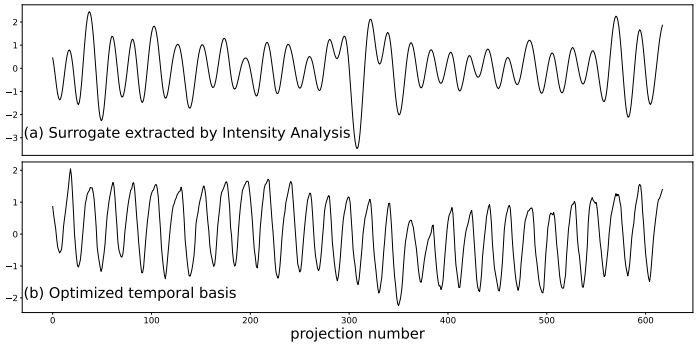

Figure 1: Input surrogate signal extracted by Intensity Analysis(a) and optimized temporal basis out of surrogate-optimized motion model(b) for one 3D CBCT scan from ROSS-LC trial.

However, the image quality from the different methods could be compared visually. Figure 2 displays the standard (non-motion compensated) FDK reconstruction, and the motion compensated FDK reconstruction using the surrogate-driven and surrogate-optimized motion models, at slices intersecting tumor for three patients from ROSS-LC trial. It can be seen that the surrogate-driven motion model already greatly reduced the motion artifacts in the scans, but the surrogate-optimized motion model further improved the sharpness of the diaphragm and visibility of details of the tumor and lung tissues.

For all the other patients from the ROSS-LC trial, the surrogate-optimized motion model produced motion compensated FDK reconstructions that were better or as good as those from the surrogate-driven motion model. The three patients shown in Figure 2 were selected to show the cases with the largest improvements of the surrogate-optimized method.

4 Discussion and Conclusion

Surrogate-driven motion models rely on being able to obtain surrogate signals that have a strong relationship with the patients' internal motion. However, in clinical practice it is often not easy or even possible to acquire suitable signals. This study has used phantom simulation data and clinical 3D CBCT scans to show that motion estimation accuracy and image quality of motion compensated reconstructions can be improved using the surrogate-optimized motion model compared with surrogate-driven motion model. It should be noted that we have also tested other surrogate extraction method such as the well known Amsterdam Shroud method [14], but the Intensity Analysis method was found to be the most robust one.

The output of our models include the estimated motion for each projection during the CBCT scan, as well as the motion compensated CBCT reconstruction image with reduced motion artifacts. The improved CBCT images could facilitate better identification of anatomical changes that occur throughout the course of radiotherapy. The estimated motion can be used to perform dose calculations and to define targets that account for the motion.

Our code was run on an Intel Core i7-10700K CPU of 3.8GHz and 8 cores. The surrogate-driven approach took on average half an hour to fit the model. However, the time to fit the surrogate-optimised models was considerably longer (8 hours), which is expected as optimising the temporal basis cannot take advantage of the stochastic subset approach. Future work will develop more advanced parallel algorithms and implementations that can be run on a GPU to reduce the computation time.

In conclusion, this study has presented a method for applying a surrogate-optimized motion model to CBCT projection data. This method has been evaluated using both simulated

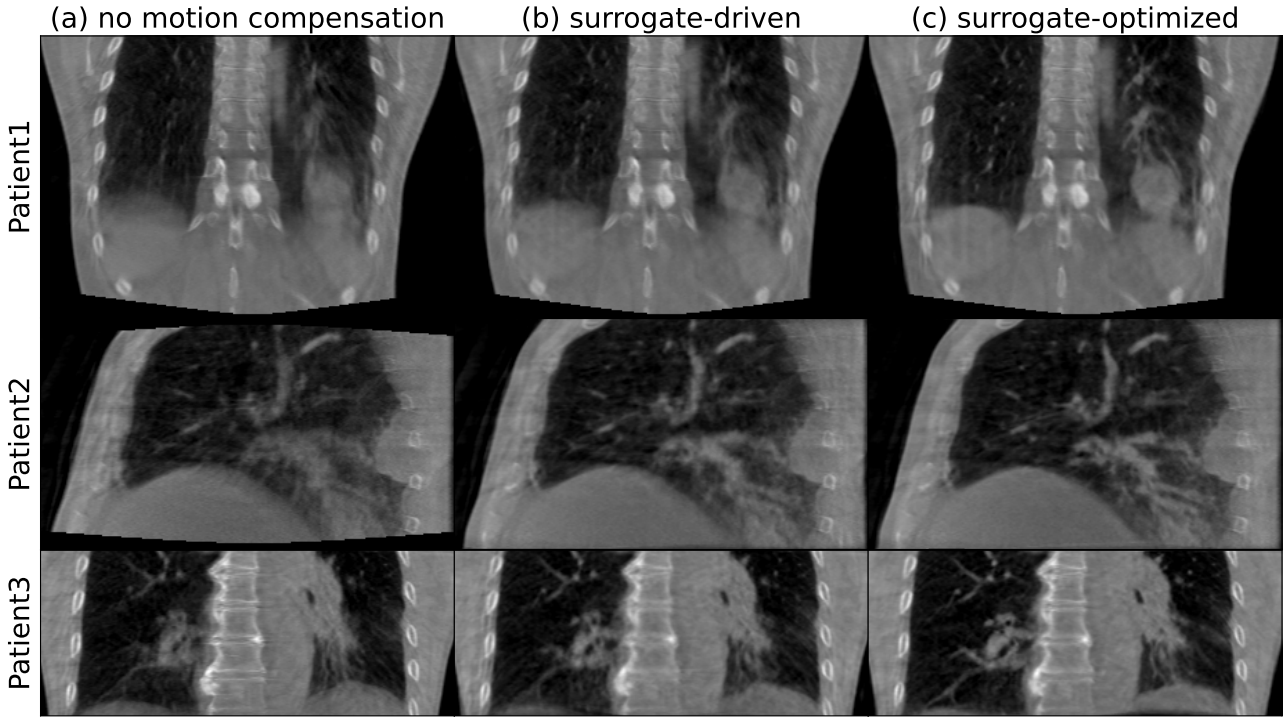

Figure 2: Comparison between (a) standard FDK reconstruction, and motion compensated FDK reconstructions using (b) surrogate-driven and (c) surrogate-optimized motion models at slices intersecting tumor for three patients in the ROSS-LC trial.

and real patient data. In the future such an approach could be of great benefit for adaptive radiotherapy treatments to lung cancer patients.

Abstract The adoption of proton therapy for the treatment of small lung tumors has been cautious due to the sensitivity of proton range to geometric and radiological uncertainties. There is however a potential of sparing dose to organs at risk if such treatments could be performed confidently. In this study a comprehensive Monte Carlo based method of evaluating the impact of these uncertainties for treatments in breath-hold and free-breathing is proposed together with a method for deforming images based on Laplace and Poisson editing. Tabulated values was used for the uncertainty parameters and free-breathing motion was simulated using tumor positions from multiple cine-CT.
A breath-hold proton plan was compared to breath-hold and free-breathing photon plans. With robust treatment planning adequate target coverage was achieved for the proton plan with the benefit of lower mean heart dose but at the cost of higher dose to the esophagus.

1 Introduction

Hypofractionated, stereotactic body radiotherapy (SBRT) for small peripheral lung tumors has improved the treatments for these patients. However, the uncertainties caused by patient setup, breathing motion and stopping power ratio (SPR) conversion from computed tomography (CT) image values have caused a cautious adoption of analogous proton therapy strategies [1].

At the same time, since the survival of these patients with early-stage disease have seen such improvements they are the ones that could benefit the most from the dose sparing of proton therapy. Robust optimization that considers the uncertainties can ensure dose coverage of the target and the use of Monte Carlo (MC) to thoroughly evaluate treatment plans has been demonstrated [2]. Given current capabilities of most proton therapy centers these patients could be treated either in breath-hold (BH) or in free-breathing (FB). The choice of treatment modality would depend on the extent of the breathing motion, breath-hold capacity, location of the tumor in the lung and estimated benefits of choosing proton compared to photon therapy.

We propose a unified framework based on Laplace and Poisson editing for creating deformed evaluation images for both BH and FB treatments were the FB motion was simulated using tumor positions from cine-CT. Further, we propose a MC framework for sampling pre-calculated perturbed dose distributions computed on the evaluation images. A BH proton plan and a BH and a FB photon plan were evaluated and compared. The results of the proposed robustness analysis for one patient is presented.

Table 1: Standard deviations for the parameters used in the robust planning and evaluation. Σ refers to systematic errors that persist during the whole treatment and σ to random errors that are different at each fraction or breath-hold.

	LR	AP	SI
Patient setup [mm] [4]			
Σ_{ps}	1.1	1.5	1.4
σ_{ps}	1.4	1.7	1.7
Breath-hold tumor position [mm] [5]			
Σ_{bh}	1.3	1.2	1.1
σ_{bh}	0.9	1.0	1.0
Stopping power ratio [%] [6]			
Σ_{ρ}		3.8	

2 Materials and Methods

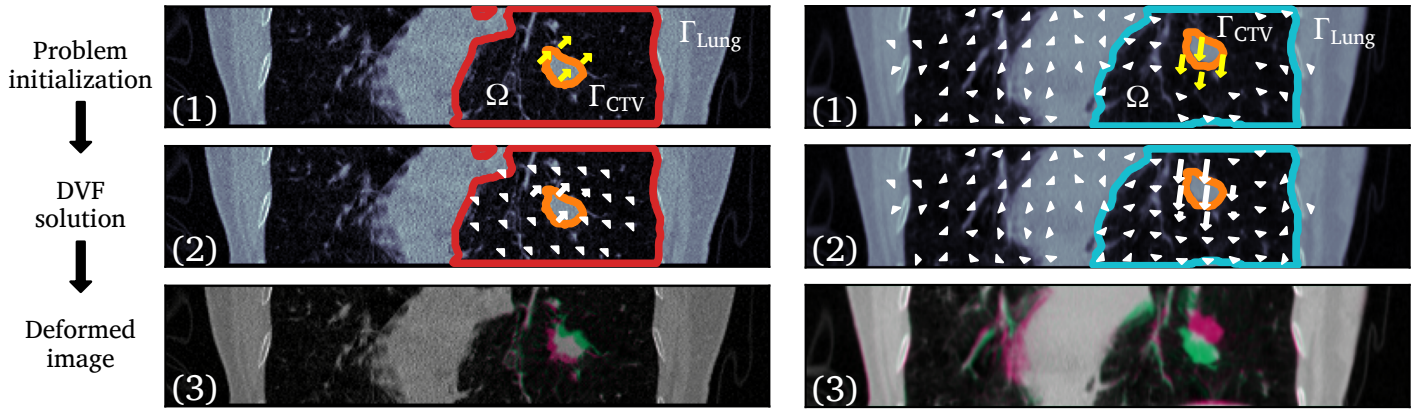
2.1 Patient image data and uncertainty values

The patient data set consisted of one breath-hold CT (BHCT), a 4DCT with ten respiratory phase images and a set of 300 cine-CT acquired at three occasions of approximately eight minutes each. Deformable image registration was used to map the 30% phase image to the other images in the 4DCT and rigid image registration was used to find the cine-CT tumor position in the 4DCT frame of reference [3].

Tabulated values were used to simulate uncertainties and are summarized in Table 1. Patient setup uncertainty was taken from Li *et al.* [4], BH tumor position reproducibility uncertainty from Josipovic *et al.* [5] and proton SPR uncertainty from Li *et al.* [6].

2.2 Robust treatment planning

Robust planning was performed for both the proton and the photon plans to the 90% confidence interval [7]. Perturba-



(a) Breath-hold (Laplace) (b) Free-breathing (Poisson)

Figure 1: Image deformation modeling using (a) Laplace and (b) Poisson editing. The DVF arrows have been scaled for the illustration.

Table 2: Robust optimization perturbations calculated using the values in Table 1 to the 90th confidence interval using the method by Buti *et al.* [7]. The SPR perturbations were only used for proton therapy planning.

	Isotropic shift [mm]	SPR [%]	4DCT
Breath-hold	7.0	4.8	No
Free-breathing	4.0	4.8*	Yes

*Proton therapy was not evaluated in free-breathing.

tions used in the planning were calculated from the standard deviations in Table 1 and can be seen in Table 2. For the FB treatment 4DCT was used to accommodate the respiratory motion.

All three treatment plans had the intention of delivering a dose in three fractions such that CTV $D_{50\%}$ = 54 Gy. The treatment planning and evaluation dose computations were performed with the RayStation treatment planning system (RaySearch Laboratories AB, Stockholm, Sweden). The photon dose computations were performed using collapsed cone and the proton doses using MC with constant relative biological effectiveness factor of 1.1.

2.3 Deformed evaluation images

A simple method of generating smooth displacement vector fields (DVF) for rigid tumor shifts inspired by the classical works on Poisson image [8] and Laplacian surface [9] editing is proposed.

Breath-hold evaluation images were constructed by solving the Laplace equation

$$\nabla^2 u = 0, \quad \text{on } \Omega \tag{1}$$

subject to a zero displacement at the surface of the lung, Γ_{Lung}, and a fixed displacement, a, set for the tumor, Γ_{CTV}

$$\begin{cases} u = 0, & \text{on } \Gamma_{\text{Lung}} \\ u = a, & \text{on } \Gamma_{\text{CTV}} \end{cases} \tag{2}$$

where the geometry and a solution is shown in Figure 1 (a). This problem was solved once for each cardinal direction and the vector field was constructed from each component scalar field, u, and applied to the BHCT.

Values for the tumor displacement were sampled at 15 positions according to a systematic error and for each such offset at 15 positions according to a random error in the BH reproducibility according to the values in Table 1 [6]. In total 225 breath-hold evaluation images were created and used.

Free-breathing evaluation images were constructed by solving the Poisson equation

$$\nabla^2 u = f, \quad \text{on } \Omega \text{ with } f = \nabla^2 v \tag{3}$$

where the source term f was computed from the background displacement with component in one direction, v. This background DVF was computed with deformable image registration that transforms the reference image to the phase-image in the 4DCT with the tumor closest to the evaluation position. This evaluation tumor position is set to one of the positions found in the cine-CT image sequences. The boundary conditions were set to

$$\begin{cases} u = v, & \text{on } \Gamma_{\text{Lung}} \\ u = a, & \text{on } \Gamma_{\text{CTV}} \end{cases} \tag{4}$$

such that the DVF at the lung boundary and outside is set to the original deformable transform, Figure 1 (b). The DVF was applied to the 30% phase image in the 4DCT.

Both the Laplace and the Poisson problems were discretized using finite differences on a coarsely sampled image grid and solved using a sparse solver. The DVFs were inverted to allow dose accumulation by applying the transform to the image element positions and resampling these values on the original grid using nearest-neighbor.

2.4 Evaluation dose and probability computations

A large set of dose distributions were computed for each plan. Systematic patient setup-error was sampled at 15 positions, one with zero shift, six positions on the cardinal axes

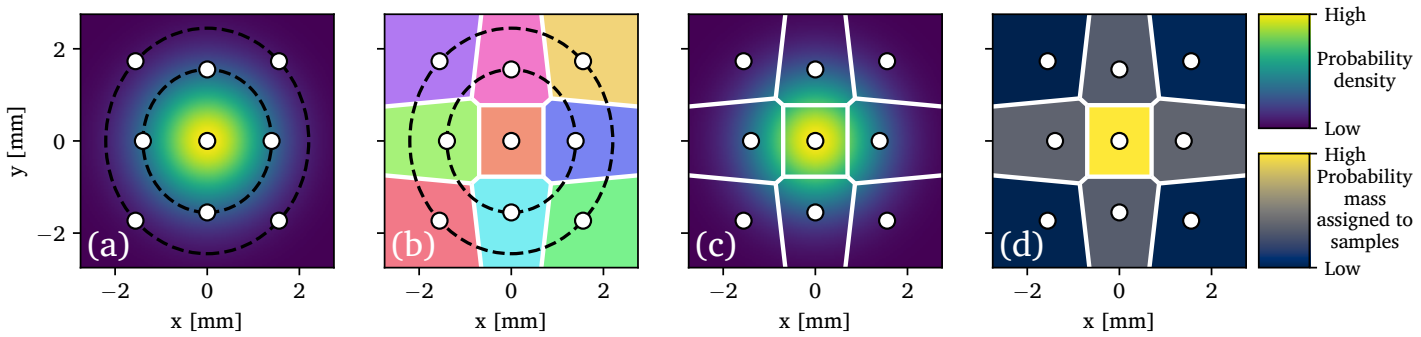


Figure 2: Positioning uncertainty and perturbations. The probability density was modeled using a normal distribution and the probability mass associated with a sample was found by MC integration of the probability density of all points in space closest to the sample.

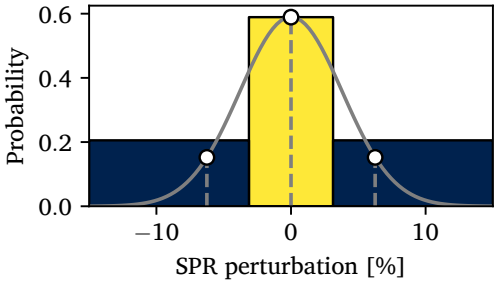

Figure 3: SPR uncertainty and perturbations.

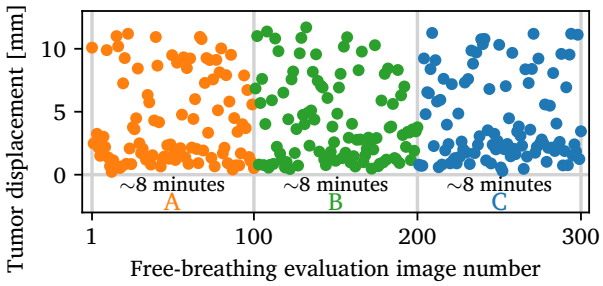

Figure 4: Vector lengths of the cine-CT tumor displacements.

at the 70% confidence interval and eight positions on the axis-aligned box at the 95% confidence interval. The same sampling pattern was used for the random setup error and both the systematic and random breath-hold tumor position error. This sample pattern is illustrated for 2D in Figure 2 where the discretized probability associated with each sample is also shown. These probabilities were calculated using MC integration of the probability density of all points lying closest to the sample as indicated by the Voronoi cells.

This sampling pattern resulted in $15^4 = 50\,625$ dose distributions for the BH photon evaluation and, with three sample positions for SPR uncertainty as seen in Figure 3, 151 875 dose distributions for the proton evaluation.

The free-breathing treatment was simulated using a set of 300 cine-CT derived tumor positions [3] divided into three according to the three imaging occasions, A, B and C in Figure 2. These were used to simulate the dose in one treatment fraction where either of the three sequences were considered as equally probable. This resulted in a total of $15^2 \times 300 = 67\,500$ photon dose distributions that were further accumulated per respiratory sequence into 675 possible fraction doses.

2.5 Monte Carlo scenario simulations and analysis

By MC sampling and accumulation of pre-computed dose distributions treatment scenarios consisting of three fractions were simulated.

For the two BH treatments it was assumed that one treatment field could be delivered in a single BH such that the proton plan was delivered in three BHs per fraction and the photon plan in seven as indicated by the number of beams in Figure 5 (a_1) and (b_1). Thus, one BH treatment scenario was simulated by sampling one SPR position, one systematic patient position, one systematic BH tumor position, then for each of the three fractions a random patient position was sampled and then one random BH tumor position was sampled for each beam direction.

One FB treatment was simulated by sampling one systematic patient position, then for each of the three fractions a random patient position and one of the three respiratory sequences seen in Figure 4 were sampled.

1000 scenarios were simulated per plan. The plans were evaluated at the 90% probability, $\mathbb{P}_{90\%}$, to achieve a certain dose metric for the CTV. The analogous analysis was performed for the organs at risk but $\mathbb{P}_{90\%}$ represents the probability of protecting the structure from higher doses.

3 Results

All three treatment plans achieved a $\mathbb{P}_{90\%}$(CTV $D_{50\%}$) in line with the intended 54 Gy, with the range of values being higher for the proton plan. The two photon plans provided similar results. The proton plan had lower mean heart dose and smaller lung sub-volume at 11.4 Gy compared to the photon plans. The dose to the esophagus was however higher for the proton plan.

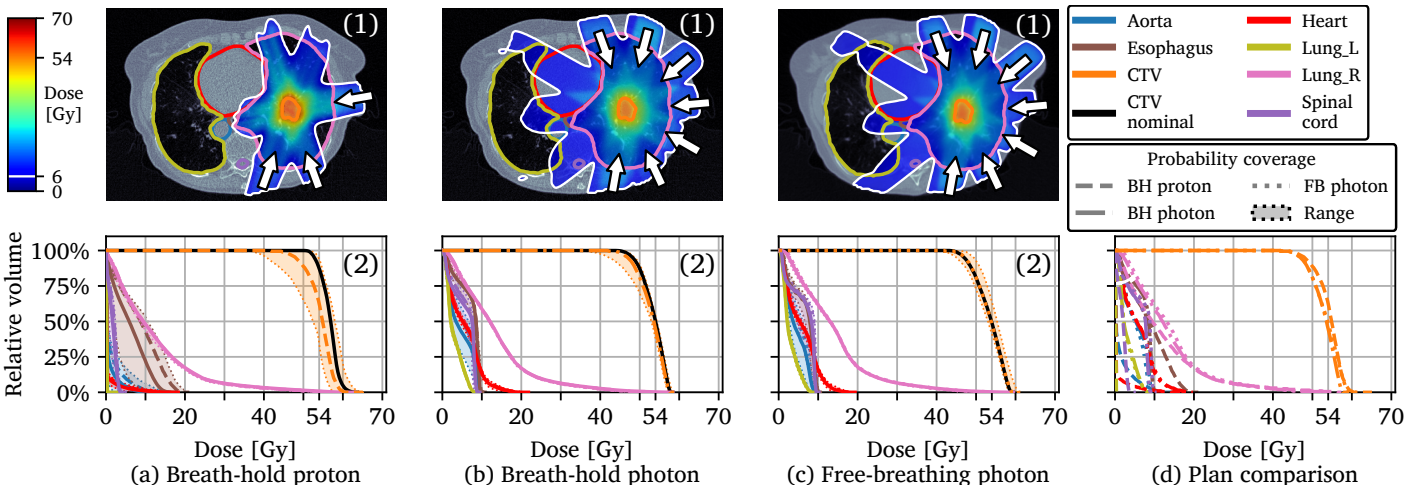

Figure 5: Nominal plan dose distributions, truncated at 6 Gy, and DVH bands. Nominal DVHs are shown as solid lines, while the $\mathbb{P}_{90\%}$ to achieve a coverage for the CTV and protection for any of the organs at risk are shown as dashed, dash-dotted and dotted lines for the three plans respectively in (a), (b) and (c) where all are shown together in (d). The range of the DVHs are shown as brighter bands.

Table 3: Resulting dose metrics.

	BH proton Nominal [min, max] ($\mathbb{P}_{90\%}$)	BH photon Nominal [min, max] ($\mathbb{P}_{90\%}$)	FB photon Nominal [min, max] ($\mathbb{P}_{90\%}$)
CTV $D_{50\%}$ [Gy]	56.9 [52.5, 58.0] (54.9)	54.0 [53.0, 54.4] (53.6)	53.9 [53.0, 55.4] (53.9)
Heart D_{mean} [Gy]	0.5 [0.2, 0.8] (0.6)	5.7 [5.3, 6.1] (5.8)	5.8 [5.5, 6.2] (6.0)
Lung $V_{11.4\,\text{Gy}}$ [cm^3]	385 [348, 390] (386)	475 [464, 479] (477)	468 [457, 480] (473)
Esophagus D_{max} [Gy]	17.5 [12.2, 21.2] (19.8)	9.6 [9.2, 12.0] (10.2)	9.9 [9.5, 10.2] (10.0)

4 Discussion

Although the proton plan did not have consistently lower doses for all organs at risk the reduced heart dose could be of clinical benefit. The quality of the proton plan will however depend on the beam angles, here at the cost of high dose to the esophagus. The DVF creation method was not validated against images with known displacements. The proposed discrete sampling schema imposed long computation times and not all dose distributions were used in the simulations.

5 Conclusion

In this study a MC based framework for the evaluation of proton and photon therapy was proposed. BH and FB plans were compared and proton BH plan demonstrated a reduced dose to the heart and lung compared to the two photon plans at the cost of higher dose to the esophagus.

Abstract Real-time cone-beam CT (CBCT) imaging provides instantaneous patient anatomy for image guidance and online treatment adaptation in radiotherapy. However, real-time CBCT imaging faces a stringent temporal constraint (<500 ms) under respiration-induced anatomical motion, leading to extreme under-sampling (only a few x-ray projections can be acquired). We proposed a joint dynamic CBCT reconstruction and motion estimation (DREME) framework to address this challenge. DREME reconstructs a dynamic CBCT from a pre-treatment conventional CBCT scan, while simultaneously deriving a deep learning-based, angle-agnostic model for real-time motion and CBCT estimation based on a single X-ray projection. Specifically, DREME uses a prior model-free spatiotemporal implicit neural representation (PMF-STINR) framework to reconstruct dynamic CBCTs and derive a data-driven motion model. The motion model, which captures the up-to-date and patient-specific motion patterns, is used by DREME to train a deep learning model to estimate real-time motion and CBCT from an arbitrarily-angled X-ray projection. DREME was evaluated using digital phantom simulations and a dataset of lung patients. The results showed that DREME can accurately solve 3D motion with high accuracy (phantom: 1.0±0.4 mm, and patients: 1.3±1.2 mm) in real time (~1.5 ms inference time for each X-ray projection).

1 Introduction

The technical advancements of radiotherapy have significantly improved its accuracy over the past few decades. However, intra-treatment motion, particularly respiration-induced motion, remains a major source of uncertainty during the radiation delivery. Real-time adaptive radiotherapy that tracks and adapts to the volumetric motion in real time can ultimately solve the challenge. However, for respiratory motion (~3-5 s per cycle), the temporal latency of real-time imaging should be < 500 ms. Within such a short duration, only several X-ray projections can be acquired for CBCT imaging and motion tracking, leading to extreme under-sampling.

Under the extreme under-sampling, conventional methods fell short in reconstructing CBCT images for volumetric motion tracking. Recently, deep learning (DL)-based approaches have been proposed for real-time imaging and motion estimation, due to their imaging processing power and fast inference time. The DL-based methods include reconstruction-based [1] and registration-based [2] approaches. Reconstruction-based methods used neural networks to directly reconstruct a 3D image from extremely limited projections (a single projection as in [1]). However, direct 2D-to-3D reconstruction without access to additional information makes a highly ill-posed inverse problem, rendering such models susceptible to robustness and generalization issues. Additional registration/segmentation is also needed after the reconstruction for motion tracking, which results in additional latency. Alternatively, registration-based methods directly solved motion fields on existing prior images for tracking. For example, principal component analysis-based motion model from a prior 4D-CT was used for real-time motion estimation [2]. While the prior information significantly alleviates the ill-posed condition, it nevertheless introduces additional biases as the prior image or the motion model can be outdated due to inter-fractional anatomical and motion variations.

To address the above challenges, we proposed to combine a recently-developed dynamic CBCT reconstruction method [3] with a DL-based, real-time motion estimation model into a joint dynamic reconstruction and motion estimation (DREME) framework for real-time motion and CBCT estimation. DREME uses a prior model-free spatiotemporal implicit neural representation (PMF-STINR) method for dynamic CBCT reconstruction. PMF-STINR reconstructs the latest patient-specific dynamic CBCTs and extracts an up-to-date motion model directly from pre-treatment onboard projections to capture both regular and irregular motion. Based on the PMF-STINR motion model, DREME further trains a CNN-based DL model to extract motion-related image features from an arbitrarily-angled X-ray projection to predict the 3D motion field and estimate real-time CBCTs. DREME was evaluated by the extended cardiac torso (XCAT) digital phantom and a dataset of lung patients, to assess its real-time CBCT imaging and motion tracking accuracy.

2 Materials and Methods

2.1 DREME workflow overview

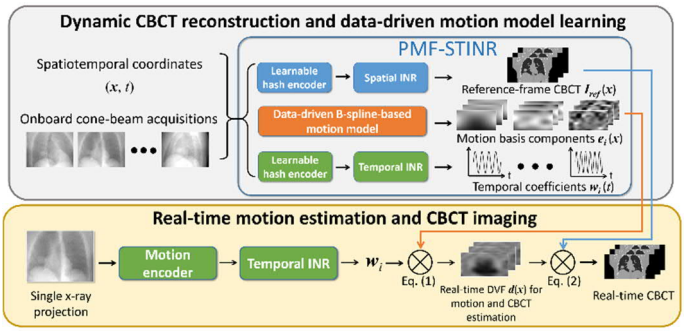

Fig. 1. Workflow of the DREME framework. (*Top panel*) In the first step of DREME, a dynamic CBCT sequence and a motion model is derived from a standard CBCT acquisition by PMF-STINR. PMF-STINR takes spatial and temporal coordinates ($\boldsymbol{x}$, t) and cone-beam projections as inputs, and reconstructs a reference-frame CBCT $\boldsymbol{I}_{ref}(\boldsymbol{x})$, a motion model of motion basis components $\boldsymbol{e}_i(\boldsymbol{x})$ (i=1-3), and corresponding temporal coefficients $\boldsymbol{w}_i(t)$ (i =1-3). The motion model, scaled by the temporal coefficients, will generate DVFs to deform $\boldsymbol{I}_{ref}(\boldsymbol{x})$ to dynamic CBCTs. (*Bottom panel*) In the second step, the learned reference-frame CBCT and motion model are used to train a motion encoder on arbitrarily-angled X-ray projections to estimate real-time DVFs for motion and CBCT estimation.

Figure 1 illustrates the two-step workflow of DREME. In the first step, PMF-STINR [3] was employed to reconstruct a dynamic CBCT sequence and a patient-specific motion model from a standard free-breathing CBCT scan. The dynamic CBCTs were generated by reconstructing a reference-frame CBCT $\boldsymbol{I}_{ref}(\boldsymbol{x})$ and solving time-varying deformation vector fields (DVFs) $\boldsymbol{d}(\boldsymbol{x}, t)$ with respect to $\boldsymbol{I}_{ref}(\boldsymbol{x})$. Here, $\boldsymbol{x}$ and t represent the spatial voxel coordinates and temporal frame index of the dynamic CBCTs, respectively. A low-rank representation of $\boldsymbol{d}(\boldsymbol{x}, t)$ was employed for dimension reduction:

$$\boldsymbol{d}(\boldsymbol{x}, t) = \sum_{i=1}^{L} \boldsymbol{w}_i(t) \times \boldsymbol{e}_i(\boldsymbol{x}), \quad (1)$$

where $\{\boldsymbol{w}_i(t)\}_{i=1}^{L}$ and $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{L}$ respectively denote the temporal coefficients and spatial components of $\boldsymbol{d}(\boldsymbol{x}, t)$, and L denotes the number of spatial components in the low-rank representation. Here L=3 was used, as it has been demonstrated sufficient to accurately describe respiratory motion in previous works. $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{3}$ made a set of basis components spanning a functional space of motion, rendering a motion model. The whole dynamic CBCT sequence was obtained by deforming $\boldsymbol{I}_{ref}(\boldsymbol{x})$ via:

$$\boldsymbol{I}(\boldsymbol{x}, t) = \boldsymbol{I}_{ref}(\boldsymbol{x} + \boldsymbol{d}(\boldsymbol{x}, t)). \quad (2)$$

In the second step, DREME leveraged the learned onboard motion model $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{3}$ and the reference-frame image $\boldsymbol{I}_{ref}(\boldsymbol{x})$ for real-time motion and CBCT estimation. Specifically, it trained a convolution-based motion encoder to extract motion-related features from an arbitrarily-angled X-ray projection. The motion encoder output a motion feature vector which was then fed into the inherited temporal INR from PMF-STINR to predict the corresponding temporal coefficients $\{\boldsymbol{w}_i\}_{i=1}^{3}$. The predicted $\{\boldsymbol{w}_i\}_{i=1}^{3}$, combined with the motion model $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{3}$, yielded real-time DVFs $\boldsymbol{d}(\boldsymbol{x})$ for motion tracking and CBCT estimation. In the following, we elaborated the details of PMF-STINR and the 2nd step motion encoder, along with the evaluation schemes of DREME.

2.2 Dynamic CBCT reconstruction (PMF-STINR)

As illustrated in Fig. 1, PMF-STINR consisted of three modules, separately and simultaneously solving $\boldsymbol{I}_{ref}(\boldsymbol{x})$, $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{3}$, and $\{\boldsymbol{w}_i(t)\}_{i=1}^{3}$. The overall reconstruction scheme was based on an emerging machine learning technique named implicit neural representation (INR) [4]. Acting as a non-parametrized universal approximator, the INRs can be used to map complex spatial images (spatial INR) and temporal variations (temporal INR) with lightweight multi-layer perceptrons to promote sparsity and under-sampled learning. PMF-STINR used a spatial INR to represent and map the reference-frame CBCT $\boldsymbol{I}_{ref}(\boldsymbol{x})$. A learnable hash encoder [5] was employed together with the spatial INR to improve the learning capacity of high-frequency image features. In parallel, PMF-STINR also used a temporal INR and a B-spline-based data-driven model to capture the motion dynamics $\{\boldsymbol{w}_i(t)\}_{i=1}^{3}$ and $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{3}$ from the cone-beam projections, respectively. The combined temporal INR and the data-driven motion model solved the time-varying DVFs $\boldsymbol{d}(\boldsymbol{x}, t)$ with respect to $\boldsymbol{I}_{ref}(\boldsymbol{x})$ to yield the dynamic CBCTs (Eq. 2). The temporal INR shared an architecture similar to the spatial INR. The data-driven motion model was learned on-the-fly during PMF-STINR reconstruction, without relying on any patient-specific prior information. To regularize the motion learning, $\{\boldsymbol{e}_i(\boldsymbol{x})\}_{i=1}^{3}$ was parametrized by a cubic B-spline interpolant, and the spatial resolution of the B-spline control points was doubled for each higher level. At each level, the B-spline control point values are learnable parameters.

The training of PMF-STINR was driven by a projection-domain similarity loss (mean squared error) and a total variation-based image-domain regularization loss, via a one-shot learning scheme. The spatial and temporal INRs and the data-driven motion model were trained simultaneously to improve the consistency and coherence between $\boldsymbol{I}_{ref}(\boldsymbol{x})$, $\boldsymbol{d}(\boldsymbol{x}, t)$, and the cone-beam projections. The one-shot learning does not require any additional training dataset and avoids the generalization issues encountered in most DL-based approaches. PMF-STINR had been demonstrated to accurately capture regular and irregular respiratory motion with high spatial (<=2 mm^3) and temporal (~0.1 s) resolutions. Further details of PMF-STINR can be found in our recent manuscript [3].

2.3 Real-time motion and CBCT estimation

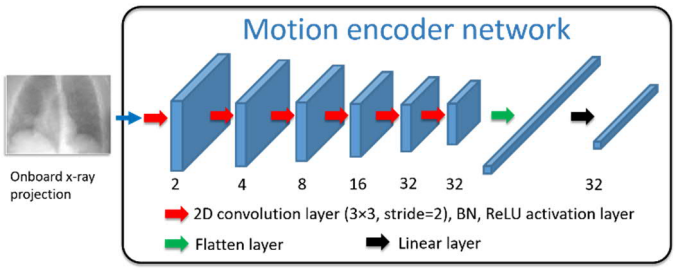

Fig. 2. Network architecture of the angle-agnostic motion encoder. The input of the motion encoder was an arbitrarily-angled X-ray projection, and the motion-related image features were extracted by a series of 2D convolution layers to yield a 32-element feature vector.

The dynamic reconstruction by PMF-STINR yielded an up-to-date, patient-specific motion model; and a reference-frame CBCT reflecting the latest patient anatomy. To use the same motion model and reference CBCT for real-time motion and CBCT prediction, we replaced the hash encoder of the temporal INR by a 2D convolution-based motion encoder (Fig. 2) in the 2nd step. By PMF-STINR, the hash encoder encoded temporal indices for the temporal INR to derive corresponding temporal motion coefficients (Fig. 1). These coefficients were then used to weight the motion model to derive dynamic DVFs and deform the reference CBCT to dynamic CBCTs. Similarly, by the real-time motion estimation framework (Fig. 2), the motion encoder directly encoded an arbitrarily-angled X-ray projection for the temporal INR to derive real-time motion coefficients (Fig. 1). The motion coefficients, combined with the motion model and the reference CBCT, yielded real-time DVFs to generate real-time CBCTs.

To train an angle-agnostic motion encoder, we simulated digitally reconstructed radiographs (DRRs) at random angles from different dynamic CBCTs, which were generated by deforming the reference CBCT with various dynamic DVFs (with known motion coefficients). With the known 'ground-truth' motion coefficients as training labels, we used a supervised learning scheme to train the motion encoder to extract motion-related features from the DRRs for the temporal INR to predict corresponding motion coefficients. X-ray photon Poisson noise and electronic Gaussian noise were simulated and added to the DRRs to improve the model robustness.

2.4 Evaluation datasets and schemes

The overall DREME framework was evaluated by the XCAT phantom and a dataset of 4 lung patients.

2.4.1 XCAT simulation study

We used XCAT to simulate a lung patient. A spherical tumor 30-mm in diameter was inserted in the lower right lung to evaluate the real-time motion estimation accuracy. Six free-breathing motion scenarios (X1-X6) featuring various irregular motion patterns (different breathing amplitudes, breathing periods, baseline drifts/shifts, and their combinations) were simulated. For each motion scenario, dynamic/real-time cone-beam projections were simulated based on a 360° scan with 60 s scanning time and an 11 frames/s projection acquisition rate. We trained DREME on one scenario and then tested it on the remaining scenarios (for instance, trained on X1 and tested on X2-6), yielding six groups of evaluations.

The reconstructed real-time CBCTs were quantitatively evaluated using relative error (RE) and structural similarity index (SSIM), measured against the known 'ground-truth' CBCTs. The real-time motion estimation accuracy was evaluated by comparing the solved motion of the lung tumor against the known 'ground-truth'. Specifically, the lung contour in the reference-frame CBCT was propagated to the real-time frames using the solved real-time DVFs $\boldsymbol{d}(\boldsymbol{x})$. Based on the propagated and 'ground-truth' contours, metrics including Dice similarity coefficient (DSC) and center-of-mass error (COME) were evaluated.

2.4.2 Patient study

DREME was further evaluated on a dataset of four lung patients to assess its performance. Four lung patients from two sources were curated for evaluation (Table I). To evaluate PMF-STINR, a subset of the projections were sparsely-sampled from the full acquisition for PMF-STINR reconstruction, and the remaining projections were used for real-time motion estimation and evaluation. For the MDACC patients (P1-P3), we sparsely-sampled the original projections by selecting every third projection for PMF-STINR reconstruction. For the SPARE patient (P4), both sparse and full sampling datasets were available from the original source [6]. The sparsely-sampled acquisition (340 projections) was used by PMF-STINR, and the rest projections (675 projections) were used to evaluate the accuracy of real-time motion estimation.

TABLE I. Summary of imaging parameters of the patient study.

Patient ID[a]	Source[a]	Projection size[b]	Pixel size (mm^2)	kVp/mA/ms	SAD[c] (mm)/ SDD (mm)
P1	MDACC	512×384×1983	0.776×0.776	120/80/25	1000/1500
P2	MDACC	512×384×2729	0.776×0.776	120/80/25	1000/1500
P3	MDACC	512×384×1653	0.776×0.776	120/80/25	1000/1500
P4	SPARE	512×512×1015	0.8×0.8	125/20/20	1000/1536

[a]MDACC: MD Anderson Cancer Center. SPARE: SPARE Challenge [6].

[b]width (in pixel number) × height (in pixel number) × N_p (number of projections).

[c]SAD: source-to-axis distance. SDD: source-to-detector distance.

Unlike the XCAT study, the patient dataset had no 'ground-truth' real-time motion/CBCT for evaluation. Instead, we evaluated the accuracy of estimated motion at each projection by re-projecting the solved real-time CBCTs to DRRs and comparing with the corresponding X-ray projections. The Amsterdam Shroud (AS) method [7], an intensity-based, projection-domain motion extraction technique, was employed to quantify the motion differences between DRRs and the X-ray projections. By calculating the intensity gradients in the superior-inferior (SI) direction and integrating the resulting images horizontally, we can convert each projection/DRR into a line profile and then consolidate the profiles from different views to track anatomical motion. Prominent anatomies with sharp contrasts, including the diaphragms and the lung nodules, can be tracked from the AS images to compare their motion trajectories between the DRRs and the X-ray projections. We compared the trajectories using the Pearson correlation coefficient and the localization error (average point-wise distance between the two trajectories).

3 Results

3.1 The XCAT results

Table II quantitatively summarizes the mean RE and SSIM of the estimated real-time CBCTs, and mean COME and DSC of the tracked tumors. The small RE and large SSIM show that the estimated real-time CBCTs matched well with the 'ground-truth'. For real-time motion estimation, the tumor can be tracked with ≤1 mm accuracy.

TABLE II. Summary of the mean RE and SSIM of the real-time CBCTs; and the mean COME and DSC of the tracked real-time tumor motion for the XCAT study. The results were presented in terms of mean±SD.

Training motion scenario	Real-time CBCT accuracy		Real-time tumor tracking accuracy	
	RE	SSIM	COME (mm)	DSC
X1	0.143±0.008	0.985±0.002	0.9±0.4	0.904±0.036
X2	0.143±0.015	0.985±0.003	1.0±0.4	0.920±0.031
X3	0.144±0.019	0.984±0.004	1.0±0.4	0.915±0.028
X4	0.152±0.018	0.982±0.005	1.1±0.5	0.917±0.029
X5	0.166±0.006	0.980±0.002	1.0±0.5	0.916±0.022
X6	0.141±0.009	0.985±0.002	0.8±0.4	0.913±0.030

Figure 3 shows the solved real-time XCAT tumor motion trajectories in the SI and anterior-posterior (AP) directions. Due to the space limit, only the DREME results of training scenarios X3-X5 were presented. Regardless of the training scenarios, the solved real-time tumor motion in each testing scenario matched accurately with the 'ground-truth', even if the motion irregularities in the testing scenarios were not seen in the training scenarios.

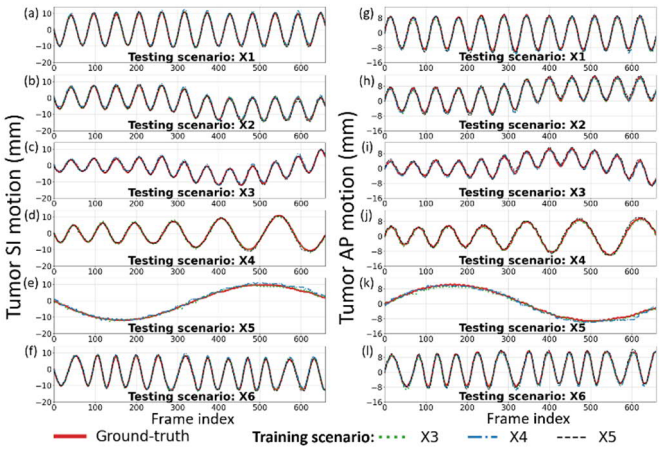

Fig. 3. Real-time XCAT tumor tracking results. The two columns show the predicted real-time tumor trajectories in the SI and AP directions, respectively.

3.2 The patient results

Figure 4 presents example AS images (a-c), and the correspondingly tracked DRR and X-ray projection motion trajectories for the patient study (d-g). Table III summarizes the corresponding localization errors and the Pearson correlation coefficients for the tracked real-time motion. The solved real-time motion trajectories achieved 1.5 to 2.4 mm average accuracy for different patients. Considering the magnification factor (~1.5) of cone-beam projections, the average tracking error reduced to 1.3±1.2 mm in the Cartesian space.

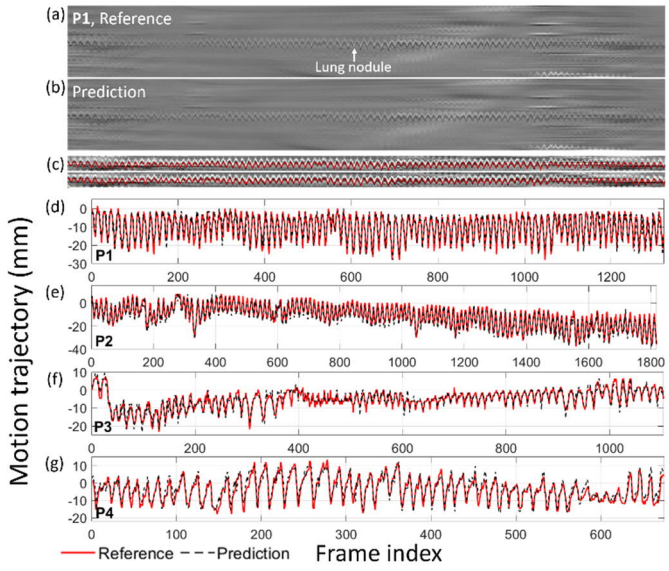

Fig. 4. **(a-b)** Amsterdam Shroud (AS) images of the P1 patient calculated from (a) the onboard X-ray projections and (b) re-projected DRRs. **(c)** Cropped AS images of the lung nodule region of (a) and (b), based on which the motion trajectories were extracted. **(d-g)** The extracted motion trajectories of the four lung patients (P1-P4).

TABLE III. Summary of the real-time motion estimation accuracy of the patient study. The results were presented in terms of mean±SD.

Patient ID	Pearson correlation coefficient	Localization error in projection space (mm)	Localization error in Cartesian space (mm)
P1	0.92	1.9±1.8	1.3±1.2
P2	0.96	2.4±2.0	1.6±1.5
P3	0.91	1.5±1.5	1.0±1.0
P4	0.93	2.1±1.7	1.4±1.1

Figure 5 presents the solved lung nodule motion curves and real-time CBCT images of P1 in three views. The mean inference time is ~1.5 ms per projection.

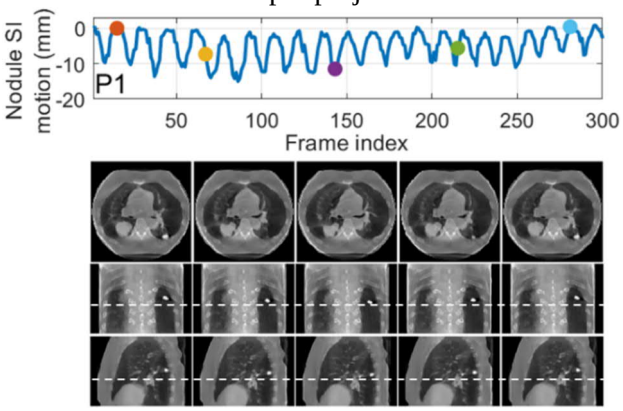

Fig. 5. Example real-time CBCTs solved for P1. The top panel shows the solved lung nodule motion in the first 300 frames, and the dots indicate the time points used to plot the real-time CBCTs in 3 views.

4 Conclusion

We developed a joint dynamic reconstruction and motion estimation framework, DREME, for real-time volumetric motion and CBCT estimation. DREME uses the latest onboard CBCT and motion model information, extracted from dynamic CBCT reconstructions, to solve the following real-time motion. The XCAT and patient results showed that DREME solves accurate real-time motion and CBCTs from arbitrarily-angled X-ray projections, paving the way for future real-time adaptive radiotherapy.

Abstract Respiratory self-gating 4DMRI offers superior soft tissue contrast compared with 4DCT without imparting any ionizing radiation or requiring an external surrogate device. Recent advancements in MR hardware and sequence design have made 4DMRI simulation an increasingly attractive option for patients with tumors in the thoracoabdominal area that may experience several centimeters of motion due to respiration. This work investigates different respiratory trace binning options and compressed sensing reconstruction in a vendor designed 4DMRI sequence. Five volunteers were scanned on a 0.55 T MRI. The k-space data was retrospectively reconstructed using both phase and amplitude binning, with 5 and 10 total bins, and both with and without compressed sensing. A denoising algorithm was applied to the reconstructed images to improve image quality. A deep learning auto-segmentation network was used to determine whether the images were of sufficient quality to produce stable segmentation results.

1 Introduction

Magnetic resonance imaging (MRI) offers superior soft tissue contrast to computed tomography (CT) imaging without imparting any ionizing radiation to the imaging subject. MRI additionally provides more variety in image quality and options compared with CT.[1] As a result, the use of MRI has increased substantially in radiation therapy planning where accurate tumor and organ-at-risk (OAR) delineation is critical to safe and effective treatment.

In radiotherapy, 4DCTs are commonly used to generate planning images throughout the breathing cycle to assess tumor and OAR motion. Respiratory correlated 4DMRI is a recent technological advancement that can also provide fundamental motion information for tumors in the abdomen or thorax that may experience several centimeters of motion due to patient respiration.[2] 4DMRI imaging data is generated without ionizing radiation, offers superior soft tissue contrast to 4DCT, and allows for imaging in any orientation whereas 4DCT is limited to transverse imaging.

As 4DMR imaging becomes commercially available and more widely used in radiation therapy planning, it is imperative that efficient workflows and tools be developed to aid in clinical utility. This includes investigating adequate binning parameters and ensuring adequate image quality. Additionally, time spent treatment planning can be substantially reduced using deep learning auto-segmentation (DLAS) algorithms. In this study, we are examining a prototype 4DMRI sequence using a 0.55 T MRI scanner. Our investigation involves exploring various binning strategies, reconstructing the MRIs both with and without compressed sensing, and implementing an additional denoising filter. The resulting images are additionally evaluated using an in-house developed DLAS network to assess the feasibility of auto segmentation.

2 Materials and Methods

Five healthy volunteers were recruited for 4DMR imaging on a 0.55-T MRI system (MAGNETOM Free.Max, Siemens Healthineers, Erlangen, Germany) in accordance with an Institutional Review Board approved protocol. Images were acquired during free breathing using a prototype T_1-weighted gradient echo sequence using a phased array torso coil. The sequence utilizes a 3-D "stack of stars" k-space trajectory allowing for self-navigation.[3,4] Because the sequence uses the signal from the center of k-space to generate a respiratory motion trace, no external surrogate signal is required to sort the 4D data into the appropriate respiratory bins. Furthermore, the golden-angle radial k-space trajectory results in incoherent under-sampling artifacts and is sparse in both the spatial domain and along the direction of the motion state.[5] These properties make the results suitable for compressed sensing (CS) reconstruction. Scans were acquired using 2000 radial views to be reconstructed without CS and using 1000 radial views to be reconstructed with CS. Both types of reconstructions were performed retrospectively. The CS and non-CS k-space data were both reconstructed four times using two different bin numbers (5, 10) and binning types (amplitude, phase). This resulted in eight 4D image sets for each volunteer. Additionally, exhalation breath-hold 3D balanced steady state free procession (bSSFP) images were acquired for each volunteer to use as reference.

To improve the quality of the reconstructed 4D datasets, a block matching 3D filtering (BM3D) method was used for denoising. This model divides images into overlapping blocks and collaboratively filters similar blocks using a Wiener filter in the 3D transform domain.[6] BM3D preserves edges while reducing image noise. Denoised images were evaluated against images without denoising using a natural image quality evaluator (NIQE) score.[7]

To evaluate clinical feasibility, a DLAS network was used to segment the liver on both the original and denoised 4DMRI data sets. The DLAS network was based on MONAI (NVIDIA, Santa Clara, CA, USA) DynUnet, which is a modified nnU-Net.[8] Model training utilized an AdamW optimizer and a combined Dice Similarity Coefficient/Cross Entropy loss function. The network was previously trained on images acquired from 27 thoracoabdominal patients on a 1.5 T MRI system (Ingenia, Philips, Amsterdam, Netherlands) using a respiratory-gated T_1-weighted 3D-Axial magnetization-prepared rapid gradient-echo (MP-RAGE) sequence. Test time augmentation (TTA) was utilized to ensure stable segmentation results. Preprocessing inferences for TTA included foreground cropping, Gaussian sharpening with three different configurations, and random contrast adjustment. The five segmentation results from each preprocessing inference were averaged to form the DLAS output.

To further refine the quality of segmentation, a multi-step post-processing strategy was adopted following TTA. First, any segmentation results outside of the body were discarded. Next, Connected Component 3D (CC3D) was performed to isolate and retain only the largest segmented portion of the image.[9] Finally, binary erosion/dilation was used to detach any spurious segments that were connected to correctly segmented areas before CC3D and small object removal were repeated. Volumetric Dice similarity coefficients (DSC3D) were then calculated on the resulting segmentation results with segmentation from the 3D breath-hold bSSFP images serving as the reference.

3 Results

4D images reconstructed with CS displayed significantly ($p << 0.01$) improved NIQE scores (mean NIQE score: 12.83 ± 0.86) compared with images reconstructed without CS (mean NIQE score: 27.45 ± 16.08). Additionally, CS results displayed less visual noise and produced more stable images than the reconstructed images without CS. Amplitude binning and phase binning resulted in similar NIQE scores for images reconstructed with CS (amplitude: 12.59 ± 0.81, phase: 12.98 ± 0.85). For the images reconstructed without CS, amplitude binning produced much better results than phase binning (amplitude: 13.97 ± 0.44, phase: 31.04 ± 16.32). In all cases, the 4D MRI with 5 bins outperformed the one with 10 bins in terms of NIQE score, primarily because it had a larger amount of data available per respiratory bin.

BM3D denoising modestly improved mean NIQE scores for 4D images reconstructed with CS (BM3D: 12.17 ± 0.98, no denoising: 12.83 ± 0.86). Images reconstructed without CS saw a dramatic improvement in mean NIQE score following BM3D denoising (BM3D: 12.94 ± 1.44, no denoising: 27.44 ± 16.08). This difference in BM3D denoising efficacy is expected due to the increased noise present in the 4DMRI images that were reconstructed without CS. Images pre and post denoising are shown for amplitude binning (Figure 1) and for phase binning (Figure 2).

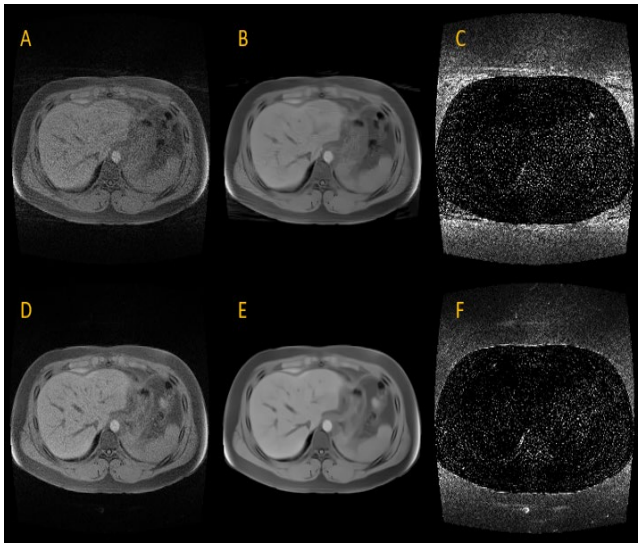

***Figure 1**: 45% **amplitude** binned images reconstructed both without CS (top row) and with CS (bottom row). Images in the leftmost column (A, D) are shown prior to BM3D denoising. Images in the center column (B, E) are shown post BM3D denoising. The rightmost column shows the difference image.*

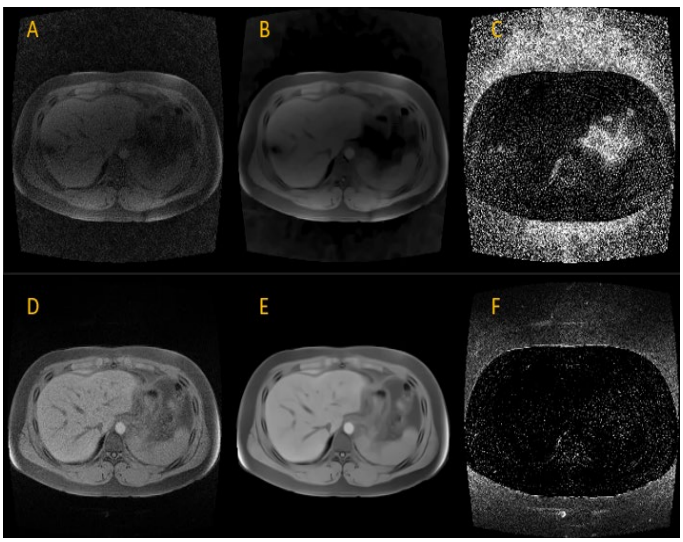

***Figure 2:** 45% **phase** binned images reconstructed both without CS (top row) and with CS (bottom row). Images in the leftmost column (A, D) are shown prior to BM3D denoising. Images in the center column (B, E) are shown post BM3D denoising. The rightmost column shows the difference image.*

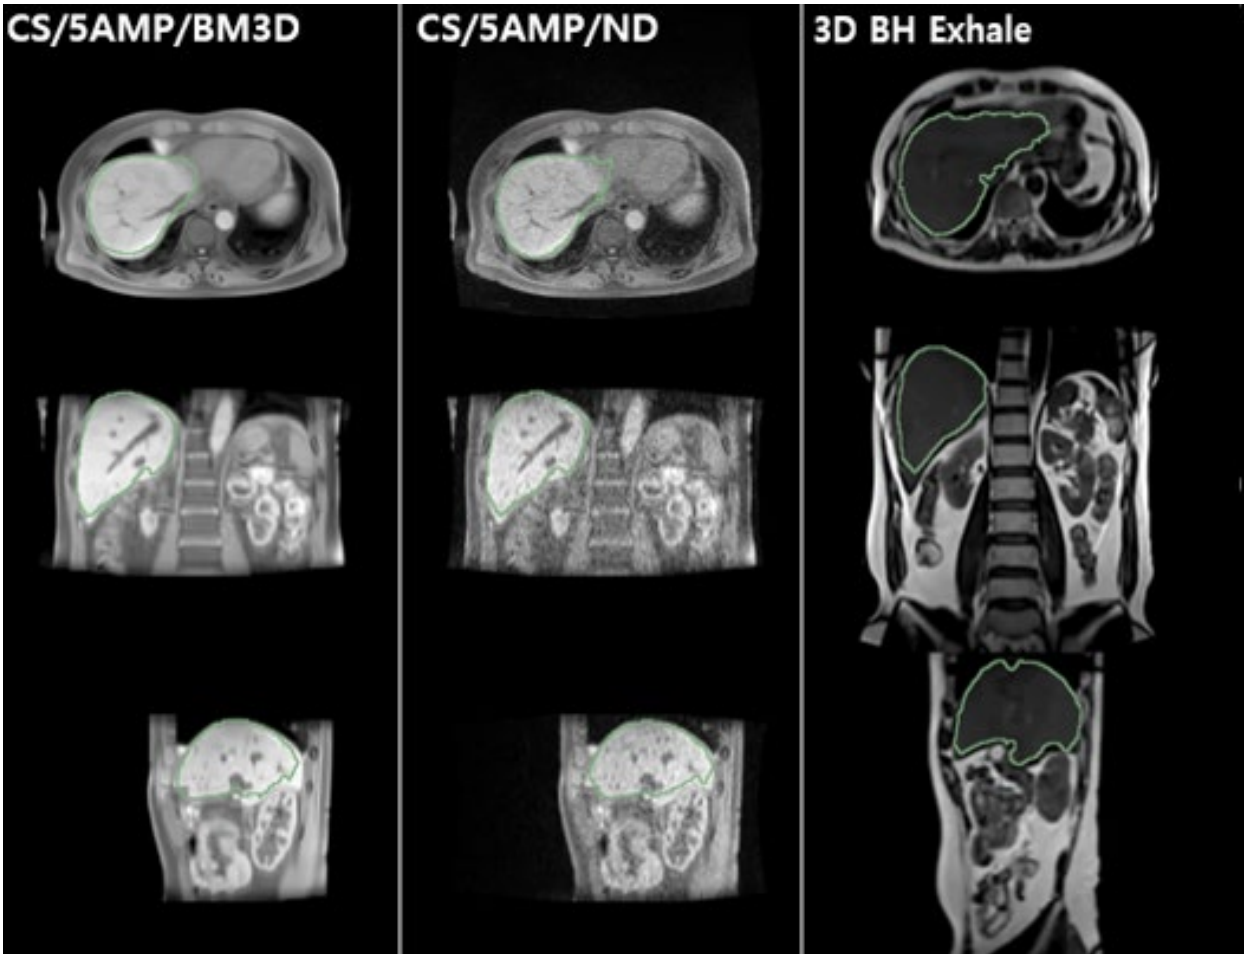

Figure 3: CS 5 amplitude bin reconstructed images with BM3D denoising (first column) and without denoising (second column). The 3D exhalation breath-hold image used as a reference image is shown in the third column. The DLAS generated liver contour is shown in green on all figures.

Segmentation was improved following denoising (DSC3D = 0.83 ± 0.11 with BM3D vs 0.80 ± 0.18 without BM3D) as shown in Figure 3. This result held for both images reconstructed with and without CS. Likewise, images reconstructed with CS showed significantly better ($p < 0.05$) DSC3D results compared to images reconstructed without CS (DSC3D = 0.87 ± 0.06 with CS vs 0.74 ± 0.14 without CS). DLAS model architecture is shown in Figure 4.

4 Discussion

Respiratory self-gating 4DMRI offers the potential for more precise motion management strategies and improved thoracoabdominal target delineation. However, these benefits are contingent upon efficient workflows that produce high quality images. While the CS reconstructed results produced satisfactory results, several phase binned 4DMRI datasets reconstructed without CS did not. Utilizing denoising algorithms such as BM3D can significantly improve non-CS phase binned reconstructions, although denoising does not always ensure segmentation performance. Subject variation additionally plays a critical role in both image and segmentation quality particularly for phase binned imaging studies.

The preliminary results in this work are promising. However, this study can be expanded upon in several ways. For example, alternative binning strategies such as dual amplitude and phase binning may become beneficial in the presence of motion hysteresis.[10] Additionally, with more volunteers the DLAS model could be trained on 0.55T images directly which should yield even better segmentation results. Future work will also focus on a wider variety of OARs. Finally, the relatively regular breathing traces seen in healthy volunteers may not be possible for patients undergoing MR simulation. Dynamic MRI phantom studies that can utilize respiratory traces acquired on surrogate systems during 4DCT simulation are warranted.

5 Conclusion

CS reconstruction produced lower NIQE scores and displayed better segmentation results than non-CS reconstruction despite being highly undersampled. Amplitude binning resulted in higher quality images and more stable results, especially for non-CS reconstructions. BM3D denoising improved image quality and aided in

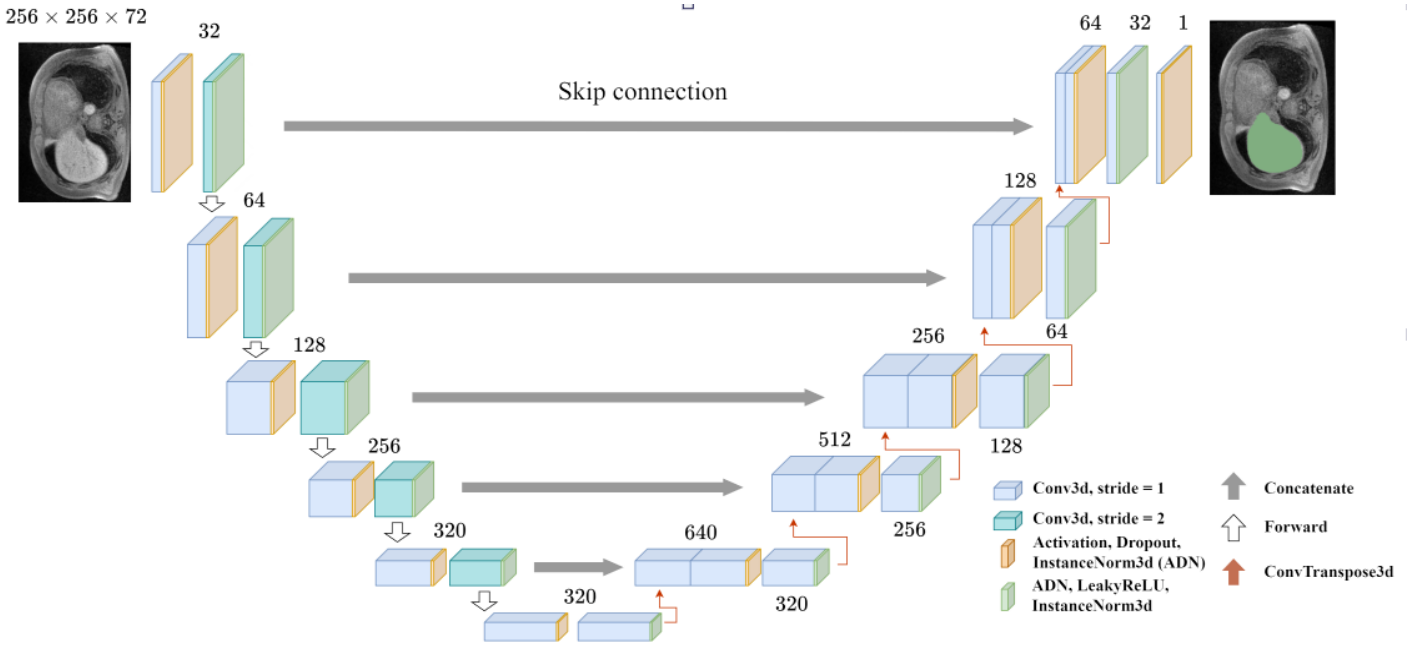

Figure 4: Deep Learning Auto-Segmentation (DLAS) network architecture. The model is based on MONAI DynUnet.

segmentation. Future work is warranted to further improve image quality and segmentation results.

Abstract Molecular Radiotherapy (MRT) holds the potential for personalized cancer treatment, yet achieving precise dosimetry remains a challenge. WIDMApp (Wearable Individual Dose Monitoring Apparatus) is a novel approach to address this by developing a method to accurately characterize the Time-Activity Curves (TACs) of organs using Time-Counts Curves (TCCs) acquired with wearable radiation detectors designed on purpose. The WIDMApp approach relies on the detectors, a Monte Carlo simulation, and an unfolding procedure. The MC simulation estimates the probabilities that the particles produced in each organ produce a signal in all the detectors. Such probabilities are then used to infer the organ activities (i.e. the TACs) given the detectors measurements (i.e. the TCCs) using a Bayesian approach. Thanks to the Bayesian formalism, this algorithm does not need to assume the TACs functional form. Utilizing the MIRD computational human phantom, we developed a Monte Carlo simulations to generate the dataset of an ^{131}I thyroid treatment. Assuming a mono-exponential washout of all the relevant organs, we simulated the measurement of TCCs and we used this dataset to test our algorithm. We assess the Bayesian algorithm's performances under varying initial conditions and data fluctuations, and compare results with those obtained by using a fitting procedure. This study indicates that the Bayesian unfolding can reconstruct organ TACs within 15% accuracy, even with significant noise and uncertainty in initial activity estimations. The obtained results pave the way for the exploration of more complex and realistic clinical scenarios.

1 Introduction

Enhancing personalization in Molecular Radiotherapy (MRT) offers significant benefits for improving treatment outcomes and minimizing toxicity. Achieving accurate dosimetry at the individual organ level is essential for understanding the unique biodistribution of radiopharmaceuticals in patients, allowing for precise calculation of absorbed doses to both normal organs and targeted tissues. Traditional dosimetric methods, which fit a limited number of Time Activity Curves (TACs) points from SPECT measurements to predefined models, lead to substantial uncertainties on absorbed dose (order of 30–100%) and poorly represent individual patient pharmacokinetics [1].

In this framework, WiDMApp (Wearable Individual Dose Monitoring Apparatus) aims at providing a precise characterization of the TACs of any organ of interest starting from Time-Counts Curves (TCCs) acquired with a limited number of radiation detectors worn by the patient during the treatment period. A deconvolution method is then used to deconvolve the detected signals and infer the organ-specific radiopharmaceutical kinetics. In a previous work [2], we demonstrated the feasibility of the WIDMApp's approach by employing a fitting process for the cumulative chi square function as deconvolution method. While the methodology exhibited significantly enhanced reconstruction accuracy compared to current state-of-the-art methods, it was constrained by the assumptions on the functional form of the radiopharmaceuticals biokinetics. This limitation prompted the exploration of a more flexible, model-independent approach through Bayesian unfolding, eliminating the need for predefined TAC's functional forms.

In the first section, we will introduce the case being examined, and provide a concise overview of the Monte Carlo simulation and the creation of the data set. In Section 2.2, we will describe the Bayesian deconvolution method. Section 2.3 will detail the stability studies conducted to evaluate the algorithm's performance. Subsequent sections will then present and discuss the findings of this study, by comparing them with he reconstruction accuracy obtained by the fit procedure used in our previous approach.

2 Materials and Methods

To compare the performance of the Bayesian algorithm with the fitting approach already published in [2], we analyzed the same dataset. Below we provide a brief summary of how this dataset was constructed.

2.1 Monte Carlo simulation and TCC generation

We used the Geant4 Monte Carlo toolkit [3, 4] to simulate a simplified ^{131}I thyroid treatment, employing the MIRD phantom for patient anatomy [5]. We focused on five organs as potential radiation sources: liver, kidneys, spleen, bladder, and thyroid, each uniformly emitting 364 keV photons resulting from the de-excitation of ^{131}Xe*, which is the final state of ^{131}I β^- decay. To detect radiation, seven sensors were strategically placed on the phantom's body: two on the thyroid and five on the other organs, all assuming 100% detection efficiency. The MC simulation is used to assess the

Organ	A_0 [MBq]	$t^{bio}_{1/2}$ [h]	$t^{eff}_{1/2}$ [h]
Thyroid	750.0	1920.0	174.9
Right Kidney	115.0	12.0	11.3
Left Kidney	105.0	10.0	9.5
Bladder	35.0	7.0	6.8
Liver	1115.0	24.0	21.3
Spleen	130.0	17.0	15.6

Figure 1: Initial activities A_0, and biological t^{bio} and effective t^{eff} decay times assigned to each organ.

probability of generating a signal in each detector, yielding a 6×7 probability matrix.
Realistic initial activities and effective half-lives for each organ [6] (reported in table 1) were used to generate Time Counts Curves over ten days, based on a mono-exponential decay model. Using the Monte Carlo output, and assuming the TACs parameters in table 1, the time-dependent signal generated by each detector, was constructed as:

$$S_i(t) = \sum_j p_{ij} A_{0j} \exp\left(-\frac{t}{t^{eff}_{1/2\,j}} \ln 2\right) \quad (1)$$

where p_{ij} are the probability matrix elements, A_{0j} the activity of the j organ at $t = 0$, and $t^{eff}_{1/2\,j}$ the effective half-life of the radiopharmaceutical in that organ.
Experimental TCCs were generated over a period of 240 hours post-administration, with a higher sampling rate for the initial 48 hours and a lower one for the remaining 8 days. This approach was strategically implemented in our previous work [2], motivated by the usage of a cumulative chi-square for fitting purposes. The variation in sampling rates was specifically designed to give equal statistical weight to data over the entire data-taking period. Contrary to our previous method, the Bayesian unfolding is done at each time step independently and so it's independent from the sampling rate. In principle, this dataset originally optimized for our previous algorithm, is not required for Bayesian unfolding. Nevertheless, to facilitate direct comparison, we are using the same dataset for evaluating both algorithms. We applied Poisson fluctuation to TCCs from eq. 1 to simulate real measurement variance. Generated signals for each detector are shown in figure 2.

2.2 Temporal Bayesian unfolding

To unfold the distribution over time from a number of counts measurements to an organ-activity distribution we use the Bayesian approach proposed in [7], which makes use of the concept of causes and effects. We define each organ's radiopharmaceutical activity as a cause C_i, and the counts detected by each sensor as effects E_j.
Using this formalism, the Eq. 1 could be written as:

$$n(E_j) = \sum_{i=1}^{n_C} n(C_i) P(E_j|C_i) \quad (2)$$

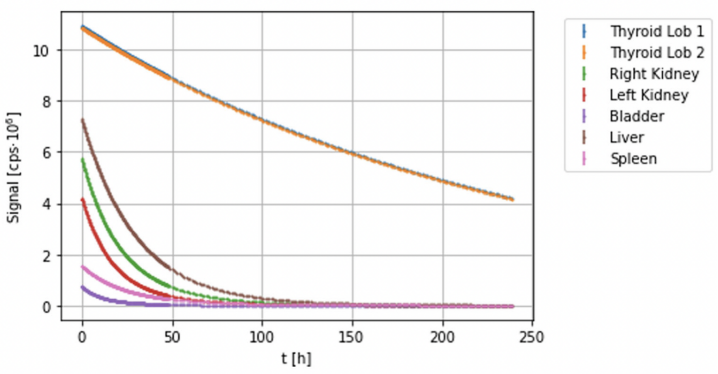

Figure 2: The simulated TCCs, one for each of the seven detectors. This dataset is the same of one of our previous works [2] to allow an easy comparison of this approach with the one already published.

which states that the number of counts in the jth detector $n(E_j)$ is a combination of the activities $n(C_i)$ of all the n_C possible sources (or causes) each of them multiplied with the probability $P(E_j|C_i)$ that the specific source (or cause) produces a signal in the considered detector.
Now the goal is to estimate the source:

$$n(C_i) = \frac{1}{\varepsilon_i} \sum_{j=1}^{n_E} n(E_j) P(C_i|E_j) \quad (3)$$

where n_E is the number of detectors (or effects), ε_i the efficiency of the $i-th$ cause to have an effect, defined as $\varepsilon_i = \sum_{j=1}^{n_E} P(E_j|C_i)$. Lastly, $P(C_i|E_j)$ is the probability that a signal in the j-th detector is due to the i-th source, and can be calculated using the Bayes' theorem:

$$P(C_i|E_j) = \frac{P(E_j|C_i)P(C_i)}{\sum_{l=1}^{n_c} P(E_j|C_l)P(C_l)} \quad (4)$$

assuming that we know the conditional probability $P(E_j|C_i)$, and the initial *a priori* probability of the causes $P(C_i)$.
Combining the Eq.s 3 and 4, we obtain the unfolding algorithm:

$$n_{t+dt}(C_i) = \frac{1}{\varepsilon_i} \sum_{j=1}^{n_E} n_t(E_j) \frac{P(E_j|C_i)P_t(C_i)}{\sum_{l=1}^{n_c} P(E_j|C_l)P_t(C_l)} \quad (5)$$

where we explicitate that the i-th cause at time $t + dt$, $n_{t+dt}(C_i)$, is estimated from its value at time t, $n_t(C_i)$. From the unfolded sources in eq. 5, we can estimate the posterior probabilities of the causes as:

$$P_{t+dt}(C_i) = \frac{n_{t+dt}(C_i)}{\sum_{l=1}^{n_c} n_{t+dt}(C_l)} \quad (6)$$

to be used as the *a priori* probability for the subsequent temporal step. Referring to our case under study, we observe that:

- $n_t(E_j)$ is the number of counts $S_j(t)$ on each detector j at a given fixed time t;
- $n_t(C_i)$ is the activity $A_i(t)$ in organ i at the same time t;

- $P(E_j|C_l)$ is the probability that a particle generated within the i-th organ produces, directly or indirectly, a signal in the j-th detector, called p_{ij} in our previous work. We estimate it with Monte Carlo simulations.

- $P_t(C_i)$ is the *a priori* probability at time t that a particle is produced in the i-th organ. It corresponds to the i-th organ activity, $n_t(C_i)$, normalised by the activity of all the body, i.e.: $\sum_{l=1}^{n_c} n_t(C_l)$.

The Bayesian unfolding, described in Eq.s 5 and 6, needs as a first step an estimation of the organs activities, $n_{t=0}(C_i)$, which could be achieved performing a SPECT scan at the beginning of the treatment. Subsequently, it iteratively estimates the activity of all organs through a sequential process over time.

2.3 Stability of the deconvolution algorithm

To evaluate the Bayesian unfolding's robustness and facilitate a direct comparison with the fitting methodology, we conducted stability studies similar to those performed in our previous work. Specifically, we evaluated the TACs reconstruction performances as a function of:

- the initial values A_{0j} used as starting point of the deconvolution algorithm (hereinafter referred to as *priors*), to test the impact of uncertain values derived from SPECT scan;

- the amplitude of random uniform fluctuation on signals, to evaluate the impact of external noise sources, such as detector mispositioning.

For the former, we executed the unfolding process 100 times, each with priors at $t = 0$ randomly chosen from a uniform distribution centered around their true values, varying the distribution's half-width from 10% to 90%.

The unfolding algorithm's resilience to noise was tested by dispersing data points with uniform noise ranging from 5% to 40%. We repeated the unfolding process 100 times for each level of noise, starting each unfolding with priors uniformly distributed around the true values, with a fixed half-width of 50%.

For each stability study, the TACs obtained from the 100 minimizations (100 for each distribution amplitude), were averaged and their variance calculated. The cumulative activity A^{tot} for each organ, has then been determined by integrating the TACs over the measurement campaign's duration with the WIDMApp sensors, i.e. from time $t = 0$ of radiopharmaceutical administration, to time $t_f = 240h$.

The obtained results regarding the cumulated activity are presented in the subsequent section.

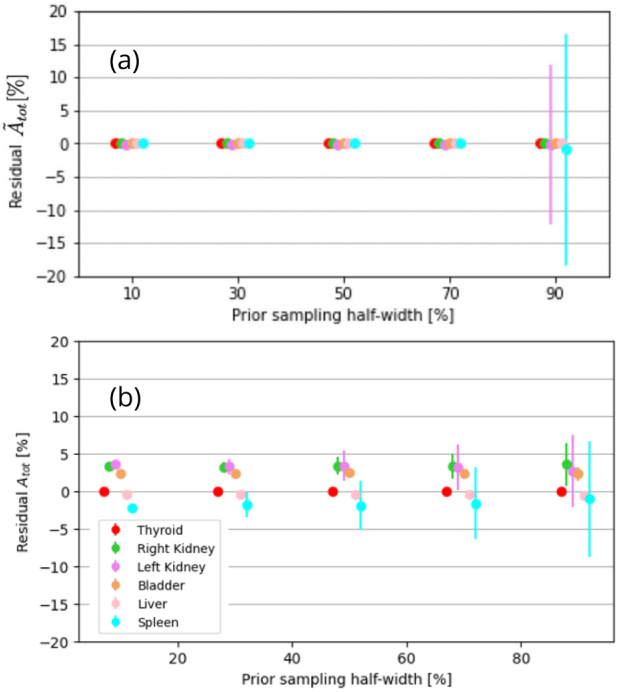

Figure 3: Percentage residuals between the organs cumulated activities A^{tot} resulted from the unfolding procedure and their true values obtained with the parameters reported in table 1, as a function of the width of the uniform distributions from which the priors are sampled. In plot (a), there are results obtained with the fit procedure, in plot (b) those obtained with Bayesian unfolding.

3 Results

3.1 Stability of cumulated activity estimate with respect of priors

Figure 3(b) illustrates the algorithm's stability in estimating the cumulated organ activity in the presence of only poissonian noise, showing how this accuracy varies with the uncertainty of the uncertainty on priors A_{0i}. Specifically, the percentage residuals between the cumulative activity A^{tot} estimated by the unfolding process and the true values calculated using parameters from table 1, are presented as a function of the half-width of the distribution from which the priors were sampled. These results are compared with the results obtained with the fit procedure in 3(a).

We can see that in the case of Bayesian unfolding, the estimated activities exhibit a slight bias (order of a few percent) even when starting with priors close to the true values. Nevertheless, these biases remain almost constant up to 80% higher/lower than the truth, with uncertainty always remaining below 15%.

3.2 Stability of cumulated activity estimate with respect of data dispersing

In Figure 4 we report the combined effect of the priors choice and data fluctuations on cumulated activity. The percentage residuals A_j^{tot} between the estimated and actual cumulated

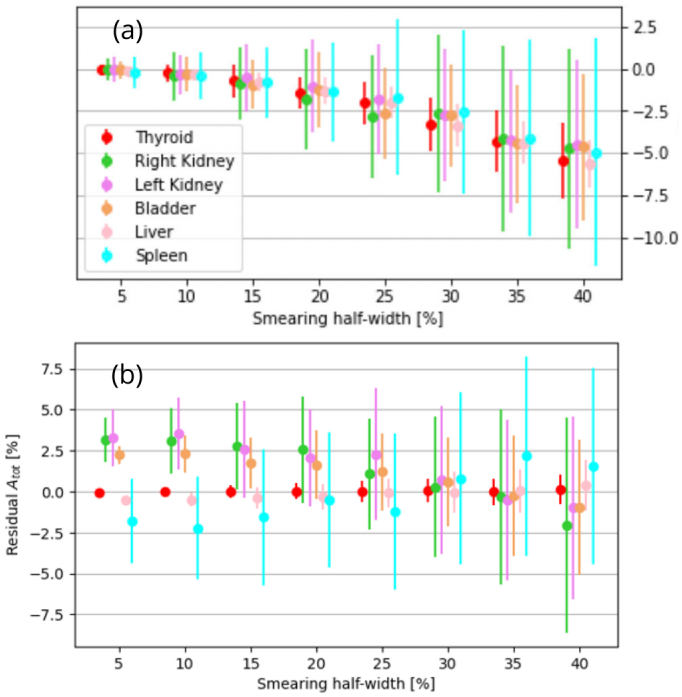

Figure 4: Same as fig. 3 but as a function of the data dispersions considered. In plot (a), there are results obtained with the fit procedure, in plot (b) those obtained with Bayesian unfolding

activity are plotted as a function of the percentage dispersion on data, with starting priors extracted from a uniform distribution with half-width of 50%. Also in this case, the results obtained by the fit approach 4 (a) are compared with the actual results 4 (b).

In the case of the fit procedure, we can see that the A_j^{tot} values are systematically underestimated, with an increasing trend as the half-width of the distribution increases, introducing an offset in the determination of the curves' integrals. The results obtained with Bayesian unfolding exhibit biases with respect to true cumulated activity similar to those obtained in the priors-dependent study, but still less than 2.5%. Notably, the offset found in the cumulated activities for kidneys, spleen, and bladder, are due to the significantly larger activity magnitudes in the thyroid and liver for the studied case. Minor deviations in these two organs' activity estimates cause larger variations in the others, while maintaining the cumulative reduced chi-square of unfolded curves near 1. Overall, the fit procedure yields better results with low smearing rates, whereas Bayesian unfolding outperforms with higher data fluctuations, achieving accuracy within 15%, up to 40% uniform noise in measured signals.

4 Discussion

Application of the Bayesian algorithm in the case of thyroid treatment with ^{131}I demonstrates performances quite comparable to the previous fitting approach. However, the results are considered satisfactory due to the Bayesian algorithm's two main strengths: its capacity for instant-by-instant deconvolution without assuming a predefined functional form for TACs, and its independence from the sampling rate. The only dependency on the latter lies in the assumption that the posterior at time t becomes the prior at time $t + dt$. If the dt interval increases substantially, the reconstruction accuracy may decrease. Despite this, the high sampling rate allowed by WIDMApp's wearable detectors effectively avoid this limitation.

Additionally, the results could be further improved by iterate more time the Bayesian unfolding per each time, using the previous estimation at the same time as prior.

Although in this simple case described by mono-exponential TACs the results do not clearly outperform the fitting approach, the flexibility of the Bayesian algorithm allows for application to more complex scenarios where the functional form cannot be assumed a priori, and traditional methods may fail.

5 Conclusion

This work introduces a novel Bayesian unfolding approach for reconstructing organ-specific time-activity curves (TACs), significantly enhancing personalized dosimetry in Molecular Radiotherapy (MRT). Our findings demonstrate the capability to reconstruct organ TACs with accuracy within 15%, even under conditions of up to 40% uniform noise in measured data and with initial activity uncertainties of 50%. This new methodology surpasses the previous fit technique in that no assumption is made regarding the functional form on the biokinetics of the drug. Subsequent studies will be carried out to test the algorithm's effectiveness in more complex scenarios, which include functional forms consisting of initial uptake and double-exponential decay, and by using the ICRP phantom

Rapid Auto-Planning for Cervical Brachytherapy: Direct Dwell Time vs. Dose Prediction with Deep Learning Networks

Lance Moore[1], Karoline Kallis[1], Kelly Kisling[1], Nuno Vasconcelos[2] and Sandra Meyers[1]

[2]Department of Electrical and Computer Engineering, University of California, San Diego, La Jolla, USA

Abstract Treatment planning for cervical brachytherapy is often performed manually and can take over an hour. Automated planning leveraging deep learning models could significantly reduce planning time, improving the patient experience. The goal of this work was to assess a new approach to automated planning: using a neural network to directly predict dwell times (VGG model). This model was compared to an automated planning method that uses a neural network to predict 3D dose (OPT model), followed by an optimizer to convert dose to dwell times. Models were developed using 1803 prior cervical brachytherapy treatment plans, with a 68%/16%/16% train/test/validation split. The dataset included 7 different types of implants, featuring some combination of tandem, ovoids, ring, and/or needles. The VGG model used a 16-layer 3D VGG regression network, while the OPT model employed a Cascade U-Net. Automated plans were compared to clinical plans using the mean absolute error (MAE) and mean error (ME) in dose and dwell times. The resulting automated plans were very similar to clinical plans for both models, as evidenced by low MAE (OPT=3.4%, VGG=4.7%) and ME in dose (OPT=0.1%, VGG=0.6%), and low MAE (OPT=7.3s, VGG=8.0s) and ME (OPT=0.2s, VGG=0.7s) in dwell times. While the OPT model featured slightly superior performance, the direct dwell time prediction of the VGG model reduced computation time. Both methods of automated planning could provide high clinical value for brachytherapy procedures.

1 Introduction

Brachytherapy is an important component of the standard of care for cervical cancer. Treatments are customized to patient anatomy on imaging, but this treatment planning is often performed manually and can take over an hour [1]. Automated treatment planning could significantly reduce treatment time, decrease the use of hospital resources, standardize treatment, and improve patients' experience.

Automated, knowledge-based planning uses models trained on prior patient data to generate an optimal treatment plan for a new patient's anatomy. Three solutions have been proposed for knowledge-based brachytherapy planning of cervical cancer [2–4]. Two groups have trained deep reinforcement learning models to autonomously adjust parameters such as inverse optimization objectives and weights [3] or dwell times [2]. These methods rely on objective functions that incorporate dose metrics for target and organ contours. However, cervical brachytherapy often delivers prescription dose to additional regions that are not contoured, such as the uterus and parametrium, and therefore this dosing could not be included in such an objective function.

An alternative is automated planning based on 3D dose prediction from a 3D U-Net [4,5]. One group has shown that the 3D dose can be predicted using 3D inputs of standard anatomical contours and applicator geometry for tandem-and-ovoids (TO) [5]. An optimizer can then iteratively determine the dwell times for each dwell position that replicate this 3D predicted dose, generating an automated treatment plan in a few minutes [4]. These U-Nets can learn common dose shapes, avoiding the need for additional target contours beyond the high-risk CTV (HRCTV).

The above method is limited by the accuracy of the CNN, which may predict physically impossible dose distributions. Cortes at al reported reduced accuracy in high dose regions near applicators [5]. Further, it requires a 3D predicted dose intermediate and a separate optimizer, which increases computation time. The purpose of this work was to develop a deep learning model for direct dwell time prediction. Automated plans produced using these two methods were compared to clinical plans to assess performance.

2 Materials and Methods

Deep learning models were developed using 1803 prior high dose-rate brachytherapy treatment plans for cervical cancer for 475 patients (from 2009-2023). The train/test/validation split was 68%/16%/16%. The approximate applicator breakdown in each dataset was 40% TO, 6% TO with 4-10 needles (TON), 14% tandem-and-ring (TR), 16% TR with 3-6 needles (TRN), 3% tandem only (T), 18% T and 3-21 needles (TN) and 2% pure interstitial with 3-18 needles (N). Two automated planning techniques based on deep learning models are described below.

Model inputs

Planning CT images and DICOM-RT files were exported from the treatment planning system and used to generate model inputs. Binary contour masks of HRCTV, vaginal HRCTV (if present), bladder, rectum, and sigmoid were extracted from DICOM structure sets. Applicator masks were produced by extracting dwell position coordinates from the plan DICOM file and setting a 3x3x3 voxel box centered on each dwell position to 1. Glowing masks, which encode the distance of each image voxel to a structure with an inverse square fall-off, were also produced. Voxels inside a structure were set to 1, then for each image voxel, the summed total inverse squared distance from that voxel to every structure voxel was calculated. The intensity of voxels outside the structure were normalized by the maximum value outside, and voxels inside the structure were set to 1. Glowing masks were produced for anatomical contours and the applicator mask.

A dose-rate kernel was produced by exporting the 3D dose matrix for a single dwell position from the treatment planning system and dividing by the dwell time. This kernel was mapped to each dwell position in each applicator to produce 3D single-dwell position dose-rate kernels, which were used as an input for one model. Four applicator dose kernel inputs were produced by summing

dose-rate kernels for all dwell positions in a given applicator type (tandem, ring, ovoids and needles) with uniform dwell time weighting.

Dose prediction and optimizer model

This model (termed "OPT") used a 3D Cascade U-Net [6] with a mean square error (MSE) loss function to predict the 3D dose. The inputs included 5 binary contour masks, a binary applicator mask, and 4 applicator dose kernels. The model consisted of 2 in-series U-Nets, each containing 5 encoding layers and 5 decoding layers (Figure 1A). Each encoding layer contained 2 in-series depth-wise separable convolution blocks. Each block contained a 3D grouped convolution followed by an instance normalization, ReLU activation, a 3D point-wise convolution, a second instance normalization, and a second ReLU activation function. A 3D maxpool operation performed at the end of each encoder block served to reduce the feature map dimensions. In the decoder layers, the convolution blocks were preceded by a transposed convolution to increase the dimensions of the feature maps prior to cross concatenation with the feature maps from the corresponding encoder layer. At the termination of each U-Net, two additional convolution blocks were appended to reduce the number of feature maps and generate the final 3D dose prediction. To employ the cascade mechanism for the network, the penultimate feature maps from the first U-Net were concatenated with the inputs to the second U-Net prior to feeding the images to the model.

Model dose predictions were then converted into deliverable treatment plans using a COBYLA optimizer, which minimized the MSE between the 3D dose calculated for a given set of dwell times and the predicted dose [4].

VGG model

This model (termed "VGG") used a 16-layer 3D VGG [7] regression network to directly predict dwell times. Model inputs included the planning CT image, glowing contour and applicator masks, and single-dwell position dose-rate kernels. Due to memory limitations, a maximum of 200 dwell position kernels could be included, which meant that 4 plans were excluded. If a treatment plan lacked a contour or 1 of the 200 dwell positions, that channel was left blank.

The model followed a standard VGG archetype, with sequential convolutions in the encoder portion of the network and a multi-layer perception (MLP) decoder (Figure 1B). In the encoder, each convolution block consisted of a standard 3D convolution followed by a 3D batch norm and a ReLU activation. A 3D max pool was used after the second, fourth, seventh, tenth, and thirteenth convolution blocks to reduce the feature maps prior to flattening. Before the MLP, a length 200 dwell position token vector was concatenated to the flattened feature vector. This vector contained a one-hot encoding of the number of dwell positions in the plan. This vector injects plan information deep into the network to assist the model in predicting dwell times only for valid dwell positions. The MLP in the decoder consisted of three layers, each followed by a ReLU activation function and a dropout layer with probability 0.1. The decoder produced a vector of size 200, i.e. dwell times for the 200 possible dwell positions. The absolute value of the predictions ensured that no negative dwell times were predicted.

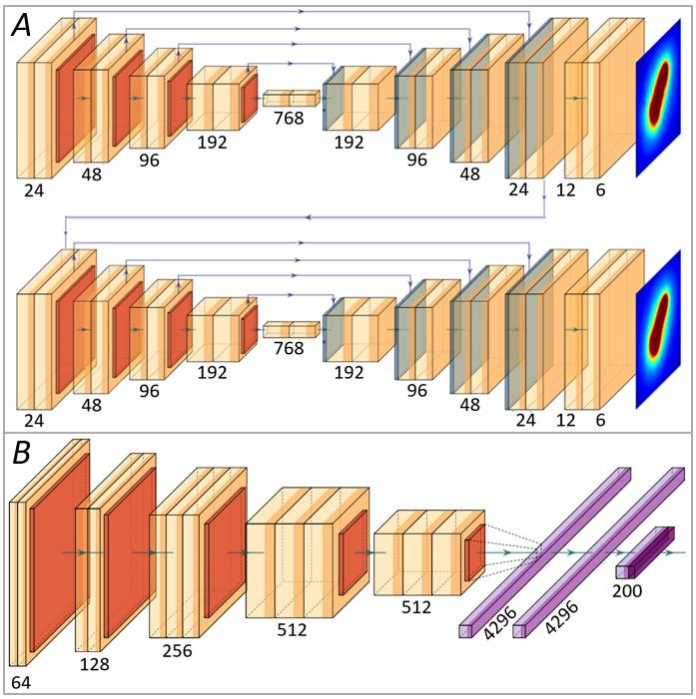

Figure 1. Model diagrams for (A) Cascade U-Net and (B) VGG network. Yellow blocks indicate a convolution block, orange indicates a maxpool, blue blocks indicate a transposed convolution, and purple indicates a fully connected layer. The numbers below the blocks depict the number of filters or channels.

Each predicted dwell time was multiplied by the corresponding dwell position dose-rate kernel and then the 3D predicted dose was computed by summing over all dwell positions. The loss function for this model compared the 3D predicted dose to the 3D clinical plan dose. A 3D squared error matrix (SE) was computed between the predicted ($Dose_{pred}$) and clinical ($Dose_{clin}$) distributions using equation (1) below.

$$SE = (Dose_{clin} - Dose_{pred})^2 \qquad (1)$$

The final MSE loss function was computed from the voxel-wise mean of the SE matrix, weighted by each of the 5 glowing contour masks ($Glow_Mask_i$), per equation (2).

$$MSE = mean(SE + \sum_{i=1}^{5} SE \cdot Glow_Mask_i) \qquad (2)$$

Training methods and hyperparameters

Data augmentation was employed during model training to delay overfitting. Both networks used an AdamW optimizer, a weight decay of 1e-4, and a one-cycle learning rate scheduler to anneal the learning rate over the course of training (peak learning rate 1e-3). Models were implemented using the PyTorch framework and trained for 500 epochs on a single GPU node with four 32GB NVIDIA V100 SMX2 GPUs. The validation set performance was

checked at the end of each epoch and the best performing checkpoint was selected as the final model.

Comparing model performance

Automated plans were compared between the models using the following metrics: the voxel-based mean error (ME, representing bias) between the 3D auto-plan and clinical dose, the voxel-based mean absolute error (MAE) in dose, and the ME and MAE between auto-plan and clinical plan dwell times. The ME in clinical metrics (HRCTV D90 and D2cc of organs) were also compared. A positive ME indicates the clinical dose or dwell times were higher than the auto-plan.

3 Results

Figure 2 shows example dose distributions and dwell times for the two automated plans compared to the clinical plan for three patients. While there were some differences in dwell times, the general trends in the dwell time distributions were similar, and the resulting dose distributions were nearly indistinguishable.

Box plots of MAE in dose over all voxels and dwell times, broken down by model and applicator type, are displayed in Figure 3. Averaged over all plans, the MAE and ME in dose were 23.2 cGy (3.4%) and 0.8 cGy (0.1%) for the OPT plans, and 31.6 cGy (4.7%) and 4 cGy (0.6%) for the VGG plans. MAE and ME in dwell times were 7.3 s (1.4% of the total plan dwell time) and 0.2 s (0.0%) for the OPT plans, and 8 s (1.6%) and 0.7 s (0.1%) for VGG plans.

Figure 4 shows boxplots of ME in clinical metrics for each model, all plans combined. For the OPT model, rectum D_{2cc} showed the lowest ME of -0.2%, while HRCTV D90 had the largest ME of 2.8%. The VGG model showed the best performance for bladder, with a ME of -0.7%, and the largest ME for HRCTV D90 (6.7%).

4 Discussion

In this work, we demonstrate the value of two unique, deep learning-based methods for automated planning of cervical brachytherapy. These models were trained and validated on a dataset of over 1800 treatment plans with 7 different applicator implant types. To our knowledge, this is one of the largest datasets that has been used for dose prediction or automated planning with deep learning in radiotherapy, and the greatest variety of brachytherapy implants that have been included in any single brachytherapy deep learning model thus far. Both methods produced treatment plans that were similar to clinical plans, as evidenced by the near-zero mean errors and low mean absolute errors in dose and dwell times. We believe that these facts qualify this work as a substantial and significant step forward in the field of brachytherapy. Despite the variability in the data due to the numerous applicator types included, performance was quite similar between applicator types, demonstrating that a single model was adequate.

The performance of the OPT model was slightly superior for most metrics. The tradeoff for these superior results is the time required for the optimizer, which took 30 s on average and up to 3.2 minutes (for plans with the most dwell times) on a computer with an Intel(R) Core(TM) i7-8700 3.2GHz processor. In contrast, the VGG model can directly predict dwell times in a matter of seconds, which is very valuable for real-time planning in the clinic. To our knowledge, this is the first deep learning model to directly predict dwell times for automated planning. Another study used a CNN to predict dwell positions and times for plan verification [10], but used the clinical 3D dose as input.

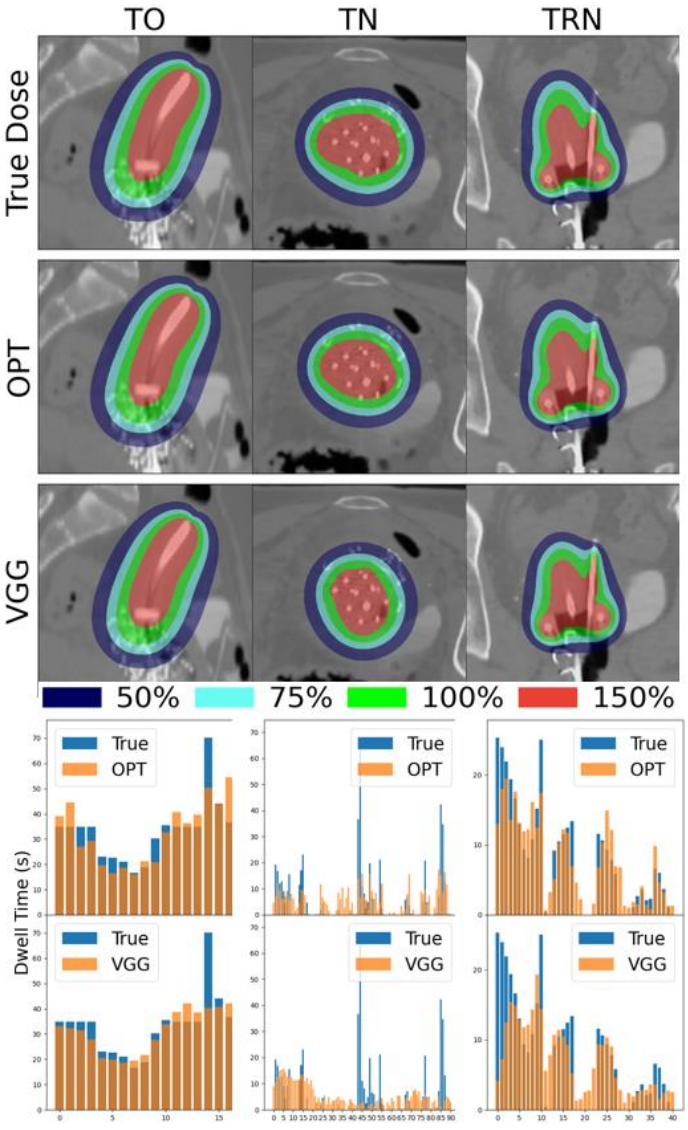

Figure 2. Comparison of dose distributions and dwell times for the two automated plans and clinical plan for three random patients. Isodose color washes (where 100% is the prescription dose) are overlaid over coronal (TRN), axial (TN), and sagittal (TO) CT images.

The VGG model directly incorporates a dose rate kernel exported from the treatment planning system. This kernel is used to compute a physically realistic dose from predicted dwell times for known dwell positions, which is compared to the clinical dose in the loss function. Thus, physical constraints for dose delivery are forced within the VGG model itself. In contrast, the OPT model was not

bound by physics and predicted dose distributions that featured larger errors at high dose. However, it appears that the optimizer was able to correct for most of those errors.

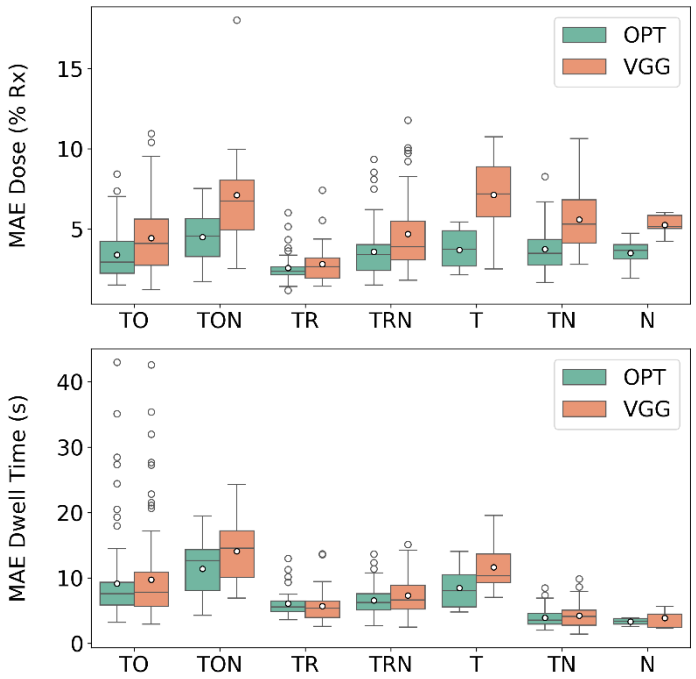

Figure 3. MAE in dose over all voxels (relative to prescription dose) and dwell times, comparing automated plans to clinical plans for each model and applicator. White circles overlaid on boxplots indicate mean values.

One limitation of the VGG method is that it can only support plans with less than 200 dwell positions. We expect that this model could improve further with a few modifications, which will be explored in future work. Currently, the model loads dwell position images into sequential channels, meaning the first dwell position channel is always loaded with the first dwell position in a plan. Shuffling these dwell positions could avoid over-emphasizing the first channels. We employed a dose-based loss function to account for the fact that slight variations in dwell times could result in approximately the same dose. However, we plan to try incorporating dwell time error in the loss function in the future.

In future work, we will continue to refine these models in pursuit of yet more accurate results, and test more sophisticated models. While the OPT model utilized only binary contour and applicator inputs, we found VGG model performance improved when incorporating glowing masks. Future work will explore the use of glowing masks in the OPT model as well. Blinded physician evaluation will be used to evaluate clinical acceptability of automated plans.

5 Conclusion

Two deep learning models were trained to produce automated treatment plans for cervical brachytherapy. The best-performing model predicted the 3D dose as an intermediate step, followed by an optimizer to convert the dose to a deliverable treatment plan. The second model directly predicted dwell times in a matter of seconds, reducing computation time. Both methods produced automated plans that were comparable to clinical plans, and thus could provide great clinical value by significantly reducing planning time.

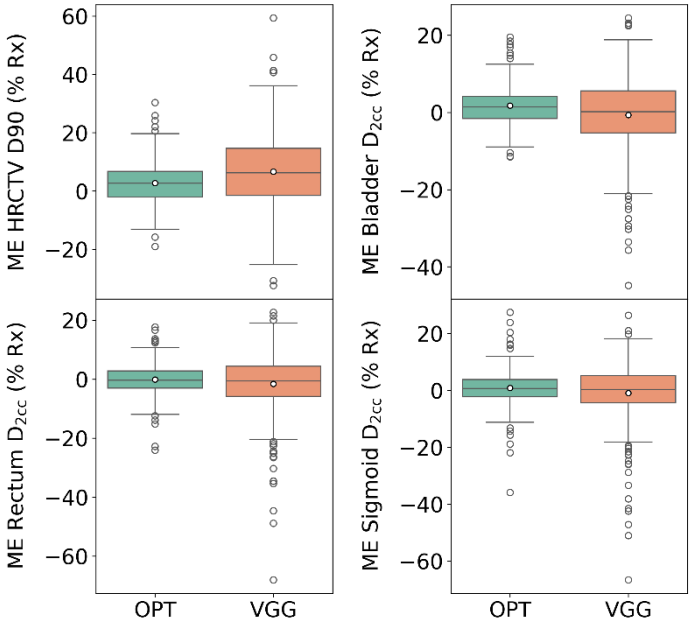

Figure 4. ME in clinical metrics for each model as a percent of the prescription dose, where a positive value indicates the clinical plan metric was higher than the automated plan. White circles overlaid on boxplots indicate mean values.

Abstract Deep learning has been used to automate and speed up the manual contouring step for organs at risk (OARs) and targets in radiotherapy. In cervical cancer high dose-rate brachytherapy, OARs far from the radiotherapy target are not considered during treatment planning, which is driven by the OAR dose to 2 cubic centimeters ($D2cm^3$) closest to the target. Accuracy in distal OAR segmentation does not necessarily translate to dosimetric impact. To align with the clinical requirements, in this study, a distance-penalized loss function was developed to guide the network's attention towards the near-to-target OAR regions, ensuring highly accurate proximal OAR segmentations. Models trained with the proposed loss demonstrated improved geometric and dosimetric performance. A clinical acceptability test was conducted, by a physician scoring the auto-contours and recording the time to rate and revise. Additionally, a novel geometric metric, weighted Dice Similarity Coefficient (wDSC), was introduced as a better indicator for $D2cm^3$ accuracy compared to commonly used evaluation metrics (Pearson correlation coefficient, r=-0.55 for wDSC; |r|<0.22 for other metrics).

1 Introduction

Brachytherapy plays a vital role in cervical cancer treatment, providing improved survival rates over other advanced radiotherapy techniques such as intensity-modulated radiotherapy and stereotactic body radiation therapy[1] Delineating the radiotherapy targets and organs at risk (OARs) is the essential basis of obtaining treatment plans and is conventionally performed manually. The emergence of deep learning (DL) technologies demonstrated fast and accurate auto-segmentations on magnetic resonance (MR) images [2], [3].

The OARs treatment planning for brachytherapy is driven by the OAR dose to hottest 2 cubic centimeters ($D2cm^3$), which resides near the target[4]. The contouring accuracy must be high for the OAR regions proximate to the target, while discrepancies in distant regions are not expected to translate to dosimetric impact. Recent studies have shown that optimizing the precision of the regional-focused network is achievable through tuning the loss function in convolutional neural network (CNN) training, such as penalizing the loss function with distance maps[5].

Furthermore, it is essential to utilize appropriate geometric evaluation metrics as indicators of clinical acceptability. Surface Dice Similarity Coefficient (sDSC)[6] and added path length (APL)[7] are vital for assessing clinical acceptability in external beam radiotherapy auto-segmentation, highlighting the time saved and clinical acceptance. Yet, the correlation between these metrics and dosimetry remains understudied, especially in brachytherapy, where the doses received by the OARs are predominantly determined by their proximity to the target regions. This gap underscores the necessity for a new geometric evaluation metric tailored for brachytherapy dosimetry accuracy.

We address these issues by (1) incorporating a distance map to penalize the loss function for enhanced near-to-target OARs segmentation; (2) introducing a novel geometric metric, the weighted DSC (wDSC), which prioritizes accuracy in near-to-target regions, consistent with $D2cm^3$ considerations. Geometric evaluations, dosimetric analysis, and clinical acceptability test were conducted. We found that the CNN model, trained with our distance-penalized loss function, outperformed the baseline model in both geometric and dosimetric performance. Furthermore, wDSC demonstrated the highest correlation with dosimetric accuracy compared to the existing evaluation metrics.

2 Materials and Methods

2.1 Patient data

A dataset of 170 T2-weighted MR images with clinically used contours was built from 56 patients undergoing EBRT and high-dose-rate (HDR) brachytherapy from 2014 to 2019 at the Princess Margaret Cancer Center with Institutional Review Board (IRB) approval. The TNM stage of all the patients ranged from T1b to T4a. All the patients were first treated with EBRT with prescription doses of 45 Gy in 25 fx or 50.4 Gy in 28 fx and received HDR brachytherapy treatment as 7 Gy × 4fx or 8 Gy × 3fx. All patients were treated with interstitial ring and tandem applicators (Elekta) and scanned on a Siemens Verio 3T MR scanner. The median image size is 320×320×38 voxels, and the median image spacing is 0.625×0.625×3.0 mm^3. Clinically used contours, reviewed by experienced radiation oncologists (ROs), included the high-risk clinical tumor volume (HR-CTV), bladder, rectum, sigmoid, and small bowel. The dataset was split into subsets at the patient level: 45 patients (150 cases) as the training set for five-fold cross-validation and 11 patients (20 cases) as the testing set.

2.2 Distance-penalized loss function and training details

Distance-penalized (DP) maps, labelling which voxels were near the target/applicator, were generated to penalize the loss function for indicating the spatial relevance

information. Distance transformation was performed on a binary mask where the clinically used HR-CTV (Figure 1(a)) was labelled as 1, calculating the distance between each voxel to its nearest non-zero voxel (Figure 1(b)). Second, the inverse square law was applied to the distance-transformed map to produce the DP map (Figure 1(c)), which was normalized to a range of [0, 1]. Consequently, voxels nearer to the HR-CTV were allocated higher error penalties, reflecting their increased importance in treatment planning.

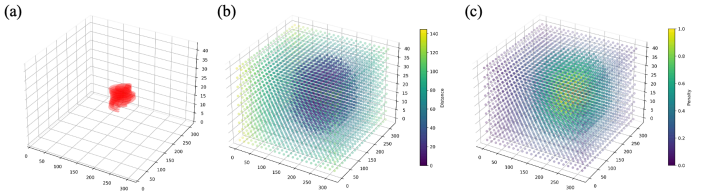

Figure 1. Examples of (a) HR-CTV, (b) Distance transformation based on HR-CTV, and (c) Normalized distance-penalized (DP) map. Points in (b) and (c) are downsampled with slice intervals of (15, 15, 5) along (x, y, z)

The DP map was used to penalize two commonly used loss functions, cross-entropy (CE) loss and the Dice loss part of the DiceCE loss[8]. The penalized loss functions, distance-penalized cross-entropy (DPCE) loss and distance-penalized DiceCE (DPDiceCE) loss, are defined by

$$L_{DPCE} = -\frac{1}{N}\sum_{c=1}^{C} D^c \odot \sum_{i=1}^{N} g_i^c \log p_i^c \qquad [1]$$

$$L_{DPDiceCE} = L_{DPDice} + L_{CE}, \qquad [2]$$
$$where\ L_{DPDice} = 1 - \frac{2\sum_{c=1}^{C} D^c \odot \sum_{i=1}^{N} g_i^c p_i^c}{\sum_{c=1}^{C}\sum_{i=1}^{N} g_i^c + \sum_{c=1}^{C}\sum_{i=1}^{N} p_i^c}$$

where g_i^c and p_i^c are the ground truth label and the network prediction of class c at voxel i. N and C are the number of voxels and classes, respectively. D^c is the distance penalty term of class c from DP map. $\odot$ is the Hadamard product. By incorporating the DP map into the loss function, the pixels that are closer to HR-CTV would be assigned larger weights.

The nnU-Net pipeline[8] was employed with the 3D full-resolution U-Net architecture. Four models were trained using two baseline, non-DP loss functions (CE loss and DiceCE loss) and two DP loss functions (DPCE loss and DPDiceCE loss). The patch size was 256×256×28. The models were trained for 200 epochs with a batch size of 2. The proposed framework was implemented in Python 3.9.7 using PyTorch 1.11.0. The training and testing were conducted using an NVIDIA Tesla V100 GPU with 32GB memory. The training and testing code is available on GitHub: https://github.com/bhklab/BrachyNewLoss

2.3 Geometric evaluation – New metric

We introduced a new evaluation metric, the weighted Dice Similarity Coefficient (wDSC), specifically designed to evaluate near-to-target OAR segmentation performance. Given that D2cm^3 measures the dose received by the 2cc of an OAR nearest to the radiotherapy target, the wDSC emphasizes the accuracy of proximal OAR regions to HR-CTV by incorporating a weighted factor in the original volumetric DSC (vDSC). The weights are derived from the voxel distances to HR-CTV, as represented in the DP map. The wDSC is defined by

$$wDSC = 1 - \frac{\sum_{i=1}^{N} \frac{i}{N} * (1 - vDSC_i)}{N} \qquad [3]$$

where N is the number of cropped volumes; $vDSC_i$ is the vDSC between the i-th cropped volumes of label and prediction; the weight of the i-th cropped volume is $\frac{i}{N}$. As shown in the illustration (Figure 2), the cropping occurs based on the DP map from center to the boundary. Each cropped volume has an associated weight, diminishing as it moves from center to boundary. Therefore, the discrepancies between the prediction and ground truth near the target have a higher impact on the wDSC value compared to those at the boundary. In this study, we used N=100 to crop each case into 100 cropped volumes. Each cropped volume was small enough that this approach can be considered continuous weighting. A Wilcoxon signed-rank test was utilized to analyze the statistical differences in the wDSCs between models trained with CE and DPCE, as well as between models trained with DiceCE and DPDiceCE loss functions, to determine the effectiveness of incorporating a distance penalty term in improving the delineation of proximal-target OARs.

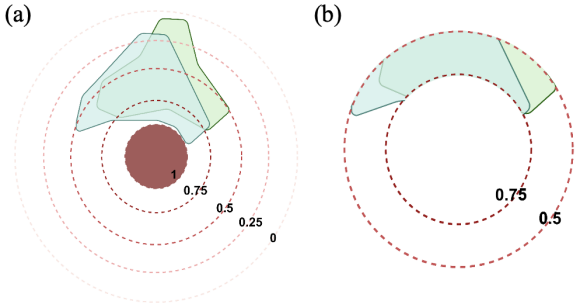

Figure 2. The illustration of wDSC between ground truth (lighter green) and network prediction (darker green). (a) Both are first cropped into N volumes based on the values in the distance map. In this example, N=4; the weights of each cropped volume = (1, 0.75, 0.5, 0.25). (b) A zoom-in version of volumes with weight = 0.75. Assume $vDSC$ = 0.8 between these two cropped volumes; the weighted $vDSC$ loss is 0.75*(1-0.8). The final $wDSC$ is $1 - \frac{total\ weighted\ vDSC\ loss}{N}$, iterating through all cropped volumes. From boundary to the center, the weights are $(\frac{1}{N}, \frac{2}{N}, \ldots, \frac{N-1}{N}, 1)$. In this study, we used N=100.

In addition, commonly used evaluation metrics were used to assess the whole organ segmentation performance, including vDSC, 95% Hausdorff Distance (HD95), surface DSC (sDSC)[6], and added path length (APL)[7].

2.4 Dosimetric evaluation

The dosimetric difference between manual contour and DL-generated contour was calculated to evaluate the dosimetric impact. The clinically used treatment plan was applied to the auto-segmentation to calculate $D2cm^3_{auto}$. The absolute D2cm^3 difference was quantified as $D2cm^3_{diff} = \text{abs}(D2cm^3_{auto} - D2cm^3_{clinical})$, indicating the D2cm^3 discrepancy between DL-based auto-contour and clinical contour. An absolute $D2cm^3_{diff}$ value closer to zero indicated that the auto-contour aligned better with the dosimetric requirements. The correlations between each geometric evaluation metric and D2cm^3 difference were evaluated to explore the best indicator of dosimetric accuracy. The linear regression was performed, employing the Pearson correlation coefficients to quantify the strength of the relationship. Wilcoxon signed-rank test was used to analyze the statistical differences between the clinical D2cm^3 values and the D2cm^3 values obtained from each loss function.

2.5 Clinical acceptability test

A radiation oncology fellow rated the DL contours on a five-point scale[9], where contours with a score of 5 (Use-as-is) or 4 (minor edits) were clinically acceptable and below 4 were not acceptable. The fellow would revise the auto-contour where it failed to meet clinical standards. The time taken for rating and revising was recorded.

3 Results

3.1 Correlation between geometric metric and D2cm^3 difference

The strongest correlation observed was between wDSC and D2cm^3 difference among all geometric evaluation metrics, which exhibited a Pearson correlation coefficient (r) of -0.55, indicating a moderate negative correlation. In contrast, the other four standard geometric evaluation metrics demonstrated weak or negligible correlations with the D2cm^3 difference with r of -0.15 for vDSC, 0.22 for HD95, -0.20 for sDSC, and 0.00 for APL.

3.2 Geometric evaluation

The newly proposed metric, wDSC, indicated that the model trained with the DP loss functions constantly yielded more accurate near-to-target OAR segmentation when compared to their respective non-DP counterparts. DPCE loss outperformed CE loss for the rectum, sigmoid, and small bowel, with mean wDSCs of 0.94 vs. 0.93, 0.89 vs. 0.88, and 0.86 vs. 0.85, respectively. Similarly, DPDiceCE had increased wDSCs, compared to DiceCE in rectum (0.94 vs. 0.93), sigmoid (0.90 vs. 0.89), and small bowel (0.87 vs. 0.85). There was a statistically significant improvement in small bowel with p-values of 0.008 for the CE group and 0.017 for the DiceCE group.

The DP group outperformed the non-DP group across four standard metrics. The most notable improvement was observed between DiceCE and DPDiceCE in small bowel with mean vDSCs of 0.74 and 0.77, mean HD95 of 23.95mm and 19.04mm, mean sDSCs of 0.52 and 0.55, and mean APL of 27.69cm and 27.01cm.

3.3 Dosimetric evaluation

The models trained with DP loss functions constantly demonstrated a reduced mean absolute $D2cm^3_{diff}$ than their non-DP counterparts (Table 1), indicating an enhanced accuracy in dosimetry. Furthermore, while each group had several outliers with large $D2cm^3_{diff}$, DP loss functions had smaller standard deviations, suggesting greater consistency in their performance. The only comparison that yielded a statistically significant difference was between CE and DPCE in the small bowel (p-value=0.012).

Table 1. Absolute $D2cm^3_{diff}$ between non-DP loss function and DP loss function (CE vs DPCE and DiceCE vs DPDiceCE) in four OARs. Smaller value indicates a more accurate D2cm^3. The values are represented as mean (±std). The two groups with statistically significant difference are underlined.

	CE	DPCE	DiceCE	DPDiceCE
Bladder	0.12 (±0.11)	0.10 (±0.10)	0.13 (±0.12)	0.11 (±0.10)
Rectum	0.16 (±0.21)	0.12 (±0.15)	0.12 (±0.14)	0.11 (±0.16)
Sigmoid	0.15 (±0.16)	0.13 (±0.11)	0.11 (±0.09)	0.10 (±0.09)
Small Bowel	<u>0.25 (±0.27)</u>	<u>0.18 (±0.21)</u>	0.22 (±0.26)	0.16 (±0.12)

3.4 Clinical acceptability

The clinical acceptability ratings (Figure 3) showed that DP group had marginally superior performance compared to the non-DP group. The model trained with DPCE loss had more clinically acceptable contours (with a score of 5 or 4) than CE loss in two out of four OARs (rectum and sigmoid). There were equal or higher number of contours rated as clinically acceptable using the DPDiceCE compared to DiceCE loss, except for sigmoid.

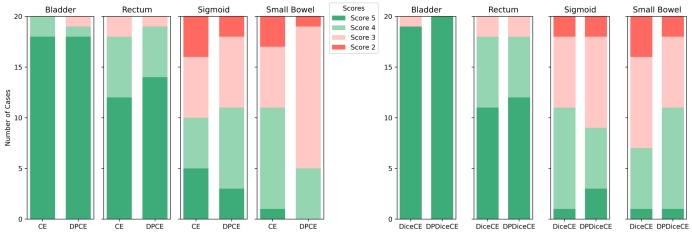

Figure 3. Clinical acceptability ratings between CE and DPCE (left) and between DiceCE and DPDiceCE (right) in

four OARs. Clinically acceptable scores (5 or 4) are in green shaded. Not acceptable scores (3 or 2) are in red shaded.

The average time required for reviewing an entire case was 0.73 minutes (ranging from 0.2 to 3.83 minutes); the average time to revise the contours in one case was 4.64 minutes (ranging from 0 to 19.12 minutes). For each loss function specially, the mean times for review and revision were similar for non-DP and DP loss functions. However, a notable difference was observed in the maximum time required for revision. The DP loss functions demonstrated a reduced maximum revision time (12.22 minutes for DPCE and 10.83 minutes for DPDiceCE), in comparison to the non-DP loss functions (19.12 minutes for CE and 15.27 minutes for DiceCE).

4 Discussion

In this study, wDSC, the new metric we proposed, was found to be the best indicator of D2cm^3 accuracy in image-guided brachytherapy compared to the four standard geometric measures. The models employing the DP loss functions showed improved performance in segmenting OAR regions close to the target, which led to more precise D2cm^3 calculations with reduced variations and a decrease in the time required to correct poorly segmented cases.

This study is the first to focus the CNN model's attention on near-to-target OAR regions, thereby enhancing dosimetric accuracy in brachytherapy. Compared to the two prior studies[2], [3], our model that incorporated the DP loss function achieved comparable or superior whole organ segmentation performance while exhibiting reduced D2cm^3 difference[3]. Furthermore, we included the clinical acceptability test, which revealed that most of the bladder and rectum contours, and approximately half of the sigmoid and small bowel contours, met clinical acceptability criteria. Although some contours failed to meet the clinical standard, their D2cm^3 differences remained within the range of inter-observer variations[10], [11].

Our study introduced and validated the wDSC as a new geometric evaluation metric, demonstrating its superior correlation with D2cm^3 difference in comparison to existing standard metrics. Our findings underscore a potential limitation in relying solely on standard metrics, which may not accurately represent dosimetric acceptance in brachytherapy applications despite being widely used in automatic medical image segmentation studies.

This work has several limitations. First, this was a single institutional study with a relatively small cohort size. More data from patients treated in our institution are being collected and will be used to reduce the model bias. we intend to validate the model's performance across multiple institutions in future studies. Second, wDSC was evaluated exclusively on cervical cases. We aim to expand the applicability of wDSC by validating it on prostate brachytherapy cases. Furthermore, the clinical acceptability test of the model involved only one fellow. More ROs will be involved to assess the inter-observer variations and contribute to a more robust evaluation.

5 Conclusion

We developed a DP loss function to guide the model for accurate near-to-target OAR segmentation in MR-guided cervical brachytherapy. The model with the proposed loss showed improved geometric and dosimetric performance. We introduced a new geometric metric, wDSC, which was demonstrated to be a better indicator of D2cm^3 accuracy in cervical brachytherapy.

Automatic target propagation strategies for MRI-guided cervical brachytherapy

Rita Simões[1], Eva C. Schaake[1], Eva E. Rijkmans[1], Marlies E. Nowee[1] and Tomas M. Janssen[1]

[1] Department of Radiation Oncology, the Netherlands Cancer Institute, Amsterdam, the Netherlands

Abstract The target structures required for cervical cancer brachytherapy treatment planning are delineated by radiation oncologists using both imaging and clinical information. The segmentations are made manually from scratch at the first brachytherapy fraction. For subsequent fractions the segmentations from the first fraction are rigidly propagated. This process is time- and resource-intensive, which makes the workflow inefficient and, since the patient is waiting with the applicator in situ, uncomfortable for the patient. In this work, we compared different strategies for automatic target propagation from the first to the second and third fractions. Registration-based approaches performed the worst, while segmentation-based approaches that take prior patient-specific information into account reached the best performance. In particular, patient-specific fine-tuned deep learning segmentation models are a promising strategy for automating the target propagation workflow.

1 Introduction

The standard-of-care treatment for locally advanced cervical cancer patients consists of external beam radiotherapy with concurrent chemotherapy followed by three to four fractions of image-guided adaptive brachytherapy. At each brachytherapy fraction an MRI is made with applicator in situ. The radiation oncologist manually delineates three target volumes following the EMBRACE II study guidelines [1]: the gross tumor volume (GTV), the high-risk clinical tumor volume (HR-CTV) and the intermediate-risk clinical tumor volume (IR-CTV). The GTV is defined as the macroscopic disease visible on the daily MRI. The HR-CTV is defined as the GTV plus the whole cervix and adjacent residual pathologic tissue, as determined via imaging and clinical examination. The IR-CTV is defined as the pretreatment tumor area plus a margin surrounding the HR-CTV [1]. The IR-CTV is therefore partially defined by information which is not present in the daily brachytherapy MRI images, as in general the tumor regresses during the course of external beam radiotherapy. The target structures delineated manually at the first brachytherapy fraction incorporate these patient-specific clinical decisions. An important question is how to optimally propagate this information from the first to the subsequent fractions.

In our clinic, structures are propagated with rigid registration, after which the radiation oncologist checks and manually edits them. This process, particularly the manual editing, is time and resource intensive and represents a bottleneck in the brachytherapy workflow. As a result, in our clinic a dedicated team of two radiation oncologists, two RTTs and one physicist can typically treat only two patients per day. Importantly, the time spent during manual segmentation is also unpleasant for the patient, as they need to wait immobilized in bed, with the applicator in situ, until the treatment plan is ready to be delivered. Automating (even if only partially) this process is likely to help speed up the entire workflow, improving logistics and patient comfort. Different approaches for automatically propagating patient-specific prior information have been proposed in the literature. The first has been traditionally used in various radiotherapy applications and consists of performing rigid or deformable image registration between the previous and current fraction scans and propagating the segmentations accordingly [2, 3]. Although registration methods inherently take patient-specific information into account, they are often not the best option when large deformations are present [3].

Alternatively, auto-segmentation methods can be employed. However, conventional auto-segmentation methods rely only on a single input image. Recently, strategies to incorporate patient-specific prior information into auto-segmentation models have been proposed, namely in the context of online adaptive radiotherapy. One strategy consists of training an auto-segmentation model with not only the image of the current fraction but also patient-specific information from previous time points as extra input [4]. Another strategy consists of fine-tuning a pre-trained, population-based model with the previous fraction(s) of the same patient, thereby overfitting the model and rendering it patient-specific [5-8].

In this work, we compare various approaches for automated target segmentation during the second and the third cervical brachytherapy fractions: 1) using rigid registration (our current clinical practice), 2) using deformable registration, 3) segmentation model trained on images as single inputs (without patient-specific prior); 4) segmentation model that takes as inputs both the current fraction image and the previous fraction segmentations; 5) patient-specific segmentation models resulting from fine-tuning the model in 3) with the previous fraction image and segmentations.

2 Materials and Methods

DATASETS

Two datasets of axial T2-weighted MRI images and the corresponding target segmentations made by a radiation oncologist and reviewed by another one for clinical practice were retrieved from our clinical database. The first dataset consisted of data of 209 cervical cancer patients (575 brachytherapy treatment fractions; median 3 fractions per patient) treated with brachytherapy between 2011 and 2019. This dataset was used for training and validating the auto-segmentation models. An additional dataset of 29 patients

(79 fractions; median 3 fractions per patient) treated between February 2022 and August 2023 was collected. This dataset was used for independent testing of all different target propagation and segmentation approaches. In this test dataset, the first treatment fraction was segmented by the radiation oncologists manually from scratch, with pre-treatment diagnostic information available. For the second and third fractions, the structures were in clinical practice rigidly propagated from the previous fraction by a radiation technology therapist. The propagated structures were then checked and manually edited by a radiation oncologist. A second radiation oncologist reviewed all structures. Both structure sets (rigidly propagated and manually edited) were retrieved from the database. All segmentations and registrations were performed in Mirada RTx. The institutional review board approved the study (IRBd20276). Informed consent was waived considering the retrospective design.

METHOD 1: RIGID REGISTRATION

The rigidly propagated structures retrieved from our database were defined, in this study, as the outputs of the first target propagation method that we aimed to evaluate. As this method is used in our current clinical practice, it served as a benchmark for comparison.

METHOD 2: DEFORMABLE REGISTRATION

For the second and third fractions, the multi-modality deformable image registration tool available in Mirada RTx was used with its default parameters to register the previous fraction to the current fraction image. The clinical segmentations were propagated according to the resulting deformation field.

METHOD 3: IMAGE-ONLY SEGMENTATION

The first dataset was split into 168 patients (455 fractions) for training and 41 patients (120 fractions) for validation. A 3D nnU-Net model was trained to segment the daily MRI using the default parameters [9]. The inputs to the model were the axial T2 images. The final model was the one which performed best in the validation set over the course of the pre-defined 1000 training epochs.

METHOD 4: IMAGE + PRIOR SEGMENTATION

A subset of the first dataset containing only the second and third fractions was used to train a model that took as inputs both the current fraction image and the previous fraction's segmentations. The resulting dataset consisted of 150 patients (277 fractions) for training and 39 patients (75 fractions) for validation. The toolbox `elastix` [10, 11] was used with parameter file *Param0001* [11] to automatically rigidly register the previous fraction to the current fraction images. The structures were propagated accordingly. A 3D nnU-Net model was then trained for 1000 epochs to segment the daily MRI using both the daily MRI and the registered segmentation of fraction 1 as input channels. The final model was the one that performed best in the validation set during training.

METHOD 5: PATIENT-SPECIFIC FINE-TUNING

For each patient in the second dataset, the previous fraction image and the corresponding clinical segmentations were used to fine-tune the population-based model (method 3), resulting in patient- and fraction-specific overfitted models. Similarly to [5], we allowed for training of all layers. Fine-tuning was stopped after 5 epochs, as it was empirically observed that results changed only negligibly after that. For the prediction of the third fraction, the patient-specific model obtained after training on the first fraction was further fine-tuned for 5 epochs on the second fraction. The nnU-Net framework was used for this purpose.

PERFORMANCE EVALUATION

For the second and the third fractions of each patient in the test set (50 fractions in total), the clinically used manual segmentations were geometrically compared with the segmentations resulting from the various target propagation strategies using the surface Dice (with a tolerance of 3 mm) [12], the mean surface distance (MSD) and the added path length (APL) [13]. These metrics were used as these have been shown to correlate more strongly with manual editing time than e.g. the Dice coefficient [13]. Pairwise comparisons between the performance of the different approaches were tested for statistical significance with the Wilcoxon signed-rank test.

3 Results

The performance of the various target propagation approaches is depicted in Figure 1. Both segmentation methods that employ a patient-specific prior (4 and 5) generally outperformed the registration-based (methods 1 and 2) and image-only segmentation (method 3) techniques. The patient-specific fine-tuned models consistently outperformed deformable registration and the image-only segmentation model. Results were statistically significant ($p \leq 0.05$) for all structures and metrics. Compared to the current clinical practice of rigid registration, the patient-specific models were statistically significantly better for the three structures in at least one of the metrics: surface Dice and MSD for the IR-CTV, surface Dice for the HR-CTV and all metrics for the GTV. This approach also significantly outperformed the image+prior segmentation approach for all metrics and structures, except for the surface Dice and MSD in the GTV. The image+prior segmentation model significantly outperformed the image-only model in all metrics for the GTV and in the surface Dice and MSD for the IR-CTV.

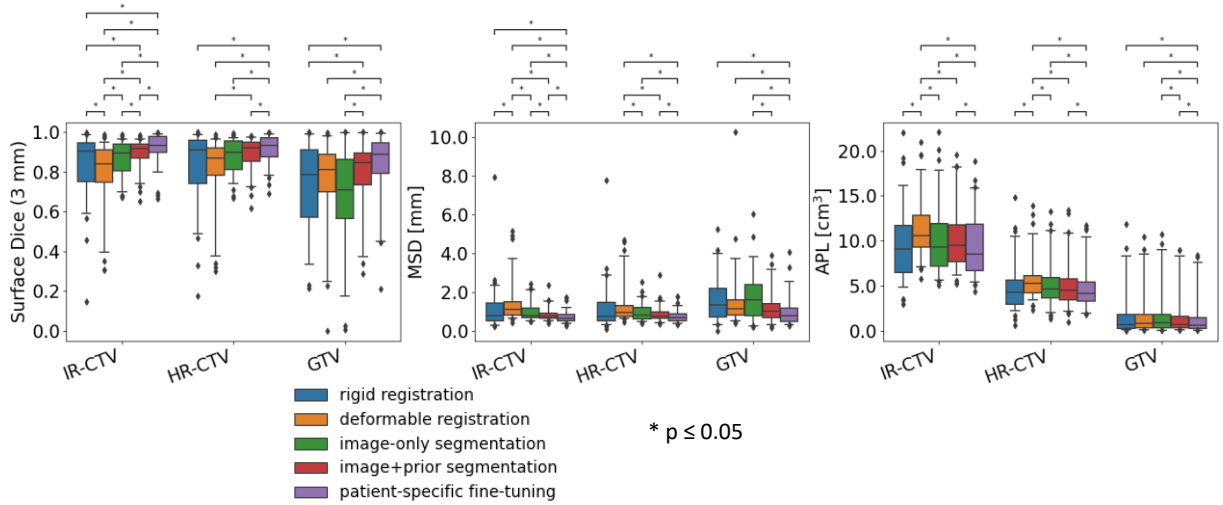

Figure 1 - Performance of the different target propagation approaches for the second and third fractions of the test set patients.

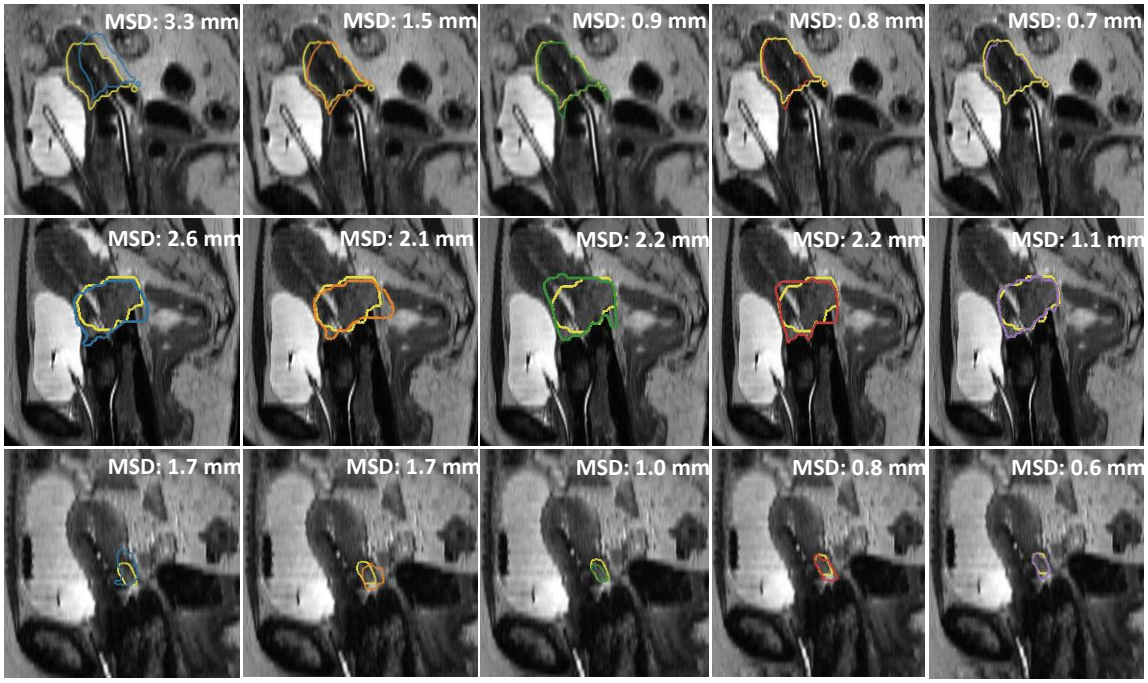

Figure 2 – Examples of IR-CTV (top row), HR-CTV (middle row) and GTV (bottom row) segmentations on the T2 images of three different patients (sagittal view, cropped). The ground truth is depicted in yellow and the outputs of the different target propagation methods are identified by different colors (conform Figure 1): a) rigid registration; b) deformable registration; c) image-only segmentation; d) image+prior segmentation; e) patient-specific fine-tuning.

Figure 2 shows segmentation examples of the IR-CTV, the HR-CTV and the GTV in three different patients. In the case of the IR-CTV, the rigid propagation failed to position the structure. Deformable registration improved upon rigid registration but failed at segmenting high contrast regions such as the uterus boundaries. The image-only segmentation model was able to correctly detect these boundaries but over-segmented the IR-CTV caudally. The patient-specific methods were able to capture the radiation oncologist's intent by ending the delineation caudally at the correct place. In the case of the HR-CTV, the patient-specific fine-tuned models clearly outperformed the other approaches, including the image+prior segmentation model. In the GTV example, the rigidly propagated structure is larger than the ground truth, indicating tumor regression. The deformable registration and the image-only segmentation model respectively over- and under-segmented the GTV considerably. The two patient-specific methods outperformed the other approaches.

4 Discussion

The patient-specific methods outperformed the registration- and image-only segmentation approaches for target propagation in the second and third fractions of cervical cancer brachytherapy. In particular, the patient-specific fine-tuned models yielded the best performance for most metrics and structures.

The registration-based methods performed generally worse than the segmentation-based methods. The IR-CTV is partially defined by information that is not present on the images, so its boundaries are not necessarily strictly anatomical. Additionally, inter-fraction anatomical changes in the pelvic region can be large [14], rendering methods

that are purely based on image registration less suitable for this task. Deformable registration performed actually worse than rigid registration for all structures and metrics. A possible explanation is that the images were registered globally. Defining an area for local registration would have possibly resulted in improved registrations.

The image-only segmentation model performed on average comparably to the rigid registration but was able to improve upon it for the poorest-performing cases. This indicates that an image-only segmentation approach may be a suitable strategy for assisting the radiation oncologists in manually segmenting the first fraction, for which no segmentation starting point is available. The image+prior segmentation model, however, significantly outperformed the image-only segmentation model for most structures and metrics. This demonstrates the benefit of incorporating patient-specific information into the auto-segmentation model.

We hypothesized that the propagation of the IR-CTV would benefit most from the incorporation of patient-specific information, since this structure is defined as the pre-treatment tumor area. Because the tumor often regresses during the course of treatment, this information is generally no longer present in the brachytherapy MRI images. Indeed, for most performance metrics the two patient-specific segmentation methods significantly outperformed the other techniques.

The GTV is defined as the visible tumor on the daily images, however, tumor auto-segmentation is a complex task due to the large heterogeneity in shape, size and texture of these structures. Adding extra patient-specific information might therefore help in simplifying the task. Indeed we found that, for the GTV, the patient-specific fine-tuned segmentation models significantly outperformed the other methods in all metrics. This indicates that tumor auto-segmentation also benefits from patient-specific information, even in the presence of inter-fraction tumor regression.

It is worth noting that the ground truth delineations used in this study were obtained by editing the rigidly propagated structures. The performance of the rigid registration method is therefore likely overestimated, as the radiation oncologists were biased towards these structures. A more realistic estimate would require the manual segmentations to be performed without a starting point. However, this data was not available as this is not done in clinical practice for the second and third fractions.

5 Conclusion

In this study we compared the performance of various automatic approaches for propagating the three target volumes over the course of brachytherapy for cervical cancer patients. The patient-specific approaches outperformed both registration- and image-only segmentation approaches. In particular, fine-tuned segmentation models have the potential to reduce clinical staff workload, thereby improving the treatment efficiency and increasing patient comfort.

Abstract Diffusing alpha-emitters radiation therapy (DaRT) is a brachytherapy technique using ^{224}Ra seeds. This treatment utilises the high linear energy transfer (LET) and short range of α-particles. Treatment planning of DaRT requires a good understanding of the dose from all particles in the ^{224}Ra decay chain. Geant4 and Geant4-DNA are used in this study to simulate a DaRT seed and the DNA damage due to this treatment. Simulations show the majority of the dose is delivered in the first 3 weeks following insertion, therefore there is little additional dose delivered if seeds are not removed following treatment. The dose close to the seed is predominantly due to α-particles, however the contribution of electrons becomes greater at radial distances beyond 4 mm. It is therefore important to include the contribution from all particles in treatment planning. The DNA damage surrounding the seed becomes less complex with distance, due to the change in particle spectrum. The radiobiological effectiveness (RBE) has been calculated as a function of number of double strand breaks (DSBs) and complex DSBs. RBE_{DSB} is approximately 2 close to the seed and tends to unity with distance. RBE_{cDSB} is greater, in the range 5-7, close to the seed but also tends to unity with distance. This should be considered when determining the spacing between seeds to ensure the required therapeutic effect is maintained. The reduced RBE with distance from the source results in less complex, more easily repaired, damage to surrounding normal tissues. Hence DaRT has the potential to be a conformal treatment delivering a high RBE to the treatment volume.

1 Introduction

Diffusing alpha-emitters radiation therapy (DaRT) is an interstitial brachytherapy treatment using seeds containing ^{224}Ra. This treatment takes advantage of the multiple alpha decays in the ^{224}Ra decay chain. α-particles have a high linear energy transfer (LET) and short path length, therefore highly lethal doses can be delivered close to the seed. DaRT also benefits from the additional treatment range due to the diffusion of the daughter nuclei in the decay chain, in particular ^{220}Rn and ^{212}Pb. This increases the effective treatment distance to several millimetres [1] enabling better tumour coverage whilst maintaining good spatial protection of surrounding normal tissue. DaRT is currently undergoing several clinical trials, including a prospective trial treating locally recurrent squamous cell carcinomas [2].

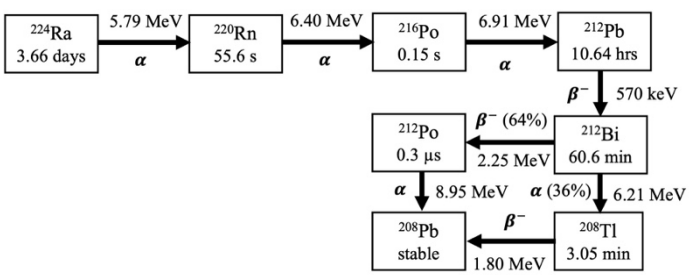

Figure 1 – ^{224}Ra decay chain.

A good understanding of the DNA damage surrounding the seed is needed for the treatment planning of DaRT. All particles in the ^{224}Ra chain, see Fig. 1, contribute to the DNA damage. Due to the diffusion of daughter nuclei, the particle spectrum (the type of particle, the energy of particle and quantity of particles) will vary with distance from the ^{224}Ra seed. The energy and particle type affect the induced DNA damage, therefore an understanding of the particle spectrum is important for the treatment planning of DaRT.

2 Materials and Methods

This study uses Geant4 (version 11.1) [3,4,5] and the low energy extension Geant4-DNA to simulate a DaRT seed and the initial DNA damage due to this treatment. Two individual simulations are used. Firstly, the DaRT seed is simulated, and the particle spectrum saved in a phase space file at specified distances from the seed. Secondly this phase space file is used as the input to the DNA damage simulation.

2.1 DaRT seed simulation

The DaRT seed is simulated as a stainless-steel cylinder with radius 0.15 mm and length 6 mm [6] as shown in Fig. 2. ^{224}Ra ions are placed at a depth of 0.15 nm. The Geant4-DNA physics constructors *G4EmPenelopePhysics* and *G4RadioactiveDecayPhysics* are used to simulate electromagnetic interactions and radioactive decay.

The whole decay chain of ^{224}Ra is simulated. Daughter nuclei from these decays which enter the tumour due to recoil slowly diffuse away from the seed. Only the diffusion of ^{220}Rn, ^{212}Pb and ^{212}Bi is simulated. ^{216}Po and ^{212}Po have relatively short half-lives and therefore it is assumed that diffusion away from their parent nuclei is negligible. ^{208}Tl has a longer half-life, however the diffusion constant is

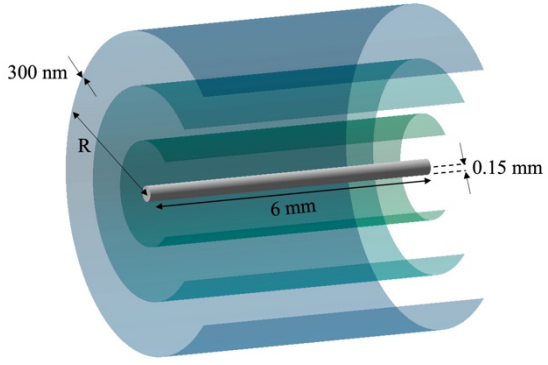

Figure 2 – DaRT seed simulation geometry.

uncertain and has therefore not been included in the simulation. The diffusion of ^{220}Rn, ^{212}Pb and ^{212}Bi is simulated using a random walk with diffusion constants: D_{Rn} = 1.12x10^{-3} mm^{2}s^{-1}, D_{Pb} = 1.22x10^{-5} mm^{2}s^{-1} and D_{Bi}= 6.78x10^{-7} mm^{2}s^{-1} [1].

Some decay products are removed from the tumour environment via biological processes. In particular ^{212}Pb can bind to surrounding molecules such as proteins and be removed via vascular routes. The amount of leakage has been found to vary significantly with tumour size between 12-90% [6]. Therefore, the leakage has been simulated to have a probability of 50%. It is assumed that the leakage of all other nuclei is negligible.

Particles which are not removed due to leakage are all tracked. Any particles crossing rings at specified distances from the seed, see Fig. 2, are saved to the phase space file for the DNA damage simulation.

2.2 DNA damage simulation

A previously developed simulation [7] is used to simulate the direct and indirect damage due to DaRT from which the yield of DNA strands breaks is calculated. This model requires an input particle distribution, see Section 2.1, and a DNA model.

The DNA model consists of a small section of a cell nucleus as shown in Fig. 3. The *fractaldna* python package (version 0.6.0) [8] was used to produce straight and turned segments of solenoid chromatin fibre. These segments are placed along a self-avoiding walk.

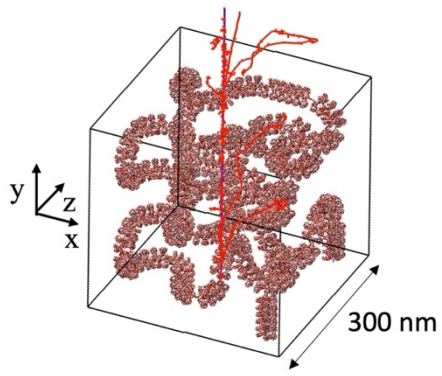

Figure 3 – α-particle crossing the simplified cell nucleus. Deoxyribose molecules are shown as red and grey spheres.

The *G4EmDNAPhysics_option7* physics constructor was used for all volumes, which tracks particles down to the nanoscale in liquid water. Therefore, all volumes in the simulation are considered to be liquid water.

The methodology for simulating direct and indirect damage is described in [7] and is described here briefly.

To calculate the initial distribution of direct stand breaks energy depositions are accumulated within 0.35 nm of each deoxyribose-phosphate molecule. The linear damage model [9] is then applied with a minimum of 5 eV and a maximum of 37.5eV. For indirect strand breaks a 40.5% probability [10,11] of a strand break occurring following a reaction between a hydroxyl radical and the deoxyribose-phosphate backbone is used. The radiolysis of water is simulated up until 5 ns, and radicals more than 9 nm from the deoxyribose-phosphate backbone are removed from the simulation to simulate scavenging by the medium [10,11].

Isolated strand breaks are easy for a cell to repair, whilst many strand breaks in close proximity are potentially more difficult to repair and more likely to lead to cell death [12]. Strand breaks have been classified using the methodology presented in [13]. Double strand breaks (DSBs) are considered to be the most lethal damage. A DSB contains at least one strand break on each of the DNA strands within 10 base pairs. DSBs can be further classified into simple and complex DSB. Only one strand break on each strand within 10 base pairs is considered to be a simple DSB. A DSB containing more strand breaks within 10 base pairs is a complex DSB.

The radiobiological effectiveness (RBE) is a commonly used metric for comparing high LET therapy to conventional low LET therapy. It can be calculated [14]:

$$RBE = \frac{Dose_{endpoint/photon}}{Dose_{endpoint/quality}}$$

where the endpoint is a biological quantity of interest. DSBs are more difficult to repair than simpler strand breaks, and therefore are considered to be the main cause of cell death [12]. Therefore, in this work the endpoint considered is DSB induction. For the low LET photon comparison, the same DNA model was used to calculate the strand break yield from a ^{60}Co source at a radius of 5 mm from the centre of the cell nucleus.

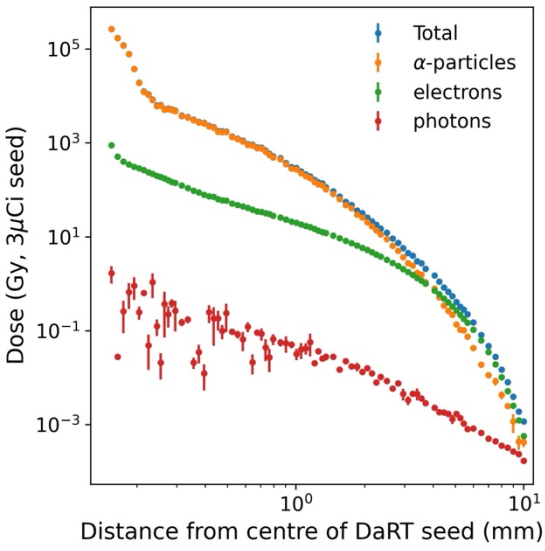

Figure 4 –Dose as a function of radial distance from the centre of a 3 μCi/cm DaRT seed, for all particles, α-particles (including delta electrons), electrons, and photons.

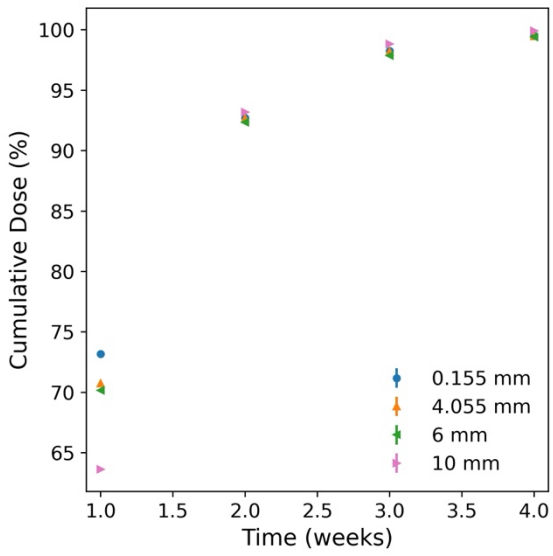

Figure 5 – Cumulative dose as a percentage of the total dose as a function of time since seed insertion.

3 Results and Discussion

Figure 4 shows the dose from the DaRT seed as a function of distance due to α-particles, electrons and photons. There is a sharp fall off in dose with increasing distance. Tissue more than 4.3 mm from the seed receives less than 1 Gy which allows DaRT to be a very conformal treatment. Close to the seed α-particles deposit the majority of the dose. However, the contribution of electrons increases with distance. At distances greater than 4 mm electrons deposit the majority of the dose, whilst photons deliver a much smaller dose at all distances. This change in particle distribution is important for the effectiveness of the treatment, as α-particles produce more complex, harder to repair strand breaks than electrons and photons.

Figure 5 shows the percentage of the total dose delivered at four distances from the seed as a function of time after insertion. After 3 weeks at least 98% of the dose is delivered at all distances from the seed. Therefore, for superficial treatments the seeds can be removed after 3 weeks with little impact on the delivered dose. In contrast, for treatment sites where seed removal is not feasible the extra dose delivered to surrounding tissue is not significant.

As expected, the change in particle spectrum with distance affects the yield of DNA damage. Figure 6 shows the yield of strand breaks, DSBs and complex DSBs normalised to the dose at a given distance from the seed. DNA damage due to α-particles is the major source of damage for all types of strand break close to the seed. However, the contribution due to electrons increases for individual strand breaks and DSB becoming greater than α-particles beyond distances of 3.0 mm and 5.8 mm, respectively. α-particles have a higher LET than electrons and therefore cause more complex damages. The total yield of strand breaks increases with distance from the seed. However, the yield of DSB decreases due to the decrease in dose deposition from α-particles. The complexity of DSB also decreases with distance from the seed. Whilst some DSB are formed due to electrons distal from the seed, there are fewer complex DSB due to the lower LET. Thus, the overall DNA damage complexity decreases with distance from the seed, simpler damage is more easily repaired and therefore the effectiveness of treatment is reduced at greater distances from the seed.

This is reflected in the calculated RBE. Both RBE_{DSB} and RBE_{cDSB} tend to unity at large distances from the seed as shown in Fig. 7. RBE_{DSB} is approximately 2 until 1.0 mm from the seed after which the RBE decreases to approximately unity. RBE_{cDSB} is much higher in the range 5-7 close to the seed, until 1.2 mm from the seed after which

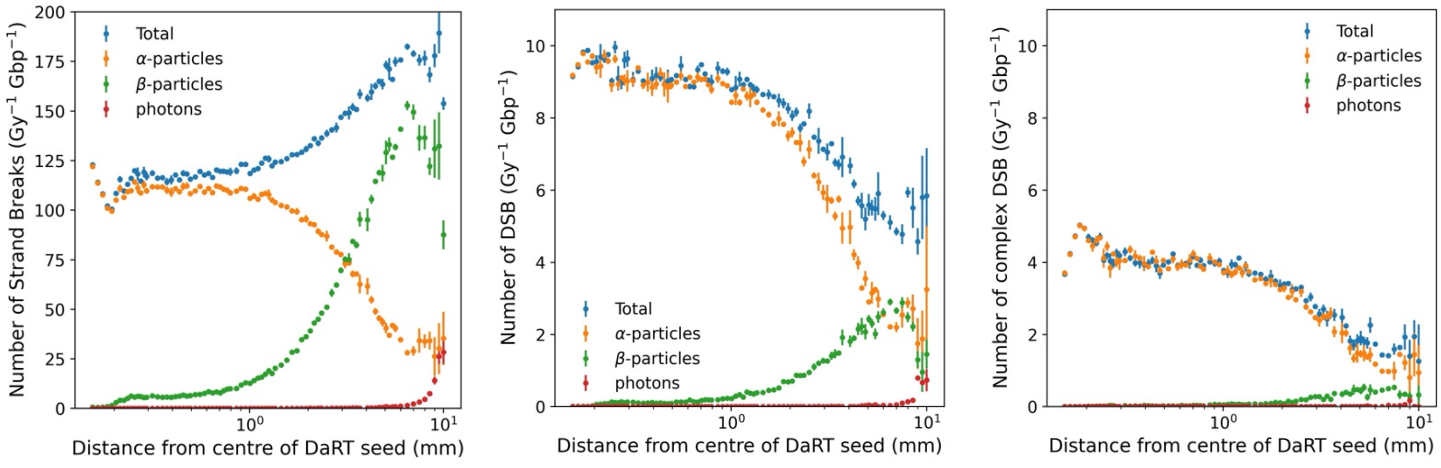

Figure 6 – Yield of (left) total strand breaks, (middle) DSBs and (right) complex DSBs as a function of radial distance from the centre of the DaRT seed for all particles, and due to particles produced due to radioactive decay (subsequent secondaries are included with the decay product).

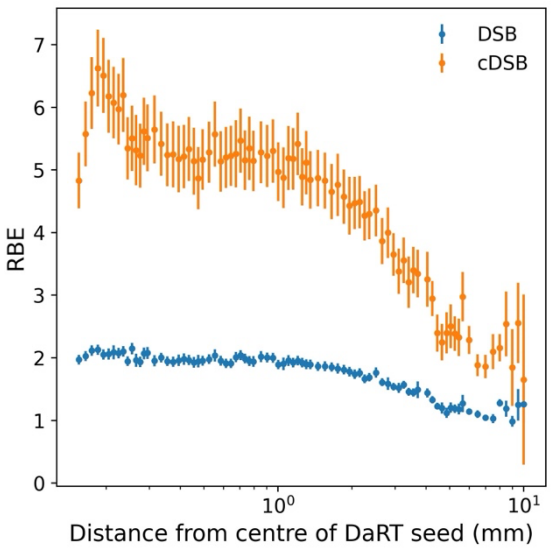

Figure 7 – RBE as a function of radial distance from the centre of the DaRT seed using ^{60}Co as the reference radiation.

it also decreases towards unity. This change in treatment effectiveness should be considered in treatment planning to determine the spacing of seeds such that the therapeutic effect is maintained between seeds. If the distance is too large the RBE between seeds will decrease. Since less complex damages are more easily repaired this could result in a reduction in treatment effectiveness. The decrease in RBE is however beneficial for surrounding normal tissues as less complex damages are easier to repair resulting in a lower probability of normal tissue complications.

5 Conclusion

The high LET and short range of α-particles allow the targeted treatment of cancer. DaRT uses ^{224}Ra seeds, which decays releasing four α-particles per decay. The aim of this study is to better understand the DNA damage surrounding a DaRT seed from all particles in the ^{224}Ra decay chain. To do this a DaRT seed and the DNA damage radially surrounding it have been simulated using Geant4 and Geant4-DNA.

The majority of the dose is delivered in the first 3 weeks following treatment, therefore the extra dose delivered from not removing seeds following treatment is not significant.

It has been shown that the distribution of particles changes as a function of distance from the seed, which affects the DNA damage. Whilst more strand breaks occur at larger distances from the seed, the complexity of damages decreases as a function of distance. The majority of the deposited dose up until a distance of 4.0 mm is due to α-particles, which having a higher LET results in more complex damages. At greater distances however, electrons deliver the greater dose. Such electrons have a lower LET and hence cause less complex damages which are potentially easier for a cell to repair. This causes the RBE to decrease with distance from the source. This is an important consideration for treatment planning to ensure the minimum tumour volume dose coverage considering the differences in RBE. However, this is beneficial for surrounding normal tissue, which receive less dose due to the rapid fall off and the RBE is lower hence DNA damage is less complex and easier to repair. Therefore, DaRT has the potential to be a very conformal treatment whilst still delivering an effective dose to the treatment volume.

A pipeline for generating longitudinal head and neck cancer radiotherapy datasets for machine learning

Kayla O'Sullivan-Steben[1], Odette Rios-Ibacache[1], Luc Galarneau[1,2], and John Kildea[1,2]

[1]Medical Physics Unit, McGill University, Montreal, Canada
[2]Research Institute of the McGill University Health Centre, McGill University, Montreal, Canada

Abstract AI and Big Data have promised to revolutionize radiotherapy. However, there is a lack of readily available large-scale datasets needed to train AI models. Therefore, we developed an image processing pipeline that automatically sorts, registers, and preprocesses DICOM images and DICOM-RT files for use in downstream machine learning and analysis tasks. We focused on the use case of head and neck cancer (HNC), where patients often undergo anatomical changes that necessitate replanning. These anatomical changes can potentially be modeled and predicted with sufficient longitudinal imaging data. Our Python-based pipeline was validated on 370 HNC patients, resulting in a comprehensive HNC dataset containing 5,402 Cone-Beam CTs (CBCTs), 530 planning CTs, and related radiotherapy data. Using this dataset, we can produce various image-related metrics and have begun training deep learning algorithms for HNC replanning predictions. Overall, our pipeline is a useful tool for collecting and utilizing longitudinal real-world radiotherapy datasets for machine learning.

1 Introduction

The use of Artificial Intelligence (AI) in radiotherapy research continues to rise, but its clinical application is often hindered by the lack of large high-quality datasets. Therefore, we developed an image processing pipeline to generate ready-to-use datasets of longitudinal imaging data, with an initial focus on predicting anatomical changes in head and neck cancer (HNC) patients undergoing radiotherapy.

Big Data and AI are rapidly evolving areas of research that have promised to address a variety of challenges in radiotherapy, including treatment planning, patient monitoring, and outcomes prediction [1, 2]. One emerging AI strategy for personalized medicine is the Digital Twin concept, a dynamic virtual representation of an object that is updated continuously with new incoming real-world data to predict the object's future behaviour [3]. Unfortunately, successful development of AI models is often limited by the lack of accessible high-quality real-world radiotherapy data for research use [1, 4]. Digital twinning, in particular, requires both historical data as well as new data for continuous model updating. While databanking initiatives like The Cancer Imaging Archive (TCIA) [5] aim to provide large collections of imaging data for research, they currently lack comprehensive longitudinally-sequential radiotherapy data such as cone-beam CT (CBCT) images for Image-Guided Radiotherapy (IGRT). Pipelines to efficiently produce these datasets would facilitate digital twinning and other AI studies reliant on time-series data.

Furthermore, the process of extracting, cleaning, and curating these large datasets for analysis and machine learning can be laborious and time-consuming. Ethical concerns around patient re-identification often further limit data sharing [1, 4]. Therefore, to comprehensively address all these challenges, we developed an image processing pipeline that automatically sorts, registers, preprocesses, and analyses the DICOM images and DICOM-RT files of patients undergoing radiotherapy so that the processed data may be easily used for future downstream machine learning and analysis tasks.

The first use-case of our pipeline is to prepare a dataset for modelling and tracking anatomical changes of head and neck cancer (HNC) patients during radiotherapy. HNC patients often experience significant anatomical changes throughout treatment due to weight loss and tumour shrinkage, which can affect the planned dose distribution and compromise tumour coverage and organ at risk sparing [6, 7]. In such cases, the patient must have their radiotherapy treatment replanned. However, in many centres, radiotherapy replanning is resource-intensive and the decision to replan is often made with short notice to the planning team, resulting in workflow disruptions and suboptimal treatment planning across multiple patients.

The long-term clinical goal of our use case is to predict the progression of HNC patients' anatomical changes over the course of radiotherapy so that replanning can be anticipated and prepared in advance. Our methodology consists of training a variational autoencoder – a neural network composed of an encoder and decoder – on CBCT imaging data. However, we were unable to find readily available datasets providing complete radiotherapy and imaging data over the course of treatment for a sufficiently large number of HNC patients. Therefore, we designed our pipeline as a tool to transform raw data from the Treatment Planning System (TPS) into machine-learning-ready data for longitudinal image-based studies.

2 Materials and Methods

Our pipeline was built and incrementally tested using the data of HNC patients treated at our centre, which are stored and managed by the ARIA oncology information system (Varian Medical Systems, Inc. Palo Alto, California, USA). The use of these data was approved by our centre's Research

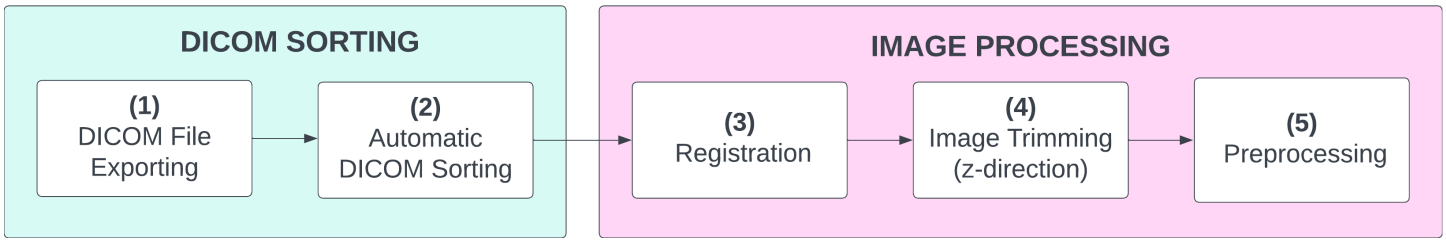

Figure 1: Schematic of our image sorting and processing pipeline.

Ethics Board. To retrieve the list of patients to be included in our study, we first queried the ARIA database for patients who were diagnosed with squamous cell carcinoma HNC and treated at our centre since 2017.

We then designed a pipeline that would start from the list of patient IDs and finish with a fully-preprocessed imaging dataset. The pipeline was coded in Python and consists of five main steps: DICOM exporting, sorting, registration, trimming, and preprocessing (Figure 1). Each step is described below.

1. Exporting: For each patient, all radiotherapy-related DICOM files are (by necessity) manually exported from the TPS. These files include planning CTs, CBCTs, image registration files, and DICOM-RT objects (RT Image, RT Structure Set, RT Plan, RT Dose, and RT Beams Treatment Record). The DICOM files are exported all at once (per patient) into a single unsorted directory and are anonymized by the TPS on export.

2. Sorting: DICOM images of different modalities (CT, CBCT, etc.) and their associated DICOM-RT and registration files are sorted into separate directories based on their metadata. When available, DICOM-RT Structure Set files, whose metadata contain the UIDs of each image slice in the reference scan, are used as an index to sort image slice files. This action accelerates the overall process by eliminating the need to open and read individual image slice DICOM files.

3. Registration: For each patient, the planning CTs and CBCTs from different time points are registered using rigid registration. Our code supports registration using both the DICOM registration files generated by the TPS as well as an optimizer algorithm that employs the SimpleITK library [8].

4. Trimming: CBCTs are cropped along the z-axis so that all images for a given patient cover the same anatomical region. The CBCTs can additionally be left untrimmed or trimmed to a specified reference point or structure in the planning CT Structure Set.

5. Preprocessing: Using OpenCV [9], a binary mask is applied to the patient's body, allowing for geometric calculations (cross-sectional area, perimeter, volume), noise removal (eg: removing the visible headrest), and image centering and cropping in the x-y plane. Additional preprocessing features include applying a window-level to the image, converting Hounsfield Units (HU) to standard pixel values, and resampling and resizing images. Preprocessing ensures that all images are standardized prior to further analysis. Finally, a simplistic outlier detection algorithm is applied using body area metrics and pixel means and variances to identify and (depending on the threshold applied) exclude low-quality and unusable images from the dataset.

To validate our work, we generated a variety of statistics and metrics relating to the imaging data. To evaluate the performance of our pipeline, we measured the execution time for each processing step for a sample patient.

3 Results

In this work, we developed and implemented a DICOM sorting and processing pipeline using Python and open-source libraries, which will be published on GitHub as an open-source tool. The pipeline was successfully tested on 370 squamous cell carcinoma HNC patients who underwent radiotherapy at our institution since 2017. This testing resulted in a comprehensive real-world retrospective radiotherapy and imaging dataset that is primed for use in analysis and machine learning.

In total, this 370-patient dataset contains 5,402 CBCT images, 530 planning CTs, and all associated DICOM-RT and registration files. 142 (38.4%) of the 370 patients had their treatments replanned, making this a reasonable dataset for research in predicting the need to replan HNC radiotherapy treatments.

From the prepared dataset, we can generate statistics on the frequency and timing of image acquisition and treatment delivery using the dates and fraction numbers embedded in the DICOM files. A summary of some of these values are presented in Table 1.

Once the images are registered, they can optionally be trimmed in the z-direction to cover precisely the same anatomical region across all images for a given patient. The amount of anatomical overlap in our dataset is shown in Table 2. An average and median overlap of 87 and 91 out of 93 slices respectively was achieved, indicating a high consistency in the imaged anatomy within an individual patient's scans.

We can also extract useful information from the preprocessed images themselves. For instance, geometric calculations such as body perimeter, cross-sectional area and volume can be calculated using the masking operation in the preprocessing step of the pipeline, allowing for a quick assessment of

	Mean	Std Dev	Median	Min	Max
Number of fractions between CBCT acquisitions	2.3	0.8	2.0	1	9
Days between planning CT and first fraction	14	5	13	5	50
Days between replan CT and first replan fraction	5	3	4	1	22
Fractions completed before replanned treatment	19	7	21	2	30

Table 1: Various statistics relating to timing of imaging acquisition and treatment delivery of the 370-patient prepared dataset.

Overlap	Mean	Std Dev	Median	Min	Max
Slices	87	9	91	33	93
Millimeters	171	16	179	64	183

Table 2: Anatomical overlap in the z-direction between CBCT images of a given patient. Each scan is taken with a set length of 93 slices and a slice thickness of 1.99 mm.

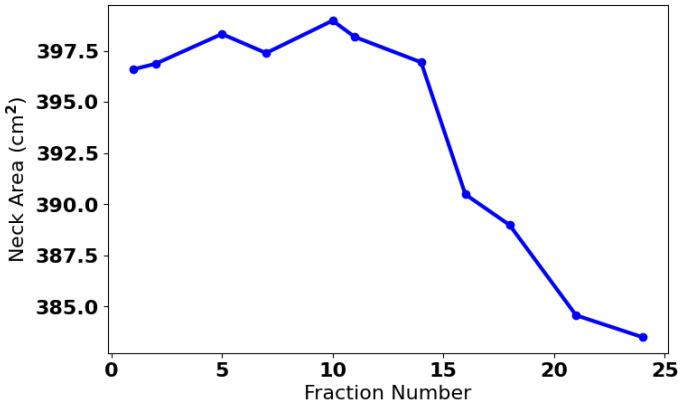

Figure 2: Cross-sectional area of a replanned patient's neck over the course of radiotherapy. The area was calculated on the image slice corresponding to the bottom of the mandible. This patient's neck area began decreasing around the 14th fraction until they were replanned at the 24th fraction.

anatomical changes that may be used for monitoring purposes. Figure 2 shows an example of the change in neck area (at the level of the mandible) of a demonstrative patient over the course of treatment before they were replanned at fraction 24.

Using the neck area metric, along with an outlier threshold set at 3 standard deviations from the mean of the image pixel values, our pipeline successfully identified several outlier images in our dataset, a subset of which are shown in Figure 3.

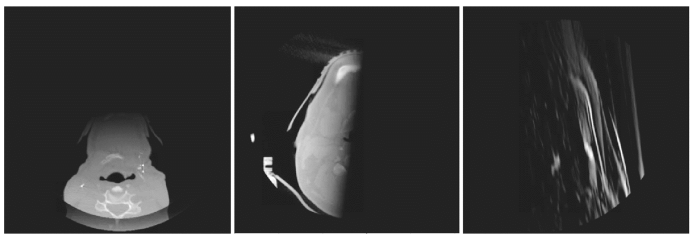

Figure 3: Examples of images successfully identified by our outlier detection algorithm.

Finally, our prepared images, and the metrics computed based on them, can be used as input to machine learning models. We are currently in the process of a training a variational autoencoder model on our prepared dataset.

Pipeline Step	Single Image	Entire Patient
1. Exporting	30 s	180 s
2. Sorting	3 s	26 s
3. Registration	11 s	60 s
4. Trimming	1 s	2 s
5. Preprocessing	1 s	5 s
Total (excl. exporting)	15 s	93 s
Total (incl. exporting)	45 s	273 s

Table 3: Approximate execution times (in seconds) of our pipeline on a sample patient with 1 planning CT and 14 CBCTs. The registration step was performed using the DICOM registration files from the TPS. The code was executed on a machine with an Intel Core Processor (SkyLake, IBRS) and 8 GB RAM.

To ensure the practicality of our pipeline, we measured the time required to process images for a sample patient. The execution times for a patient with 1 planning CT and 14 CBCTs are shown in Table 3. The approximate processing times (including TPS export times) are 45 seconds for a single image and 273 seconds for an entire patient when using the DICOM registration files from the TPS. Approximately 90 additional seconds per image are required to register images without a pre-existing registration file.

4 Discussion

The pipeline described in this work offers a solution for automating and streamlining the workflow of image processing and analysis, reducing the time needed to generate large, high-quality datasets with longitudinal images. Such datasets are essential for training machine learning models and implementing Digital Twins that rely on real-world time-series data. Additionally, since the pipeline begins with the TPS, it is possible for other centres to build similar in-house databases that can be used for research or for quality assurance and improvement purposes.

For research, the ability for different centres to efficiently generate large in-house datasets is especially important given that medical data often cannot be shared with other research groups due to privacy and ethical concerns. These privacy concerns are particularly prominent when dealing with imaging data in the head and neck region where facial recognition

may be possible. With a standardized method for procuring and processing radiotherapy and imaging data, researchers from different centres can more easily implement federated learning and external test validation.

In terms of quality assurance, the resulting prepared data can provide valuable insights and statistics on departmental IGRT and replanning workflows. For instance, statistics on the frequency and timing of image acquisition and treatment delivery could indicate the degree to which a department is following its imaging protocols. Moreover, the integration of outlier detection can reveal how often, and why, low-quality CBCT images are taken. These insights may help identify past issues and adopt preventative measures for the future. Similarly, the replan rate and average replan fraction can be compared with other centres, promoting improved standardization of care.

Our pipeline was designed not only to facilitate the aggregation of retrospective datasets, but also the continued collection of incoming imaging data. With such a pipeline in place, it becomes possible to monitor patients for anatomical changes automatically using image-based metrics such as the area presented in Figure 2.

Once we have completed the training of a varational autoencoder model on our prepared dataset, we aim to use the trained model to map latent space trajectories of HNC patients' longitudinal CBCT images and generate synthetic future CBCT images that will allow the prediction of replanning needs. As an endpoint of our current work, we intend to incorporate both the AI model trained on our dataset and a monitoring system whereby our model is continuously updated with new imaging information for a given patient. Doing so will enable live Digital Twinning for predicting anatomical changes in HNC patients.

One limitation of our work (and TPS) is that raw DICOM files currently need to be manually exported from the TPS. While this task is feasible when building a retrospective dataset as all files for a given patient can be exported at once, it would quickly become cumbersome to do each time a new image is acquired, which is needed for the clinical implementation of a Digital Twin. Thus, future work is needed to implement a fully automatic pipeline.

5 Conclusion

In conclusion, we developed an image processing pipeline that automatically sorts, registers, and preprocesses DICOM images and DICOM-RT files. We demonstrated the feasibility and utility of our pipeline by using it to create a comprehensive dataset of images from 370 HNC patients comprising planning CTs, CBCTs, and radiotherapy data. Our pipeline can facilitate efficient and consistent processing of DICOM files from various sources and modalities, as well as generate useful statistics and metrics about the data. Overall, the datasets produced by the pipeline will allow for the development of AI algorithms trained on longitudinally sequential real-world images.

Abstract There is a belief in medical research that predictive and prognostic models could aid with difficult decisions in the clinic. The rise of electronic health records makes it easier to acquire data and results in datasets including patients under-represented in trials and, hence, more difficult to make decisions for. Many models have been developed for lack of thorough validation during development and in external target populations. Current internal and external validation best practices are demonstrated using the Manchester score. This early small-cell lung cancer (SCLC) prognostic model saw clinical use despite not undergoing validation in the 36 years since its development. The model continues to separate patients by predicted survival, and following updates and validation presented here, it can be used to make 6 and 12-month survival predictions for individual patients with SCLC.

1 Introduction

There are acknowledged gaps in clinical knowledge where level 1 trial evidence is unavailable to support decision-making for many patients with SCLC. This leads to a lack of clear guidance on treating and explaining the decision-making process to the patients [1–3]. Predictive models trained on routinely acquired data sets capturing the real-world presentation of treatment and clinical outcomes of previous patients have been proposed as potential solutions to help close this gap as part of clinical decision support systems [4]. However, despite being around for more than 30 years, very few are used clinically. Multiple studies have reported guidelines highlighting issues with development and reporting that further the lack of clinical application [4–9]. Models may be developed using substandard methodology, using factors not regularly measured in the clinic; the question being answered may not be clinically relevant, and the model itself may be too time-consuming or difficult to use [5,10]. Perhaps one of the most important reasons that models do not make it into the clinics is the lack of rigorous external validation [6]. This involves assessing whether a model achieves its intended purpose, often by checking its predictive accuracy. Associated with this are challenging questions around the frequency with which models should be updated or recalibrated over time to maintain relevance as new treatments are developed or populations change [11]. Here, the Manchester score, a prognostic model developed in 1987, is used to demonstrate current validation best practices [12]. The Manchester score aimed to group patients with SCLC by survival to aid with treatment decisions; suggested examples were to provide less intensive treatments to those with poor prognosis to improve their quality of life or help choose patients eligible for clinical trials.

2 Materials and Methods

Cerny et al. began with data from 407 patients with SCLC, taken mainly from previous chemotherapy clinical trials, with the addition of some patients of poorer performance status and more severe disease [12]. A set of 61 pre-treatment variables was chosen by comparing prognostic factors discussed in the literature to the available data. Univariable analysis was used to propose candidate predictors for forward stepwise selection into a multivariable Cox proportional hazards model. The result was a linear predictor shown in Table 1, using six variables (extensive stage, Karnofsky performance status (KPS), serum lactate dehydrogenase, serum alkaline phosphatase, serum bicarbonate and serum sodium levels). An associated nomogram (the 'Manchester Score') based on the Cox model was developed by dichotomising each variable at the upper or lower normal range and assigning points. Good, bad and intermediate prognostic groups were assigned based on the patient's total number of points. The original publication did not provide survival estimates for the Manchester score risk groups nor a baseline hazard to extract them from the linear predictor.

Variable	Manchester score threshold	Linear predictor coefficient
Stage	Extensive disease	+0.63 (if extensive)
KPS	<60	-0.02*KPS
LDH	>450 U/l	+1.17*log10(LDH)
AlkalinePhosphatase	>165 U/l	+0.69*log10(Alk.Phos)
Sodium	<132 mmol/l	-8.43*log10(Sodium)
Bicarbonate	<24 mmol/l	-0.047*Bicarbonate

Table 1. shows the thresholds for using the Manchester score nomogram (add a point for each criterion met) and the equation to calculate the original linear predictor.

This validation used routinely collected structured observational data from over 2000 patients with SCLC seen at a single centre between 2013 and 2022 inclusive. Patients were included in this study if they had a confirmed SCLC diagnosis and had relevant haematology tests. The study included 1783 patients with small cell lung cancer, including those underrepresented in clinical trials. For this study, extensive-stage disease was taken as equivalent to the presence of metastases, and an average of literature conversions from the Eastern Cooperative Oncology Group (ECOG) score to KPS was used [13–16]. Blood tests had to be taken within 31 days prior to the patient's initial consultation.

The validation methodology described here follows the TRIPOD regulations, with reporting guidelines from PROBAST [5,6]. Missing data was handled using multiple imputation to avoid bias from complete case analysis and to maximise the study size [17]. Thirty imputed datasets were created using predictive mean matching, and all results were calculated on each imputed data set individually before being pooled using Rubin's rules [18]. Cerny et al. provided both the nomogram and its underlying linear predictor, which were calculated for each patient. Kaplan-Meier curves were plotted, grouping patients by good, bad, and intermediate prognoses with the same criteria used in the development paper. The score for each patient in the Kaplan-Meier curves was the median across the imputed datasets. The modern survival curves overlayed with the originals to compare survival changes between groups since development. External validation relies on two primary performance metrics: discrimination (the ability to order patients by severity of outcome correctly) and calibration (the ratio of observed to expected outcome probability)[19]. With a 95% confidence interval, discrimination was calculated for both scores using two methods: Harrel's C-index (for time to event prediction) and the area under the curve (AUC) of receiver operating characteristic curve (ROCs) plotted at 6, 12 and 24 months.

Calibration could not be calculated as the development paper failed to report survival estimates for the nomogram groups nor a baseline hazard to accompany the linear predictor. The cumulative baseline hazard for the linear predictor (as presented in the development paper with no rescaling) was calculated for 6, 12, and 24 months to improve the clinical utility and allow for survival probability estimates. These time points were chosen due to the poor median survival time of patients with SCLC, providing probabilities for short and long-term survival. The original paper claimed that the good prognostic group contained all patients surviving beyond 24 months, and the bad prognostic group contained no patients surviving beyond 12 months. Survival estimates at each time point were calculated with optimism adjustment using bootstrap resampling [4,20]. Per imputed dataset, 100 bootstrap datasets were used. Discrimination was not calculated for the internal validation of the updated model as the linear predictor remains the same, yielding the same results.

3 Results

The gender split in the modern cohort is now skewed toward females but is close to 50/50, and the average age of patients has increased by 10 years. An increase in the number of patients with extensive disease is found. There is also a difference in the number of high-performance status patients. The number of patients with KPS>60 in the modern cohort has decreased by ~20%. Overall, the proportion of patients in each Manchester grouping is roughly equivalent. The only notable discrepancy between

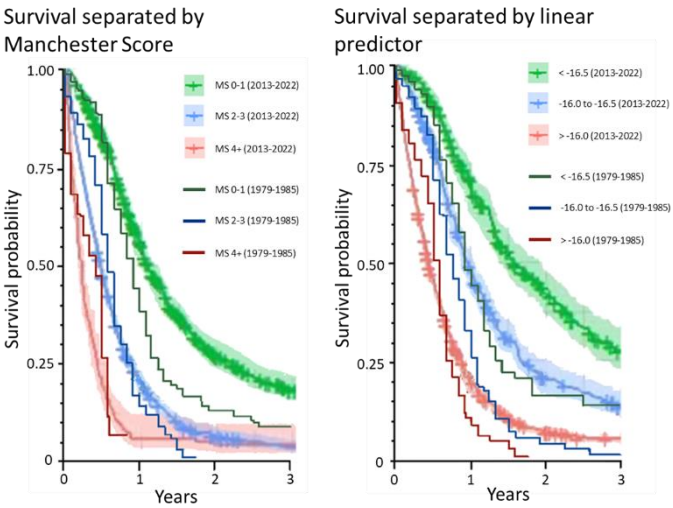

Figure 1, Overlayed Kaplan-Meier survival curves seen in the modern Manchester data set vs those presented in the 1987 development data set, grouped by Manchester Score and linear predictor (as done by Cerny et al.) [12].

cohorts is a 10% decrease in the good prognostic group and a matching 10% increase in the missing data group in the modern cohort compared to the original cohort. The Kaplan-Meier Survival curves display clear separation of the three groups when split by the Manchester score and the linear predictor. All the groups show long-term survivors (not considering any further cancers or relapses). The percentage of patients who survived to one, three and five years was 34%, 7.7% and 3.7%, respectively, within the entire modern cohort. The whole cohort median survival was 8 months. Figure 1 shows the Kaplan-Meier curves up to three years, as seen in the original paper, superimposed with the curves from the current analysis. The separation between the three groups has increased since 1987 for both prognostic scores, and the proportion of long-term survivors has increased. The median survival for the bad and intermediate prognostic groups is relatively similar for both curves; however, for the good prognostic groups, it has increased by approximately two and six months for the Manchester Score and linear predictor, respectively. The Manchester score has an AUC of 0.75, and the linear predictor has an AUC of 0.79 at 6 months. Both decrease by around 0.05 when calculated at 24 months. Harrell's C-index was 0.68 (with 95% CI [0.685, 0.689]) for the Manchester score and 0.70 (with 95% CI [0.69, 0.71]). The baseline hazard and optimism-adjusted calibration values can be seen in Table 2, along with the corresponding 95% confidence intervals. The accuracy of predictions decreases over time as 6 months has the best calibration at 1.001, and 24 months is the worst with 0.795.

4 Discussion

Various criteria exist for evaluating the level of bias in model development (PROBAST) along with the quality of reporting and validation (TRIPOD) [5,6]. The Manchester score development achieved a low risk of bias and poor reporting of model parameters. Here, an external model

validation procedure adheres to development and validation guidelines. This was achieved by using a large unselected observational dataset. Changes in population survival were directly compared by overlaying Kaplan-Meier survival curves. Discrimination was assessed using two methods. However, it was not possible to calibrate the model with solely the information provided in the original publication. Cerny et al. stratified patients by survival but provided no meaning to the groups. A survival estimate was assigned to each prognostic group, and a baseline hazard was calculated to provide individual survival probabilities based on the 1987 linear predictor. Internal validation of the survival estimates was completed using bootstrap resampling as recommended in the literature [4,17].

Time (months)	Cumulative baseline hazard	Baseline hazard 95% confidence interval	Optimism-adjusted calibration	Calibration 95% confidence interval
6	2815117	[2780317, 2837678]	1.001	[0.998, 1.005]
12	7123175	[7033155, 7198284]	0.971	[0.964, 0.978]
24	13580956	[13361570, 13756204]	0.795	[0.784, 0.811]

Table 2. provides baseline hazard estimates, and the calibration values at 6 months, 1 and 2 years with their 95% confidence intervals.

Despite being mentioned in literature discussing treatment methods for SCLC and referenced as an example in further model development papers, the Manchester score has never been validated using performance metrics[21–23]. Three previous analyses have used the Manchester score to stratify patients for Kaplan-Meier survival curves (none have the primary aim of validating the Manchester score) [22–24]. All concluded the score remained significantly associated with survival despite Kaplan-Meier curves presented by El-Hewl et al. showing no differentiation between the intermediate and bad prognostic groups. No papers provide interpretations for the survival of each group, but it can be seen from the graphs that the median survival of each group improves as the studies become more recent. However, the survival seen in the development paper aligns more closely with that of this study rather than the 1997 analysis by Maestu et al. The differences in survival between the 1987 and the modern cohort are likely reduced due to the strict selection criteria used by the trials that provided patients to the development cohort; this results in the development paper presenting disproportionately longer survival times. Survival in the modern cohort agrees with what has been reported in the literature [25–27]. Following the external validation, values for the median survival of each prognostic group or the Manchester score are reported. For the linear predictor model, updating and calibration have provided survival estimates at clinically relevant time points for patients on an individual basis.

During the analysis, stage and performance status conversions had to be utilised as standard measurement practice changed, limiting the accuracy of the validation. However, the current analysis uses fewer selection criteria than in model development, better reflecting the target population. Similarly, multiple imputation allowed all patient data to be utilised, maximising the cohort size. This is dependent on the assumption that data is missing at random. Survival trends are measured for each Manchester prognostic group and the whole unselected cohort. The survival of each prognostic group in the modern cohort has been quantitatively described in terms of overall median survival. This indicates the prognosis in each risk group and the relationship between them. Reporting the coefficients of a predictive model is necessary for future use of the model and validation. However, it is often subject to the Table 2 fallacy; the effects seen in the linear predictor are not causal [28]. A barrier to clinical use in the original model is that baseline hazard is not provided. This means survival estimates cannot be calculated, and the score cannot be externally calibrated in the modern cohort. The extraction of the baseline hazard in the modern cohort allows for survival estimates to be made in the future. Before clinical use, validation in the intended centre and population would be required. However, assessment of the optimism-adjusted calibration using bootstrap resampling is an example of current best practice for internal validation, providing a stable and approximately unbiased estimate of model performance in the represented population. It would be expected that the calibration remains close to one for all time points due to being evaluated in the same data it was developed in; however, the model's predictive ability deteriorates at later time points. This is likely due to a class imbalance at 24 months, as the median survival in the data set is 8 months.

In oncology, there are two distinct meanings for prediction and prognosis. Prediction focuses on assessing the impact of treatment on the outcome, whereas prognosis is aimed at evaluating the outcome in the absence of treatment (null intervention). In practice, assessing outcomes without intervention is difficult since patients typically receive the best available standard of care, usually involving some form of intervention, whether curative or palliative. As a result, prognostic models such as the Manchester Score are often developed without considering treatment factors, even though treatment affects the outcome. To influence treatment decisions with the aim of reducing toxicities for those with poor survival (stated to be the primary suggested use of the Manchester score), a causal analysis looking at the average causal effect of prescribed treatment on toxicities should be conducted. Alternatively, looking at the average causal effect of assessment of Manchester score use vs not use in treatment prescription on toxicity levels in patients with SCLC would provide a clear evaluation of the

impact. Following current validation guidelines, the Manchester score is fit to be used in the clinic to assess prognosis in populations similar to those shown here.

5 Conclusion

Prediction and prognostic models rarely make it into the clinic despite ample model development and promise to aid clinical decision-making and patient communication. One reason for not being used is a lack of validation and poor validation practices in the relevant target populations. To combat these issues, many guidelines have been published on conducting and reporting the development and validation of predictive models. Here, current validation best practice is demonstrated using an early predictive model for survival of patients with SCLC. The Manchester Score is a simple nomogram developed using (now) outdated methods, and information crucial to thorough validation was not reported. External validation was completed, followed by model updating and internal validation, using a large unselected observational dataset from a single centre spanning 10 years. The Manchester score successfully groups patients by overall survival time and has been expanded to make individual predictions at 6 and 12 months post-diagnosis. Factors such as the linear predictor and baseline hazard at clinically relevant time points are reported, allowing the model to be used and validated.

Abstract Microcirculation is the terminal vascular network of the systemic circulation. It has a pivotal role in the cardiovascular system. Damage to microvessels caused by radiotherapy (RT) contributes to toxicity development in a non-clarified manner. This work aims to investigate quantitatively the role of microcirculation in predicting acute toxicities after breast and prostate cancer RT. We enrolled 247 patients at a single centre for this study RT. We assessed the single-patient baseline microvasculature health status (MVHS) before RT using a microscope coupled to the GlycoCheck™ software. The system records videos (in the sublingual region) showing the live movement of red blood cells in the microvessels, analyses the microvasculature and computes the MVHS value for the overall health of microcirculation. We fitted a logistic model for the association between MVHS and acute toxicities, and we found a quantitative relationship between microvasculature health status and radio-sensitivity for patients both breast and prostate cancer patients.
The information obtained from the sublingual microscope could help personalise predictive models for toxicity and tailor them to the functional status of each patient.

1 Introduction

Microcirculation is an intricate network of arterioles, capillaries and venules that supply and drain blood from every tissue and organ in the body. The particular architecture of these microvessels varies depending on the specific structure of the vital organ they serve. An essential aspect of microcirculation is its pivotal role as the functional core of the cardiovascular system, facilitating the exchange of oxygen, carbon dioxide, nutrients, hormones, water and drugs, and as a causal factor in developing some pathologies.
Radiotherapy (RT) can contribute to microcirculation dysfunction. Indeed, the damage to the microcirculation causes endothelial cell dysfunction, increased vessel permeability and alterations in vasoconstriction and vasodilation, impacting oxygen and nutrient diffusion within the tumour and, consequently, the treatment efficacy. Moreover, RT also damages the microvessels of healthy organs, interfering with the damage recovery and toxicity manifestation process. Several trials have indicated an increased risk of normal tissue complications in patients with pre-existing medical conditions (hypertension, diabetes, use of cholesterol-lowering drugs, use of drugs for cardiac morbidity, obesity) or specific habits (smoking, alcohol abuse, low physical activity) that negatively impact the stability of the vascular system [1–5].
This work aimed to investigate quantitatively the role of microcirculation in predicting acute toxicities after breast (BCa) and prostate (PCa) cancer RT. Current RT techniques and plan optimisation for these two districts allow dose distributions highly conformed to the clinical targets, with small proportions of normal tissue receiving relevant doses. For these reasons, dose parameters are weakly associated with side effects, and the search for patient-specific features highlighting exceptional radiosensivity in still an active field of research. We included a quantitative measure of the single-patient microvascular health status (as measured by GlycoCheck™) in a predictive model for acute toxicities.

2 Materials and Methods

2.1 The study cohort

This prospective and observational study enrolled 247 patients between February 2021 and November 2023. The study cohort consisted of 143 BCa and 104 PCa patients. Women were treated with chemo RT in 25% of cases. RT was applied with a dose boost in 50% of treatments (33% as a sequential boost and 17% as a concomitant boost). Dose per fraction to PTV was 2.6-2.67 Gy in 85% of patients, 5.5 Gy in 10% of treatments and conventional 2 Gy for the remaining 5% of cases. Regarding prostate patients, 25% of them underwent adjuvant RT with 70 Gy in 35 fr. The remaining part was treated with a dose/fr in the 2-2.65 Gy range and a prescribed dose between 65 and 78 Gy.
Before RT, we trained patients to perform the baseline sublingual-microvasculature measurement (details in section 2.2). Clinicians collected the patient's condition at the baseline and at the RT end following CTCAE v4.0. We focused on the worst toxicity symptoms in each cohort, namely grade ≥ 2 erythema for BCa and simultaneous gastrointestinal (GI) and genitourinary (GU) grade ≥ 1 toxicity for PCa.

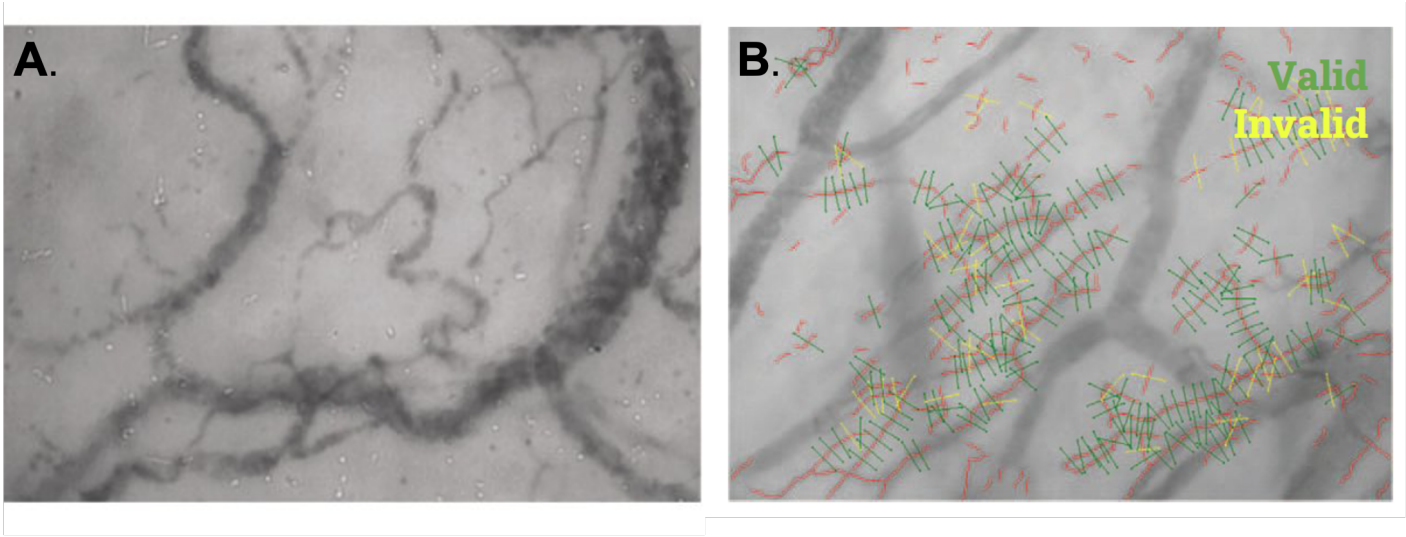

Figure 1: Glycocheck image acquisition. **A.** Frame of the videos recorded by the Glycocheck SDF Camera. **B.** After the image acquisition, the software automatically undergoes several quality check to select the vascular segments with sufficient quality for further analysis. Invalid segments (yellow) are distinguished from the valid vascular segments (green) [6].

2.2 The Instrument: Sublingual Video-Microscopy

The image acquisition of the sublingual microvasculature is performed through the GlycoCheck™ system. It comprises a handheld, non-invasive sidestream dark-field (SDF) camera coupled with a computer with the GlycoCheck software™ (GlycoCheck, Maastricht, the Netherlands). The SDF camera uses green light-emitting stroboscopic diodes (LED) to detect the haemoglobin of passing Red Blood Cells (RBC). The system acquires images in the sublingual region and extrapolates parameters representative of systemic microvascular health. The Glycocheck Software facilitates automatic image acquisition, identifying micro-vessels (with a thickness below 30 μm) during the process and analysing vascular segments along the length of the identified vessels. A single bench of measures consists of 40 frames encompassing 300 vascular segments. Next, the patient relocates the camera to a different position to record an additional acquisition. In this way, the spatial heterogeneity of the sublingual microcirculation is ensured. After acquiring images, the software analyses the vascular segments that satisfy predefined image quality criteria.
The software computes functional and morphological parameters, such as vessel diameter distribution, RBC velocity (VRBC), capillary density, capillary blood volume (CBV) and perfused boundary region (PBR) (see the Additional Material for equations).

2.3 Microvasculature Health Score

The crucial systemic measure obtained by the Glycocheck Software is the Microvascular Health Score (MVHS), which gives information about the overall health of the microvascular system. It is a synthetic and global score ranging from 0 to 15.
The MVHS computation uses all the functional and morphological parameters obtained during the recordings, such as the CBV, the capillary blood volume recruitment (CR) and the PBR [7]. More in detail, the software computes the ratio between the dynamic capillary blood volume CBV_{dyn} and PBR_{4-25} flow corrected (PBR_{4-25}-FL), so

$$MVHS_{dyn} = \frac{CBV_{dyn}}{PBR_{4-25} - FL}. \quad (1)$$

This parameter provides an overall quantitative evaluation of microvascular health. The higher the MVHS, the better the microvascular condition.

2.4 MVHS Imputation and Statistical analysis

The analysis focused on the association of MVHS with acute toxicity. MVHS summarises all the microcirculation parameters, and is automatically normalised for all patients.
The software's computation of MVHS needs a prolonged video acquisition, and it is not calculated for less compliant subjects. Consequently, we developed an imputation model to extrapolate the MVHS for patients with missing information. We based the imputation on all the available parameters. We trained the model on the entire population and tested the results on patients with the GlycoCheck™ computed MVHS. The training process was iterated until the average error between the observed and the imputed values was below 0.05.

3 Results

Forty-one/143 (28.7%) BCa patients developed grade ≥ 2 skin erythema. Sixty-three/104 (60.6%) PCa patients experienced grade ≥ 1 in both GI and GU domains.
The GlycoCheck exam was self-performed by patients. MVHS, requiring a longer video registration, was calculated

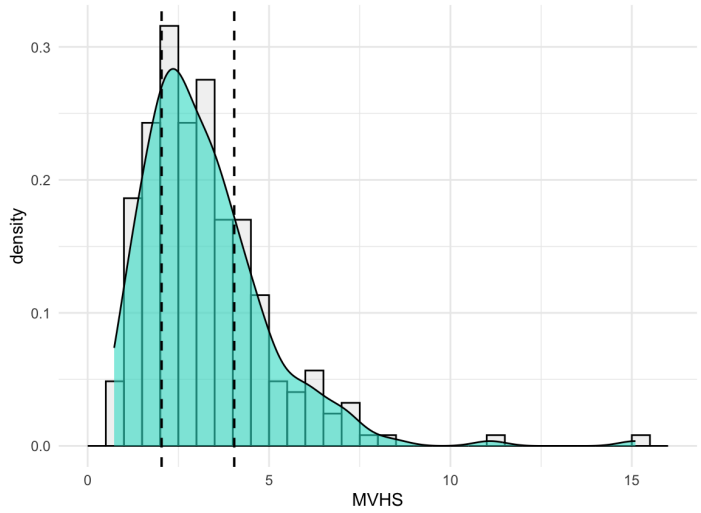

Figure 2: Density plot for the MVHS. The dashed lines represent the 1st and the 3rd quartile of MVHS distribution.

for 60% of patients, while it was obtained by multiple imputation models for the remaining part. After 250 iterations, the model reached good stability with an average error between the predicted and the observed value of MVHS equals -0.04, making the imputed values reliable.
The median MVHS was 2.87, and the 1st and 3rd quartiles were 2.04 and 4.04, respectively (see Figure 2 for the whole distribution). Stratifying for cancer type, the median MVHS was 3.06 in the BCa and 2.75 in PCa.
The logistic model coefficients were $\beta_0 = 0.58$ (constant), $\beta_1 = -0.29$ (slope for MVHS, $OR = 0.81$ for one point increase in MVHS; $p - value = 0.002$). As expected, a higher MVHS (i.e., a healthy microcirculation) protects from side effects. MVHS box plots for BCa and PCa patients stratified for acute toxicity are depicted in Figure 3.

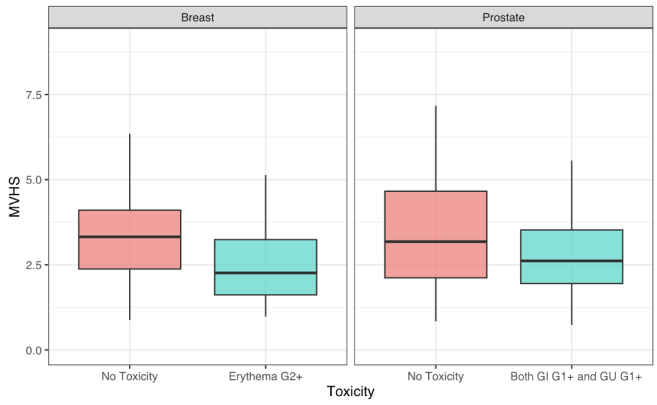

Figure 3: Distribution of MVHS between the two cohorts of patients and separated for toxicity (both $p - value < 0.0001$)

4 Discussion

We tested and quantitatively assessed the MVHS through a non-invasive tool and established the relationship between the microvasculature condition and acute radiation-induced toxicity in a cohort of BCa and Pca patients. The model confirmed an association between altered microvasculature and the damage repair mechanisms following RT, independently from the treatment region and patient sex. Indeed, MVHS distributions for breast and prostate populations were similar (p-value from t-test = 0.36), showing a negligible impact due to sex. In contrast, MVHS distributions for patients experiencing toxicity were significantly different in both the cancer cohorts (p-value <0.0001 in both cases).
From a quantitative point of view, a reduction of 1 value in the MVHS scale corresponded to an (averaged) increased risk of 23.5% of developing radiation-induced symptoms. We can define three risk classes by stratifying patients through the clinical definition of MVHS (see points of Figure 4). The low-risk group (patients having MVHS higher than 4) in which the probability of developing toxicity is 28%; the second class, representing the average patient (MVHS between 2 and 4), is at moderate risk with a toxicity rate equal to 41%. The last class (MVHS less than 2) with compromised microcirculation had a toxicity rate of 59%.
A new analysis is ongoing, including a cohort of 75 head-neck cancer patients and investigating dysphagia, xerostomia and mucositis. Considering the heterogeneity of RT treatments (and dose distributions in organ at risk) in these patients, we will include the MVHS in dose-response models for this cohort.

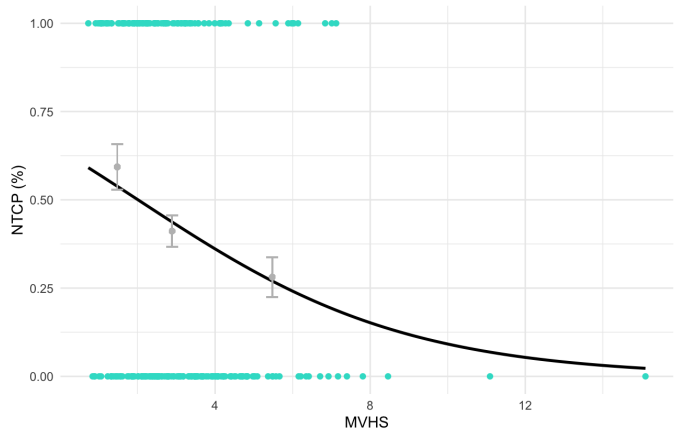

Figure 4: Normal Tissue Complication Probability as a function of MVHS. The three points show the three risk classes (low, moderate and high risk).

5 Conclusion

The study highlights the possibility of implementing a non-invasive instrument in clinical practice to gather information about microcirculation status and define the toxicity risk in different tumour districts using a patient-specific MVHS. The MVHS model predicts acute toxicity, proving a quantitative relationship between microvasculature status and radio-sensitivity in an organ-agnostic way.

The systemic functional information derived by the sublingual microscope could boost the personalisation of predictive models and tailor them to the single-patient functional status.

6 Acknowledgments

The study was supported by AIRC Investigator Grant no. 21479.

6.1 Additional material: formulas

The GlycoCheck software computes two categories of parameters: those specific to each vessel diameter class and those calculated across all diameter classes ranging from 4 to 25 μm, yielding a singular value for each subject's measurement.
Within the first category are three parameters. First, the capillary density, the RBC velocity (VRBC), and the perfused boundary region (PBR). In the second category, the GlycoCheck Software computes the microvascular blood flow, the total valid perfused microvascular density, and the parameters essential for deriving the microvascular health scores. They are the relative capillary blood volume absolute, relative, static and dynamic. In formulas:

$$CBV_{abs} = \ capillary\ density * \pi r^2$$

$$CBV_{rel} = \frac{VRBC(D \geq 10\mu m)}{VRBC(D \leq 7\mu m)}$$

$$CBV_{stat} = CBV_{abs} * CBV_{rel}$$

$$CR = 1 - slope(VRBC(D \leq 7\mu m), VRBC(D \geq 10\mu m))$$

$$CBV_{dyn} = CBV_{stat} * (1 + CR).$$

The static PBR (PBR_{4-25}) is the average PBR calculated across all diameter classes, while the dynamic PBR (PBR_{4-25} flow corrected) is the PBR_{4-25} with $VRBC(D \geq 10\mu m)$ set to 0. This minimises the possible flow-dependent variability in the PBR estimation, as the RBC penetration into the luminal glycocalyx surface can be velocity-dependent.

Abstract

The integration of Artificial Intelligence (AI) into clinical practice demands robust data preparation pipelines, especially in Radiation Oncology where challenges in data quality and access persist. This work presents a bottom-up approach for AI implementation in Indian Radiation Oncology, focusing on a prospective observational trial for predicting locoregional recurrence in head and neck cancer. The data preparation pipeline encompasses patient consenting, clinical data collection, image acquisition, annotation, curation, de-identification, and storage. The workflow, established in 2020, has successfully imaged over 1100 patients. The Data preparation involves metadata analysis, automated quality control, and integration with open-source platforms like Orthanc DICOM server and XNAT. While providing practical insights for data preparation for AI research, the work emphasizes the importance of tailored frameworks for specific healthcare contexts, outlining current practices and future considerations in the evolving landscape of AI in Radiation Oncology.

1 Introduction

The development of AI solutions that are reproducible and transferrable to clinical practice require access to large scale data for model training and optimization. Despite Radiation Oncology departments generating large volumes of imaging data and clinical routinely, quality and access to this data for AI research poses significant challenges in practice.

Implementing Artificial Intelligence (AI) in a clinical environment is a complex task. It requires resources, time, technical capacity, and multidisciplinary perspectives. Many AI frameworks outline a set of broad principles and values, but do not provide practical guidance on how these principles can be implemented and trade-offs negotiated. Such enabling factors were yet to be articulated within the context of Radiation Oncology in India, signaling the need for a bottom-up study, and localized models. In this work we report our data preparation pipeline for AI projects that involve imaging and clinical data. It was aimed to integrate seamlessly within the existing clinical workflow.

This data preparation pipeline was created as part of a prospective observational imaging trial that is on-going with the primary endpoint being Radiomics models for predicting locoregional recurrence in locally advanced head and neck cancer.

2 Materials and Methods

We have subdivided the data preparation pipeline for AI projects into multiple tasks that are typically performed in sequence. (See Figure 1).

Patient consenting: This study was approved by the Institutional Review Board. The patients treated in Radiation Oncology for locally advanced head and neck cancer were explained the observational nature of the trial and consent was obtained for their clinical and imaging data to be used for research purposes.

Clinical Data collection and curation: Clinical data are stored in disparate sources. The demographics and clinical investigations are collected and stored in our electronic medical records and managed in our hospital information system. Radiation Oncology related data such as radiation treatment notes, treatment related toxicity, treatment outcomes etc. are collected and stored in the Aria Oncology Information system. Study specific clinical data are curated, pseudonymized and stored in a Redcap database[1].

Image acquisition: Planning CT images were acquired on a Siemens SOMATOM AS. The contrast CT acquisition protocols were standardized for Head and Neck cancer for both machines. This was done after extensive phantom experiments and optimized for field of view, tube current, tube voltage, slice thickness and Image reconstruction kernels ideal for treatment planning and imaging research.

Image annotation: The CT images were annotated using Eclipse™ Treatment Planning System (Varian Medical Systems, Palo Alto, CA). Templates were created for consistent naming convention using the Eclipse Structure Templates. The gross tumor volume (GTV) was manually delineated by junior radiation oncologist and approved by senior oncologists. All contours selected for the radiomics study were reviewed by radiation oncologists with more than 15 years of experience. Repeat blind segmentation was performed for 20% of the cases to account for inter-observer variability.

Image data curation: The CT and tumour contours were moved from the Oncology Information System to a lightweight, enterprise-grade Orthanc DICOM server. The DICOM server was deployed in a Docker container in a dedicated Research Workstation.
The DICOM metadata of the stored medical images were collected. This was automated by creating a bespoke python module to analyze the DICOM metadata, specifically to verify the images for Study Description, Modality Specific image parameters (e.g. CT) and its associated series (DICOM segmentation), perform data quality control, ensure image integrity, query the images, and store the file paths in a JSON format. We also use script to check for any inconsistently labelled RT structure sets and rename them before further analysis.

Image de-identification: The curated images were pseudo anonymized by using MIRC Clinical Trial Processor (CTP), an open-source java-based application specifically designed to remove protected health information from DICOM objects[2].
All protected health information was replaced with pseudonyms or unique identifiers and the master table was well-secured and separately stored with access provided only to the researchers involved.

Image storage and Backup: The images and associated DICOM objects from TPS were backed up via S3 bucket on a private cloud setup on the Institutional research cluster and automated using customized python scripts.

The pseudonymized images were sent directly from CTP to XNAT, which is an open-source imaging informatics platform[3]. XNAT was set up in a Docker container and it allowed data to be stored for separate studies. It also provided programmatic script access to perform AI related workflows using the data from XNAT and route the analyzed data back to the database.

3 Results

Figure 1 shows the data preparation pipeline. The image acquisition, image annotation and basic storage to research environment was set up in 2020. It was used to prospectively image about 1100 patients till date treated for head and neck cancer in the department of Radiation Oncology. Other components in the workflow have been included and audited asynchronously.

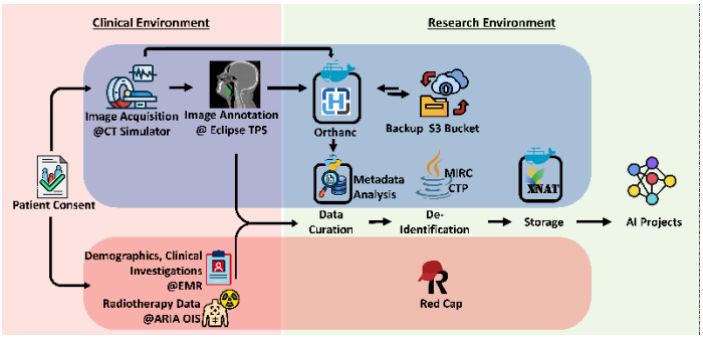

Figure 1: Data preparation pipeline for AI research in Radiation Oncology department

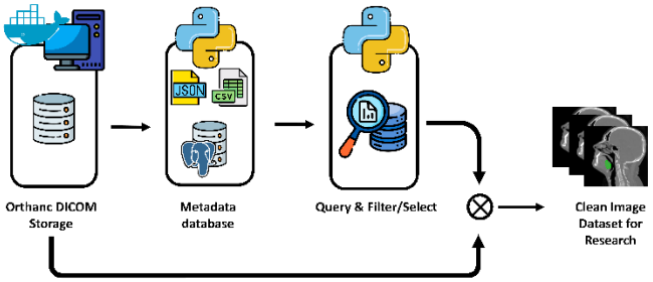

Figure 2: Image data curation workflow

Figure 2 describes the Image Data curation workflow. The Metadata was collected for images received on the Orthanc Storage. The metadata was analyzed to include only patients related to the study in question. The DICOM metadata tags included for analysis used Personal Health identifier information (Hosp ID, Patient Name etc.) Study (Study Instance UID, Date of study etc.) Series related information (Series description, Modality etc.) SOP Instance UID unique for each File and the corresponding File Path. After the completion of metadata analysis, the cleaned data was moved forward for de-identification and storage.

4 Discussion

The healthcare sector itself is not a monolith and often necessitates frameworks tailored to specific use cases or applications. In this work we share the data preparation pipeline that allows us to integrate clinical and research environments to get the data ready for AI projects.

The choice to use open-source platforms in the research environment was to ensure those processes are translatable to other institutions/groups when needed. 3D Slicer was initially set up as our DICOM listener for image data curation. However, although 3D Slicer offers many capabilities, it was not a lightweight solution and could not

handle receiving large volumes of data. We migrated to Orthanc DICOM server for receiving the data from the TPS for the as it seamlessly receives and stores data whilst large volume of data transfer happens from our multiple imaging data sources (e.g. CT simulator, TPS, PACS) for different studies.

The range of DICOM metadata tags available for querying and/or retrieval from any DICOM based PACS is limited and designed for everyday operational use rather than for audit or research purposes. As with other reported studies[4–6] we found query retrieve to be simpler on the DICOM metadata when it is stored independently from the image. We created a bespoke python-based module that could be selectively used to ensure data integrity (e.g.. ensuring availability of RTSTRUCT related to an imaging series). This allows us to check for missing data or audit the imaging protocol. This module can also be utilized as an automated procedure for all patients within the study of choice prior to visual inspection.

As reported by other research groups[7,8], XNAT was chosen for our research data since the access is built on a REST architecture which offers flexibility while interacting with the data. For example, it allows us to integrate the radiomics feature extraction on the data stored and conveniently stores the radiomics features back into the database for each individual image set. It also provides the flexibility to introduce federated learning-based AI models to learn on the data.

There are some limitations and challenges that still need to be resolved. For e.g. the data entry for clinical data is still manual entry which is both time-consuming and error prone. Next steps include creation of API that could capture some of the data fields from the EMR directly to the Redcap database.

5 Conclusion

Our work describes a meticulous data preparation pipeline tailored for AI integration in Radiation Oncology.
This work emphasizes the importance of context-specific frameworks in addressing clinical challenges. The presented pipeline contributes to the discourse on AI implementation in Radiation Oncology, providing insights for future advancements in the field.

Transfer Learning for the Detection of Lung Lesions in ^{18}F FDG PET/CT Images using GraphNet

Maryam Fallahpoor[1], Biswajeet Pradhan[1,2]

[1]Center for Advanced Modelling and Geospatial Information Systems, Faculty of Engineering and IT

[2]Earth Observation Centre, Institute of Climate Change, Universiti Kebangsaan Malaysia, Bangi 43600, Malaysia

Abstract

Early detection of lung cancer relies on advanced imaging techniques such as PET/CT scan, with ^{18}F FDG being one of the most commonly used radiotracers in PET/CT imaging. Deep learning has been demonstrated to yield promising results in automated lung lesion detection. Challenges, including data scarcity, computational costs, and robust deep learning models to detect small and complex patterns, hinder fully training deep learning models for accurate lung lesions detection. To address these challenges, this study employs sixty ^{18}F FDG PET/CT images for small and complex lung lesion detection using transfer learning with GraphNet model, alongside accurate lung segmentation and co-registration performed using Python-based codes for pre-processing. We achieved an accuracy of 82% and a sensitivity of 78.79%, which shows the potential of transfer learning with GraphNet for identifying small lesions in PET/CT scans. This approach may also help to detect radiation-induced complex lesions, offering valuable insights for treatment monitoring.

Keywords: Lung cancer; Deep learning; PET/CT; Transfer learning; GraphNet

1 Introduction

Lung cancer stands as one of the most lethal malignancies worldwide, highlighting the critical importance of early tumor detection in its early stage. The integration of ^{18}F fluorodeoxyglucose with the valuable imaging modality positron emission tomography/computed tomography (^{18}F FDG PET/CT) is one of the most successful imaging in lung malignancy detection. The radioactive nature of the ^{18}F FDG radiotracer necessitates consideration of radiation protection protocols to minimize potential risks to both patients and healthcare providers and also the development of automated procedures for diagnosis [1]. Due to the prevalence of pulmonary lesions, there is an increasing demand for approaches that guarantee both high sensitivity and efficiency in identification of FDG-avid lung lesion foci. It has been proven that artificial intelligence, specifically its application of deep learning, has yielded outstanding results in detecting lung-related malignancies using PET/CT images [2]. However, some significant challenges are present. First, limited PET/CT data availability often is a challenge for developing robust models. High computational costs, time-consuming training processes, and poor generalization are among the other challenges associated with fully training deep learning models. Additionally, there is a need to utilize a model capable of detecting small structures and patterns to identify the small size of lesions, which have the potential to develop into malignancies. In this case, transfer learning has proven to be a promising technique for using pre-trained models to address data scarcity, particularly in medical imaging applications. While valuable studies have explored transfer learning with PET/CT images [3-7], a notable drawback is the lack of employing a deep learning model specifically tailored to detect small and complex structures within the lung. In this study, we aim to detect lung lesions from ^{18}F FDG PET/CT images using transfer learning and GraphNet [8] for the detection of small lesions and complex patterns in the lung, as it addresses this critical gap in current research and holds promise for improved detection accuracy in PET/CT scans.

2 Materials and Methods

We used 60 ^{18}F FDG PET/CT images, including 30 lung cancer patients and those patients who had malignant lung lesions and 30 normal lung images. Patient preparation and image acquisition adhere to PET/CT imaging guidelines to ensure the attainment of high-quality images [9]. In this retrospective study, patients underwent 18F FDG PET/CT scans as their clinical examinations. The dataset was pre-processed by cropping and resizing all images to a standardized dimension of 120 x 120 x 80. Subsequently, PET and CT images were co-registered, and for more accurate results, lung areas were accurately segmented from the both PET and CT images using Python-based code (Figure 1). The transfer learning process using GraphNet involved using a pre-trained deep learning model trained on a comprehensive dataset of similar ^{18}F FDG PET/CT images. In this study, the last layers of the deep learning model used in full training were frozen to facilitate transfer learning, allowing the model to adapt its knowledge to the specific characteristics of the lung cancer dataset.

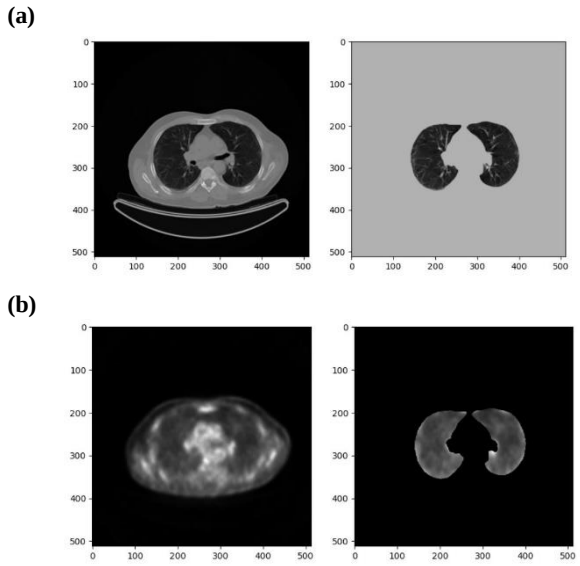

Figure 1. (a) Original CT scan and segmented lung, (b) Original PET scan and segmented lung.

3 Results

Statistical results showed the capability of transfer learning for lung lesion detection. The performance of the proposed approach revealed an impressive accuracy rate of 82% in correctly detecting lung lesions. We reached a sensitivity of 78.79%, showing the proportion of true positive identifications relative to all actual positive cases. The specificity of the present approach was 85.19% for lung lesion detection that indicates the proportion of true negative identifications relative to all actual negative cases.

4 Discussion

The results of the study demonstrate promising outcomes of using transfer learning with GraphNet for the detection of lung lesions, specifically small lesions, in ^{18}F FDG PET/CT images. By leveraging pre-existing knowledge from a large dataset of similar images, the model can adapt its understanding to the specific characteristics of the lung cancer dataset, leading to enhanced diagnostic performance. This capability could extend to detect radiation-induced lesions or changes in tissues affected by radiation therapy. For example, the model could potentially aid in identifying the impact of radiation on lung injuries or changes in tumor metabolism post-radiation therapy, enhancing the ability to monitor treatment response and assess treatment-related complications.

5 Conclusion

This study sheds light on future investigations, suggesting that transfer learning using GraphNet can be a valuable tool for optimizing small and complex tumor detection in cases where data scarcity poses a significant challenge.

Abstract Anatomical changes during radiotherapy can make highly conformal treatment plans, calculated on pre-treatment anatomy, sub-optimal or unsafe to deliver. Daily images of patients are evaluated against the treatment plan to evaluate delivery. Where delivery is deemed unsafe, re-planning will occur which, in a reactive workflow, can draw finite resources from elsewhere or may cause delays in patient treatment. In this work, we present the first use of a physics-informed convolutional recurrent neural network for longitudinal volumetric medical image data. This work aims to optimise the hyperparameters in our model for medical image data. The best performing model produced anatomical predictions at the next five treatment fractions with a mean squared error of 0.077 on images normalised between 0 and 1.

1 Introduction

Radiotherapy is delivered over a number of daily fractions. Throughout treatment, many patients will undergo changes to their anatomy, which can be systematic, for example weight loss, or random, for example rectal gas changes. Such changes can leave treatment plans optimised on a prior anatomical state sub-optimal to deliver. To ensure plans remain safe to deliver, they are evaluated on daily images, conventionally cone-beam CT (CBCT), taken prior to treatment delivery. If the plan is no longer considered suitable due to large anatomical changes, re-planning will occur. In a reactive workflow, this can draw limited resources from elsewhere [1]. Ideally, resources should be pre-allocated for a planned re-optimisation of the treatment plan. However, to enable this, we need workflows that can identify which patients and when anatomical changes are likely to manifest. This will allow efficient ahead-of-time resource allocation to reduce the clinical support and workflow disruption currently required for adaptive radiotherapy (ART).

To address this, we have drawn on machine learning methods originally deployed for analogous tasks in precipitation forecasting [2][3] and video frame prediction [4]. We adapt these frameworks and implement the first example of a physics-informed convolutional recurrent neural network (CRNN) to be used on longitudinal volumetric medical image data. Our example uses the daily CBCT images for head-and-neck cancer patients, predicting anatomy five treatment sessions into the future.

Adopting approaches shown to be successful outside of radiotherapy can help drive research into developing clinically beneficial machine learning applications, but every domain comes with its unique challenges. To implement image-based machine learning methods for clinical use, they must be adapted and optimised for medical image data. For novel approaches, the optimal design choices may not be well documented, and grid or random searches when tuning many hyperparameters may be prohibitively time intensive. This is particularly true of generative tasks using large models to handle complex data sets which may take days to train. In this study, we present our optimisation workflow to select appropriate hyperparameters for generative machine learning approaches to produce forecasts of volumetric longitudinal medical image data by aggressively pruning low performing models.

2 Materials and Methods

For this study we used an in-house data set, with ethics approval from ukCAT, a research database established at The Christie NHS Foundation Trust. It consisted of 427 series of 10 CBCT daily scans, totalling 42700 3D CBCTs, with a voxel spacing of 1 x 1 x 1 mm. CBCTs were acquired with standard in-house settings of 100 kV and 16 mA using ELEKTA XVI version 5.52. The maximum temporal gap between consecutive scans is 3 days, consistent with a break in treatment over a weekend. Each series of CBCTs was normalised to the associated planning CT. First by rigid registering of each CBCT to the planning CT using a match clip box around the vertebrae. Then secondly we used the brainstem contours to define a region used to normalise the image signal on the CBCT to the CT. The brain stem was chosen due to its centrality and consistent signal. During pre-processing for the CRNN, the image signal was normalised between 0 and 1.

2.1 Model

The CRNN architecture used in this work combines convolutional neural networks (CNNs), which effectively model spatial relationships in image data, and recurrent neural networks (RNNs), which are designed to handle temporal relationship in longitudinal data. The architecture used in this study is based on the ConvLSTM introduced by Shi et al [2], a CRNN able to more effectively model long range tempo-

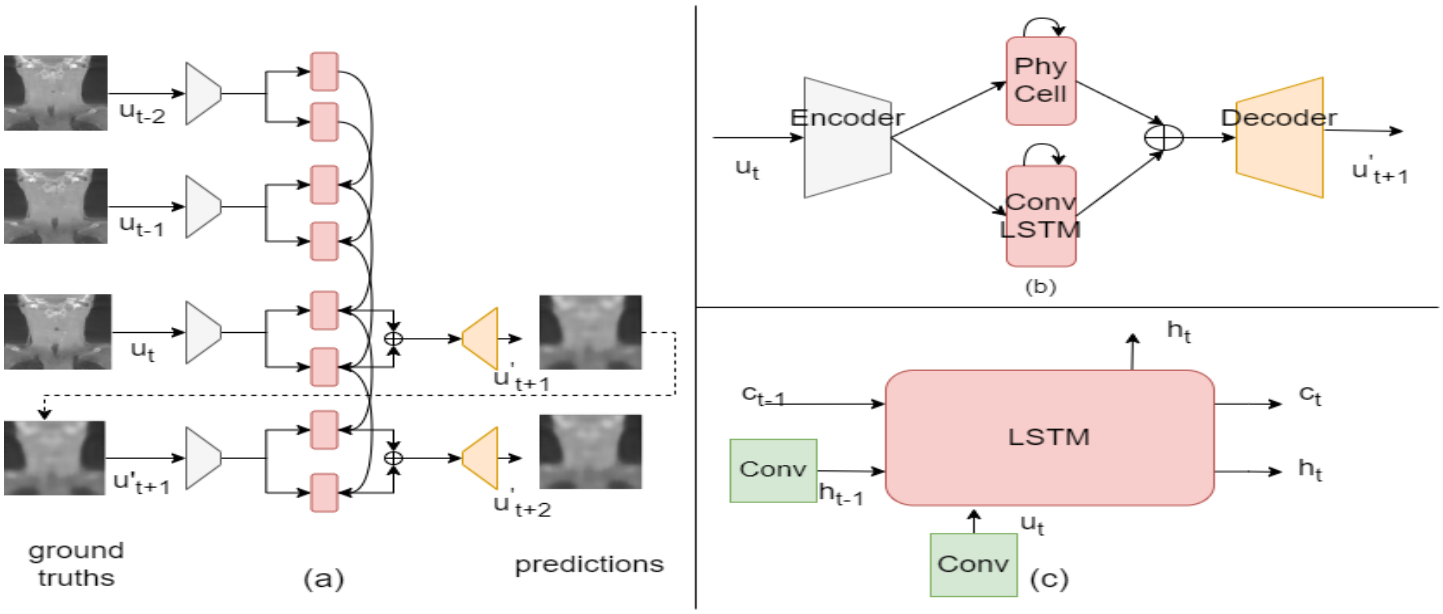

Figure 1: A schematic of the architecture employed in this work. (a) depicts the sequence to sequence architecture, unfolded in time. u_t represents the and input a time t and $u^{'}$ terms represent predictions that are also used as inputs for the proceeding time step. Arrows represent the flow of information both through the network and through time. The dashed line indicates that the input is only passed to the ConvLSTM. (b) shows the recurrent PhyCell which models physical dynamics in input data and the ConvLSTM cell, more closely examined in (c), which uses the cell state, c, to control the flow of information longitudinally through the network, also outputting the hidden state, h both as a prediction and as an input to the next layer.

ral dependencies, and the PhyDNet introduced by Le Guen and Thome [5], which employs a parallel-branch approach to encode PDEs into the model which constrain outputs to a physically plausible region. The ConvLSTM constitutes one of the branches of the PhyDNet, which is turn is part of a sequence-to-sequence model, taking 5 consecutive daily CBCTs as an input, and generating the next 5 CBCTs in the series. The generated images are compared to ground truths to measure prediction accuracy. A schematic of the architecture is displayed in Figure 1.

The final model was implemented using PyTorch Lightning 2.0.1 [6] and has 691M parameters. All training was performed on a 24GB NVIDIA GeForce RTX 3090 Turbo and an AMD Ryzen 7 3800X 8-Core Processor. With 42700 volumes, 21GB of RAM was required.

2.2 Optimisation workflow

Exhaustively tuning all hyperparameters by selecting a range of values for each and producing models for every combination would represent the most comprehensive examination possible. This would, however, be prohibitively time consuming. When making a grid search of the hyperparameter space, a large number of hyperparameters can quickly increase the time and computational resources required. The number of runs can be expressed by

$$\#(n_1 \cdot n_2 \cdot \ldots \cdot n_{n_{trials}}) \quad (1)$$

where n_1 is the number values a hyperparameter can take for a single trial and n_{trials} is the number of trials. Instead, hyperparameter tuning was split into six "phases" with the greatest conditional relationships, and were conducted consecutively. Within each phase, multiple trials are conducted and within each trial one or multiple hyperparameters are optimised. The best performing value is then used for all subsequent tuning. Simultaneous or isolated optimisation is chosen depending on the interdependence between hyperparameters. Where possible, we have tried to avoid simultaneous training to keep optimisation time to a minimum. Initial configuration for the hyperparameters are taken from PhyDNet and are updated with the tuned value at the end of each trial. The trials are detailed in Table 1. We select a range of values which feature in literature describing approaches to analogous tasks, both within and beyond radiotherapy.

Each trial involved training multiple models with each hyperparameter configuration, and was conducted using 100 sequences (roughly one quarter of the data set) for 80 training epochs. The 100 sequences were split 70/20/10 for training, validation and test sets, and the mean squared error (MSE) of each model was evaluated on the test set and is used as the trial result. Trials were conducted using the Tune [7] library, allowing for all model training to be scheduled in advance and run consecutively.

At the end of each trial, the optimised hyperparameter value(s) are noted and the five best performing model configurations were selected for full training using all 427 sequences, again split 70/20/10, for 300 epochs. The performance of the more extensively trained model was then compared to the corresponding optimisation trial model to investigate whether choices made to improve the accuracy of trial models corresponds to improved accuracy in fully trained models.

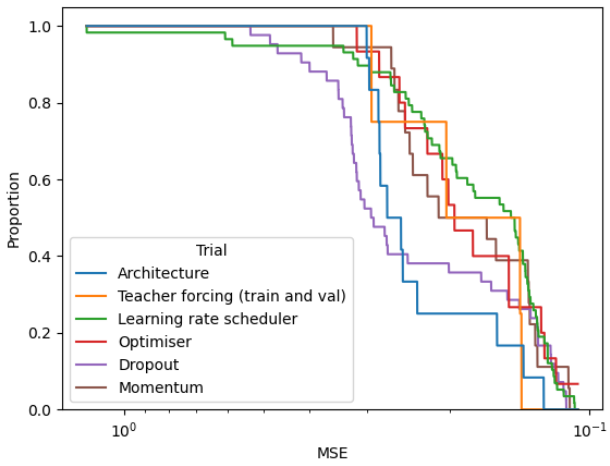

Figure 2: The proportion of six groups of hyperparameter-investigating experiments for MSE values between 1 and 0.1 (horizontal axis decreases to the right). A lower MSE (further to the right) indicates better performance, with flatter curves indicative of a greater mix of suitable and poorly performing hyperparameter options.

Hyperparameters with well documented optimal values were not tuned further.

3 Results

Using our methodology, the tuning of the hyperparameters presented here was conducted in a training time of 340 hours. Applying Equation 1 to the six trials presented here would require 32400 hours.
An example of the input, ground truths and predictions of the network is displayed in Figure 3.

3.1 Hyperparameter tuning

The MSE of all predictions made by models used in eight tuning experiments evaluated on a test set is displayed in Figure 2. Each model produced during this stage required around 2.5 hours to train. The best performing model achieved an MSE of 0.103. Other loss functions were investigated, but using MSE produced the highest accuracy and most consistent training. The best performing values for the eight most influential hyperparameters are displayed in Table 1. Where differences in accuracy could not be determined, all possible values are provided. The proportion of models reaching MSE thresholds, grouped by phase, is displayed in Figure 2.

3.2 Full training

Each model produced during this stage required around 40 hours to train. Of the five model configurations selected for full training, the lowest MSE was 0.0766, and the highest was 0.1637. Three showed an improvement on the corresponding model produced during optimisation trials, one showed

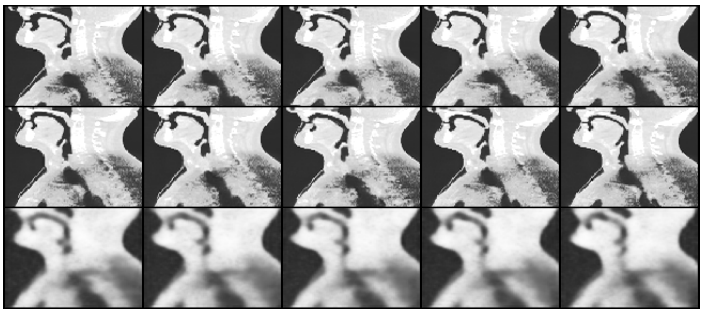

Figure 3: An example of the input to the network (top row), the ground truths (middle row) and predictions (bottom row) of the network. Each prediction is compared to the corresponding ground truth to calculate the loss, which is MSE during training.

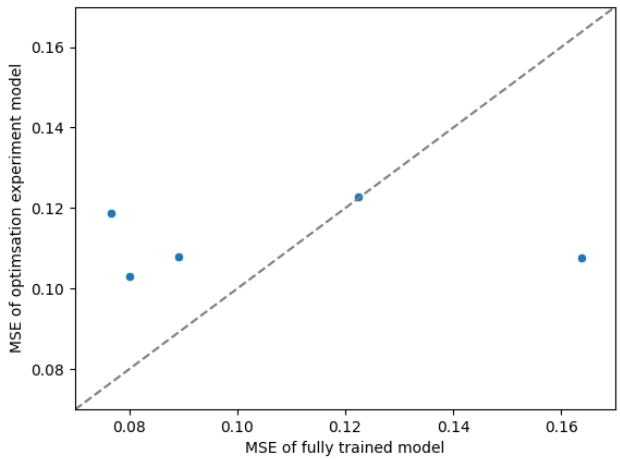
Table 1: The value(s) of eight influential hyperparamter in the top five performing models during optimisation.

Hyperparameter	Best experimental value(s)
Number of layers/nodes per layer (PhyCell, ConvLSTM)	[512,512,512,512,512,512,256, 256,128,128,64,64],[729,729]
Dropout (Encoder-Decoder, PhyCell, ConvLSTM)	0.1, 0.1, 0.25
Teacher forcing (train, validation)	-1% per epoch, -1% per epoch
Optimiser	RMSProp
Momentum (for RMSProp)	0.4
Starting learning rate	1×10^{-4}
Learning rate scheduler	ReduceOnPlateau CosineAnnealingLR+decay
Learning rate reduction factor	0.5

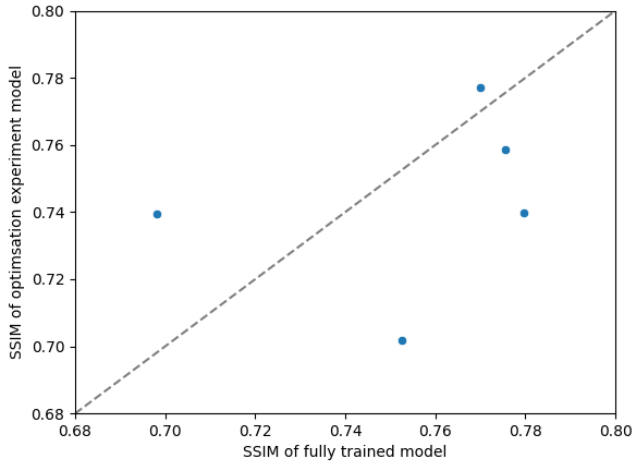
almost identical performance and one showed an reduction in prediction accuracy. A comparison of model performance between short and full training for the top five model configurations is displayed in Figure 4 using MSE and the structural similarity index measure (SSIM).

4 Discussion

In this study, we presented a physics-informed CRNN approach to predicting gross anatomical changes in HN patients being treated with radiotherapy. This represents the first time a physics-informed CRNN had been optimised for such a task. We outlined our methodology for optimising a machine learning model that has been adopted in other fields specifically for longitudinal radiotherapy data, and presented 8 key hyperparamater choices. The significantly shorter training time required to tune the model, compared to an exhaustive exploration, represents a reduction in the computational resources required to optimise the model, and increases the number of approaches that can be investigated in a given time frame.
Four of the five fully trained model configurations performed as well, or improved upon their corresponding trial models, providing evidence that the optimisation performed on subsets of the data for less training time is applicable to models trained for longer on full data sets, and only one of the models



(a)



(b)

Figure 4: A comparison of the MSE (a) and SSIM (b) for the fully trained models (horizontal axis) against the MSE for the corresponding hyperparameter configuration in the optimisation experiment (vertical axis). Points in the top left portion for MSE and in the bottom right for SSIM represent instances where the fully trained model outperforms the model produced during tuning.

showed a reduction in prediction accuracy. A possible explanation for the reduced prediction accuracy is over-fitting, despite hyperparameters associated with dropout and regularisation being optimised. This could indicate that the proposed workflow may not be valid for all hyperparameters, particularly those aiming to reduce over-fitting. Further work to better select hyperparameters used to reduce over-fitting may be required to guarantee robustness to over-fitting, where the effect may become more acute with a greater number of training epochs.

It is also important to consider that, as investigated hyperparameters are frozen after each trial, it is possible that the path selected may have left optimal parameter choices out of the testing pool. Whilst our approach attempts to mitigate this by combining related hyperparameters and deliberately ordering trials, these decisions are dependent on the workflow designer and may, themselves, not be optimal. The trade-off between speed and intensity of optimisation should be considered by the architect of the model.

The optimisation of the PhyDNet to medical image data does improve prediction accuracy, however, the uncertainty in anatomical predictions is not yet suitable for use in clinical predictions. Future work will examine any non-analogous aspects of intended use cases for PhyDNet and anatomical change due to radiotherapy. One such difference may be that the longitudinal data produced during treatment is not uniformly temporally spaced as it is for the frames of a video, increasing uncertainty in the predictions. We are currently working on adapting the network architecture to handle time-dependent inputs.

5 Conclusion

We have implemented an aggressive pruning workflow to optimise the novel use of a physics-informed CRNN on volumetric longitudinal medical image data using a series of small, ordered model training experiments. The optimisation improved the model performance compared to the baseline model published for use on similar tasks and predictions of patients' future anatomy up to one week were produced, taking around two weeks of training to complete. However, hyperparameters that dictate model performance more heavily at later training epochs may not always be able to be tuned using this workflow. We demonstrate a significant reduction in the time and computational resources required compared to a grid search, providing hyperparameter values for training large models.

i-SART: A Prototype AI-based Tool to Enhance Patient Safety in Radiotherapy

Anastasia Sarchosoglou[1], Natalia Silvis-Cividjian[2], Yijing Zhou[2], Periklis Papavasileiou[1], Athanasios Bakas[1], and Evangelos Pappas[1]

[1]Department of Biomedical Sciences, Radiology & Radiotherapy Sector, University of West Attica, Athens, Greece
[2]Department of Computer Science, Vrije Universiteit Amsterdam, The Netherlands

Abstract In the complex field of radiotherapy (RT), ensuring patient safety is crucial. Risk management is a valuable tool for aiding RT departments in achieving this goal by systematically addressing hazards in their systems. Disseminating information about potential failures has been recognized as paramount to improving patient safety globally. This paper presents i-SART, a novel web application that aims to facilitate proactive risk management and share knowledge about potential failure modes (FMs) in a timely and efficient way. Based on the Failure Modes and Effects Analysis (FMEA) methodology, i-SART features a database of 419 FMs. The innovation lies in the integration of AI techniques that engage RT professionals in an interactive learning process by generating discussions about potential failures and safety measures. The web application is a work in progress and will be released soon for user evaluation. We anticipate i-SART to effectively promote proactive learning in FMs, enhance patient safety, and pave the way for advanced AI-based risk management in RT.

1 Introduction

In the ever-evolving landscape of radiotherapy (RT), where precision is paramount, ensuring patient safety is crucial. The meticulous approach required in RT demands a comprehensive strategy to mitigate potential risks and enhance the overall safety in the patient pathway.

In RT, stringent safety standards and robust measures govern the use of radiation. Although accidents are rare, errors may occur at various stages, occasionally compromising clinical outcomes. The International Commission on Radiological Protection (ICRP) underscores the potential risks, especially those associated with new technologies [1].

To minimize the risk of failures and prevent unintended exposure, the implementation of risk management in RT has been regulated in many countries [2, 3], utilizing both reactive and proactive methodologies. Reactive risk management employs Incident Learning Systems (ILS) to collect and analyze adverse events, errors, or near misses. Notable international and national ILS, such as SAFRON (SAFety in Radiation Oncology) [4], ROSEIS (Radiation Oncology Safety Education and Information System) [5], and RO-ILS (Radiation Oncology-Incident Learning System) [6], provide valuable insights about incidents to the RT community. Proactive risk management involves the implementation of systematic methods that assist organizations in managing their weaknesses by identifying and addressing potential failures before they occur [7].

Approaches used in RT include Failure Mode and Effects Analysis (FMEA) and its variations, such as Failure Mode and Effects Criticality Analysis (FMECA) and Healthcare Failure Mode and Effects Analysis (HFMEA), as well as other methods like Fault Tree Analysis (FTA) [7], Hazard and Operability Analysis (HAZOP) [8] and the Systems Theoretic Accident Model and Process (STAMP) [9, 10].

Although many departments have successfully implemented proactive risk management, others face challenges due to limited knowledge of assessment methodologies and a lack of resources. Moreover, proactive risk management involves forward-thinking, focusing on identifying and preventing potential hazards before they manifest, which is particularly challenging especially when implementing new technologies or techniques. The World Health Organization's (WHO) Global Action Plan for Patient Safety (2021-2030) [11] emphasizes the proactive identification and mitigation of risks in healthcare, aiming to enhance patient safety. It calls for the dissemination of such knowledge, yet the vast majority of knowledge about potential risks is not disseminated and remains compartmentalized within the departments. While national and international ILS provide learning about incidents post-occurrence, there is no similar platform that promotes proactive knowledge before potential failures turn into errors.

Our research aims to bridge this gap by developing a web application, the i-SART, an Intelligent Safety Assistant in RT that facilitates proactive risk management and enhances patient safety awareness. Central to this effort is a database that gathers a large number of potential failure modes (FMs) defined as the ways or modes a process or system can fail. Innovative to our approach is the integration of AI techniques that engage RT professionals in an interactive learning process about FMs and safety measures. The advantage of i-SART is that knowledge about potential failures can be disseminated in a timely and efficient way, worldwide. We envision i-SART as a free-to-access tool for all RT users fostering collaboration and future improvements. This is a collaborative effort between the Faculty of Biomedical Sciences of the University of West Attica and the Faculty of Computer Sciences of Vrije Universiteit Amsterdam and is a work in progress.

2 Materials and Methods

Design of i-SART

The design of i-SART was based on FMEA methodology, selected for its ability to yield both qualitative and quantitative results. In an FMEA process study, a dedicated team identifies FMs, along with their causes and effects. The team assesses the FMs in terms of their likelihood of occurrence (O), lack of detectability (D), and potential severity (S). This evaluation aids in prioritizing FMs for implementing risk mitigation strategies.

I-SART used the seminal report of the American Association of Physics in Medicine (AAPM), the AAPM TG100

[12], as a benchmark. This report was developed as a proactive risk management FMEA-based methodology specific to RT.

Initially, we created a process map that depicts chronologically the sub-processes and their steps within the main RT process. The i-SART process map includes 8 sup-process and 61 steps.

1. Patient Assessment / Initial Consultation (13 steps).
2. Scheduling procedures (4 steps).
3. Imaging for RT planning (14 steps).
4. Treatment planning (TP) (10 steps).
5. Pre-treatment QA procedures (3 steps).
6. Treatment session (10 steps) (Fig. 1).
7. On-treatment quality management (4 steps).
8. Post-treatment procedures & Follow-up (3 steps).

Additionally, the specific procedure of the advanced technology/technique MR-guided adaptive RT (MRgART) was separately mapped in 12 steps.

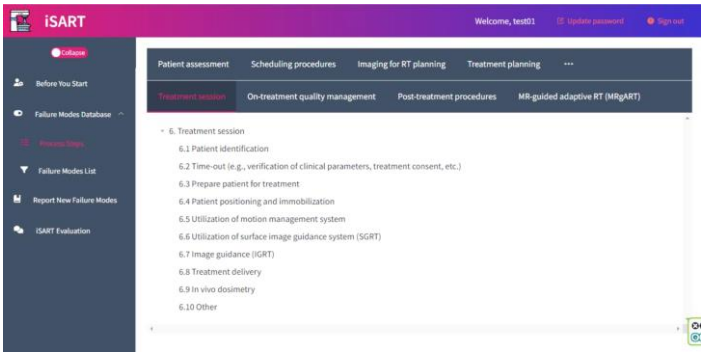

Figure 1: Sample of i-SART interface showing the steps in the treatment session sub-process.

At each step, the collected FMs (as described in the results section), their severity, causes and effects, and mitigation strategies were stored in the database. To ensure a harmonized severity (S) across all selected FMEA studies, we created a modified scale in the form of traffic lights for ease of visualization (Fig. 2).

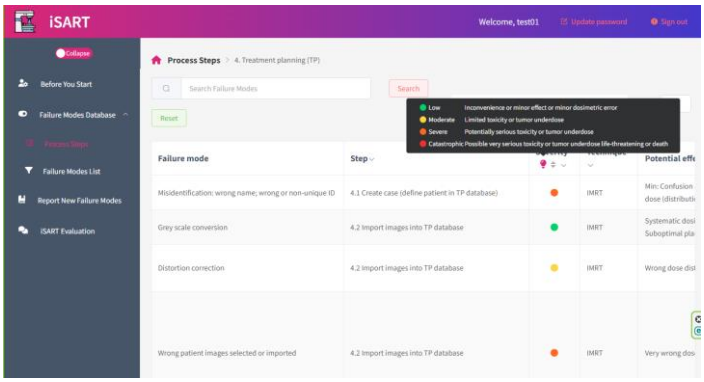

Figure 2: Sample failure modes within the treatment planning sub-process, indicating their severity using a traffic light format.

Data collection

Our research included a sample of FMEA studies that met our eligibility criteria: diversity in external photon beam RT techniques, country representation, studies conducted in English, and the provision of sufficient data to align with our design's objective of offering comprehensive information on FMs.

Technical Description i-SART

Technically, i-SART is a cloud-hosted web application with two user roles: administrator and user, each having distinct interfaces and data accesses. The administrator, who is an RT expert, manages the system and the application database.

The back-end of the web application was developed using Python 3.9 and the Django REST framework. Secure information transfer between client and server was ensured through JSON Web Token authentication. A relational database MySQL, was chosen for persistent storage of user and FM information.

The user interface of i-SART was created using Vue.js, a JavaScript based framework. FM search, filtering, and sorting functions are available. There is also an option for the user to insert in the database a new FM validated by the i-SART administrator. The administrator can also monitor statistics on FMs in various charts. Additionally, all users can evaluate the tool and provide comments and suggestions for improvement. The general workflow of i-SART is shown in Fig. 3.

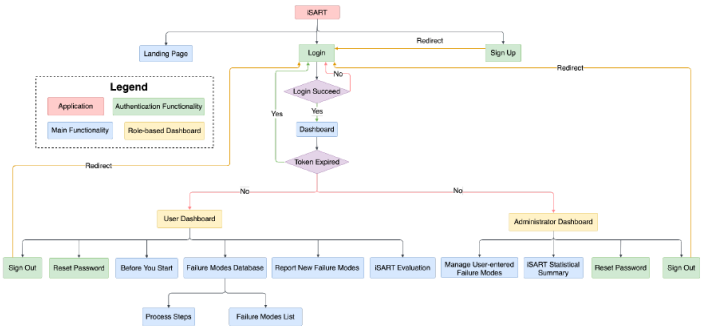

Figure 3: The general workflow of i-SART.

Experimental work on synthetic FMs

To augment the database for potential future use in machine learning, we experimented with the possibility of generating synthetic (artificial) FMs using Generative AI (GenAI) techniques such as Hidden Markov Models, ChatGPT-3, and Generative Adversarial Network (GAN) [13]. Specifically, for GAN, we employed the seqGAN model [14] with a total of 2,305 records extracted from our FMs database and incident data from SAFRON [4] (Fig. 4).

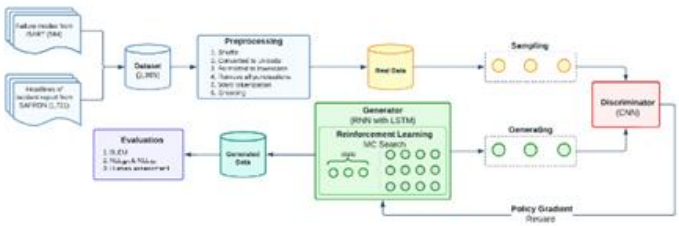

Figure 4: The architecture of the GAN-based synthetic FMs generation experiment.

Current work

We are currently working on integrating an AI tool, specifically a chatbot, into i-SART. This addition aims to elevate user interaction by generating engaging discussions about FMs. Users will have the opportunity to seek insights, clarification, and practical solutions based on white papers, seminal reports, and relevant literature, all within the i-SART. This feature not only promotes proactive learning but also serves as a valuable resource for users seeking timely and context-specific information.

3 Results

Initially, a total of 728 FMs were gathered from 10 FMEA articles and reports. The seminal AAPM TG100 report [12], which provides potential FMs in Intensity Modulated Radiotherapy (IMRT), served as the foundational source, Complementing this, seven articles were included that explored FMs in: RT process [15], 3D Conformal RT [16], lung Volumetric Modulated Arc Therapy (VMAT) [17], Surface Guided deep inspiration breath -hold (DIBH) breast RT [18], Stereotactic Radiosurgery/Radiotherapy [19] and MR guided adaptive RT [20, 21]. Additionally, data from two unpublished reports from the UK investigating breast VMAT and lung Stereotactic Body Radiation Therapy (SBRT) were incorporated.

To identify duplicate FMs across the articles and reports, we utilized a semi-automated approach, initially employing AI-based Natural Language Processing (NLP) algorithms. Results were subsequently manually reviewed by researchers to confirm duplications. We also merged common-ground FMs that included supplementary information while excluding ambiguous or insufficiently detailed FMs from our database. The total number of FMs in i-SART is currently 419 as illustrated in Fig. 5.

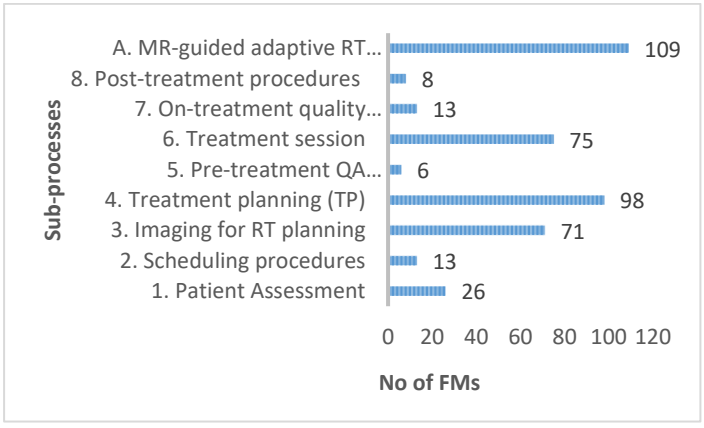

Figure 5: Number of FMs per sub-processes from 1 to 8. MR-guided Adaptive RT is indicated by the letter A.

Our experiments with GenAI to augment the FM database resulted in very few interesting and sensible new FMs, most probably due to the small size of the training dataset, which will hopefully increase, as i-SART will gain more users. The results were not incorporated into the database. However, these explorations lay the groundwork for potential future work.

We will soon release the application for user evaluation to assess its effectiveness and identify areas for improvement. We anticipate that users will contribute new FMs to enhance the database, fostering continuous growth and knowledge exchange.

4 Discussion

Proactive risk assessment within RT has garnered recognition as an essential tool for preventing incidents and errors. While national and international ILS offer valuable insights into lessons learned from past events, there is a noticeable gap in proactive learning on potential risks. Our research aimed to bridge this gap through the development of i-SART, an intelligent Safety Assistant in RT.

Built upon the FMEA and AAPM TG-100, i-SART takes a systematic approach to create a large database of potential FMs in RT process. The integration of an AI chatbot will further enhance user engagement by generating discussions about FMs and safety measures. Additionally, the tool provides a platform for users to contribute new FMs, promoting continuous knowledge exchange. It may also become useful for RT vendors by offering insights into potential risks based on real-world practice. Furthermore, i-SART has the potential to complement free–access ILS, contributing to an overarching approach to risk management for the wider RT community.

Acknowledging its limitations, i-SART currently does not encompass all existing techniques and technologies in RT, focusing on the most widely used ones. Due to the limited number of studies used, generalizations cannot be made, and the tool cannot be considered as a 'one-size-fits-all.' It is indicative and informative, prompting reflection on the user's practice while aiding in the identification and mitigation of potential risks promoting proactive learning.

Looking ahead, we anticipate i-SART to drive further innovations in integrating AI techniques and providing a substantial dataset for machine learning applications, FMs predictions and synthetic FMs generation while also encompassing other proactive risk management methodologies.

5 Conclusion

In this paper, a prototype of i-SART is presented, which is a web application designed to promote proactive learning in

patient safety in RT. By integrating AI capabilities and employing the FMEA methodology, i-SART provides a dynamic platform for proactive risk management. We anticipate i-SART to enhance patient safety awareness and facilitate valuable knowledge exchange, particularly crucial as new techniques and technologies continually emerge. Envisioning the continuous evolution of i-SART, our hope is i-SART to become an essential safety assistant in the hands of every RT professional.

Abstract Tumors decrease in size and change in shape with the progress of radiation therapy. Changes in tumor size are checked during treatment through Cone-beam Computed Tomography (CBCT). We predict CBCT based on deep learning using treatment plan information. A total of 376 data sets were used, and one data set was planning CT (pCT), dose map, RT structure, and CBCT. The study used a modified pix2pix model. Generator inputs are pCT, dose map, and RT structure, Generator output is predicted CBCT, and actual CBCT and predicted CBCT are distinguished through discriminator. In the PSNR, SSIM, and FID of the test sets, the averages were 10.03, 0.25, and 359.90, and the best performances were 14.11, 0.36, and 290.80. This study predicted tumor changes over the course of treatment using treatment plan information. Prediction of tumor changes can be used as a reference for when to change treatment plans.

1 Introduction

Radiation therapy (RT), a critical component in cancer treatment, varies in duration, ranging from as brief as 4 days to as extended as 30 days. Radiation therapy can cause changes in tumor morphology. The response of tumors to radiation therapy is influenced by a multitude of factors, including the tumor's initial size, the patient's unique physiological characteristics, and the type of concurrent chemotherapy administered. In [1], gross tumor volume (GTV) decreased by 24.7% in the first repeat computed tomography (CT) of lung cancer patients, and GTV decreased by 44.3% in the second repeat CT. Persisting with the initial treatment plan without accommodating these dynamic changes in tumor characteristics could potentially diminish therapeutic efficacy and inadvertently harm surrounding normal tissues. To address this, adaptive radiation therapy (ART) has been introduced, which considers these evolving tumor dynamics.

ART introduces an innovative approach by incorporating a planning CT (pCT) scan midway through the treatment process, enabling the re-establishment of the treatment plan. This revised plan is tailored to optimize treatment efficacy, taking into account changes in tumor volume and the patient's body during the course of therapy.

In a recent retrospective study, Hoppen, Lea, et al. [2] investigated the efficacy of applying daily online ART in patients with stage 3 non-small cell lung cancer. Their findings demonstrated significant improvements in local tumor control and a concurrent reduction in toxicity.

A notable advancement in this field is the Ethos™ (Varian Medical Systems, Palo Alto, CA), which facilitates treatment adaptation by generating new plans using in-device CT imaging and automated segmentation. However, this process is time-consuming, and the daily requirement for a new CT scan imposes a significant burden on the patient. In our approach, we leverage deep learning techniques to determine the most opportune moments for implementing ART.

In conventional ART methods, daily monitoring of tumor volume and anatomical changes is conducted using cone beam CT (CBCT) acquired during the treatment process. A new treatment plan is formulated when these changes are deemed significant. Our methodology utilizes RT structure, dose maps, pCT, and patient data derived from the treatment plan to generate CBCTs that correspond to treatment date alterations (Fig. 1). These generated CBCTs serve as viable substitutes for actual CBCTs in monitoring tumor size alterations and act as indicators for determining the optimal timing to establish a new treatment plan. Essentially, this implies that changes in tumor size can be preemptively identified using deep learning prior to administering radiation treatment.

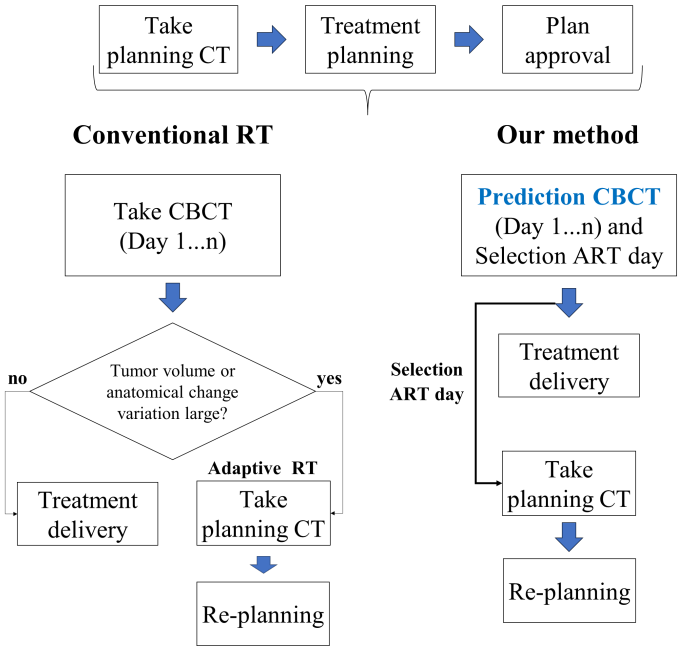

Figure 1. Comparison of the workflow of our method with a conventional radiotherapy workflow.

2 Materials and Methods

2.1 Dataset

The study protocol, including patient recruitment and data collection methods, was approved by the Institutional Review Board of the Samsung Medical Center (IRB number 2023-04-049-001), utilizing a retrospective data collection approach. Our dataset comprised data from 16 lung cancer patients treated at Samsung Medical Center. Among these patients, 9 underwent ART, resulting in a total of 25 treatment plans (16 initial plans, 9 adaptive plans) and 376 CBCT images. The treatment plan data encompasses pCT, RT structure, and dose map images. In the RT structure, only the Planning Target Volume (PTV) was utilized, and the dose map reflects the cumulative dose as of each treatment date. The treatment dates varied across patients, ranging from 5 to 20 days. Since a CBCT is acquired at each treatment session, the distribution of CBCTs corresponds to the treatment dates. For our analysis, three types of treatment plan images were used as input data, with CBCTs serving as the output data (Fig. 2).

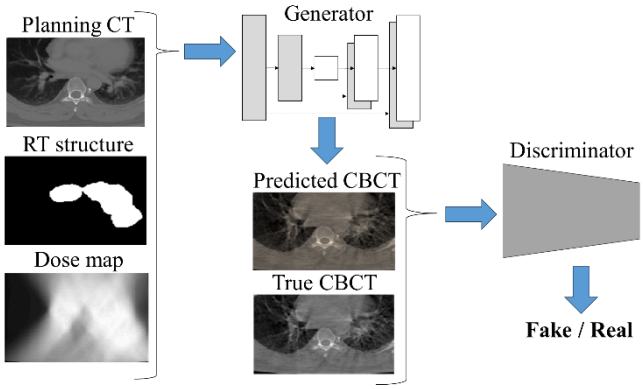

Figure 2. Deep learning-based CBCT prediction model.

2.2 Preprocessing

In the preprocessing stage, treatment plan data and CBCT were aligned at the same spatial location through image registration and then resampled to a uniform resolution of 256 x 256. For the z-axis, we selected 64 slices centered around the PTV. Subsequently, image cropping was performed to adjust the image size to 128 x 128 x 64, with a pixel size of 2.5 mm. The dimensions of the input data for our deep learning model were set to 3 x 128 x 128 x 64, while the output data size was maintained at 128 x 128 x 64. For testing purposes, the first day CBCT images of the 13 patients who underwent ART were used, and the remaining data served as the training dataset.

2.3 Network

For CBCT prediction, our model employs 'pix2pixCon', a variant of the 'pix2pix' framework, which itself is based on Generative Adversarial Networks (GANs). Pix2pix is widely recognized as an image-to-image translation model operating under the principles of conditional GANs [3]. The pix2pixCon model consists of two key components: a generator, responsible for creating CBCT images, and a discriminator, tasked with differentiating between generated and actual CBCT images. Notably, the generator in pix2pixCon adapts the modified U-net architecture, while the discriminator employs a multi-scale approach, utilizing both original and half-scale discriminators. The loss functions employed in this model include L1 loss, the Structural Similarity Index (SSIM), and cGAN loss. For optimization, the Adam optimizer was used, with a learning rate designed to decrease gradually as the training progresses.

$$Loss\ function = cGAN + L1 + SSIM$$

2.4 Evaluation

The results are evaluated through SSIM, Peak signal-to-noise ratio (PSNR), and Fréchet Inception Distance (FID) of actual CBCT and predicted CBCT. The ideal value, PSNR is the maximum value minus the minimum value, SSIM is 1, and FID is 0.

3 Results

Figure 3 visualizes the three central slices from the test dataset. While the predicted CBCT images appear somewhat blurrier compared to the actual CBCTs, they accurately replicate the CT's shape, including the tumor's morphology. The region of interest (ROI) difference effectively mirrors the tumor's Hounsfield Unit (HU) values seen in the actual CBCTs.

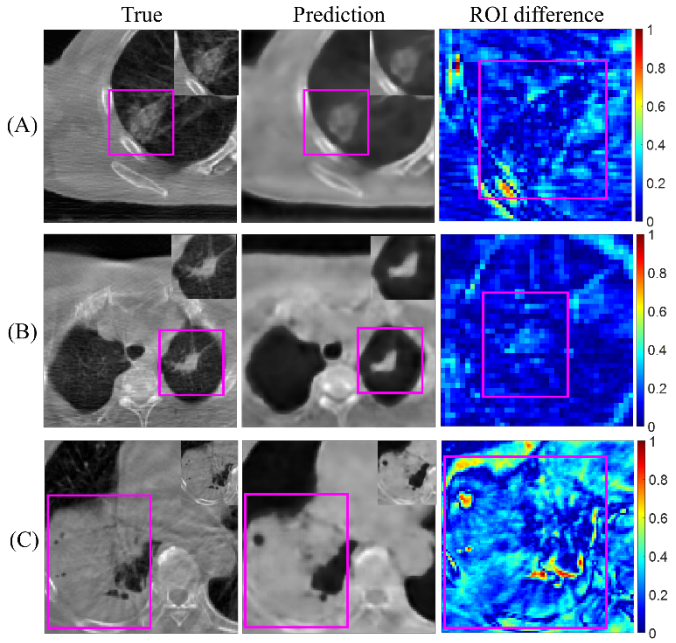

Figure 3. Comparison of predicted CBCT and true CBCT.

Table 1 presents the quantitative evaluation results for the entire test dataset. Among the cases, Case 9 exhibited the highest PSNR at 14.12. Case 1 scored the best in terms of SSIM and FID. However, it is noteworthy that none of the cases achieved values close to the ideal benchmark.

Table 1. PSNR, SSIM, and FID analysis results for the all-test case.

Case	PSNR	SSIM	FID
1	12.89	0.36	290.8
2	7.07	0.17	369.13
3	10.86	0.26	347.28
4	12.41	0.29	414.59
5	4.13	0.14	328.86
6	9.62	0.23	367.97
7	8.38	0.2	367.7
8	10.8	0.29	422.86
9	14.12	0.32	329.98
Mean	10.03	0.25	359.91
STD	2.95	0.07	39.38
Ideal	48	1	0

4 Discussion

In our study, we utilized treatment plan data and the pix2pixCon model to prediction CBCT images over the course of treatment. As illustrated in Figure 3, the predicted CBCT shape in Cases (A) and (B) closely resembles the actual CBCT, with a notably smaller ROI discrepancy in the tumor area compared to surrounding regions. However, in Case (C), characterized by a larger tumor size, a significant difference in ROI is observed. Our findings suggest that when the tumor shape is distinctly visible, the predicted image bears a close resemblance to the actual image. The efficacy of CBCT prediction using the pix2pixCon model hinges on selecting the appropriate tumor type. Despite similarities in overall tumor shape even in instances of large tumors, our results indicate a need for further model refinement and comprehensive data analysis.

Table 1 presents a comparative analysis of the performance metrics across the entire test dataset. It is evident from the data that in all cases, the PSNR and SSIM values did not surpass 50% of the ideal benchmark. Additionally, the FID scores are reported in the three-digit range. The evaluation includes not only the tumor but also the surrounding area. As can be seen from the ROI difference, there is a large difference in the area surrounding the tumor. If only the tumor area is compared, it appears that better results will be obtained.

Given that the efficacy of using predicted CBCT in actual treatment hinges on its congruence with the actual CBCT images, the SSIM, as an evaluative metric, holds significant importance. To enhance performance, it is imperative to consider modifications to the model's structure and to incorporate additional patient data.

This study is subject to certain limitations. As depicted in Figure 3, the diversity in tumor shapes poses a challenge; accurate prediction becomes difficult without training on a wide variety of tumor morphologies. Predominantly small-tumor datasets hinder our model's ability to accurately predict size reductions in larger tumors. Moreover, in cases where the tumor shape is indistinct, there is a risk of it being indistinguishable from the lung parenchyma. To overcome these challenges and enhance prediction accuracy, we aim to employ additional datasets and ensure a more balanced data representation in future studies.

Nevertheless, applying our research to ART could enable the prediction of tumor responses to radiation doses before treatment. This would allow for more precise dosing prescriptions and facilitate the implementation of patient-specific, customized treatments. Previous research has explored the use of time-series models like long short-term memory [4] and recurrent neural network [5] for predictive purposes. However, our study represents a pioneering effort in employing a generative model, specifically a GAN, for the prediction of radiation dose responses. This novel approach marks a significant advancement in the field by integrating dose information through a GAN model. Personalized Ultra fractionated Stereotactic Adaptive Radiotherapy (PULSAR) has recently shown excellent effectiveness in treating tumors along with immunotherapy [6]. The prediction of tumor size change in our study can be used as an indicator of tumor change for using PULSAR in actual treatment.

In this study, 9 CBCT images from the first day of ART treatment were employed as test data. These initial day CBCTs are hypothesized to closely resemble the treatment pCT, primarily because the treatment is conducted based on the previous day's plan information. Going forward, our plan involves using the predicted CBCT for formulating subsequent treatment plans and conducting ART treatments along with Dose-Volume Histogram (DVH) analysis. Additionally, we aim to elevate the quality of CBCT images, to the level of pCT by incorporating a deep learning-based image quality enhancement model. This approach will enable us to conduct a comprehensive analysis of the treatment plan and DVH for CBCTs across all treatment days, thereby establishing quantitative indicators to determine the most suitable dates for implementing ART.

5 Conclusion

This study predicted tumor changes over the course of treatment using treatment plan information. Prediction of tumor changes can be used as a reference for when to change treatment plans. Further study will improve the accuracy by increasing the number of data, develop better data processing methods, and refining the prediction model.

Abstract
A deep learning classification model was trained on 2D γ-maps to relate 2D γ-analysis to clinically relevant dose volume histogram (DVH) metrics for in vivo treatment verification using electronic portal imaging device (EPID) dosimetry. The aim of the model was to classify γ-maps into two categories: 'error' and 'no error'. It is hypothesized that it should be possible to detect 5% 3D dose differences with this method. Measured and predicted portal dose images for lung cancer patients were compared per beam using γ-analysis. Ground truth classification was based on DVH metrics derived from 3D dose recalculations on daily cone-beam CT. The γ-maps together with their corresponding label were used as input for convolutional neural networks (CNNs). Results showed that training performance was good, but indicated overfitting, seen by lower performance on the validation set. A ground truth classification based on exceeding clinical constraints for OARs resulted in the best performing model. This study showed that applying deep learning for relating 2D γ-results to DVH metrics has the potential for implementation of decision protocols in clinical practice, but the CNN architecture implemented here is unable to result in useful models.

1 Introduction

For lung cancer patients, anatomical changes during radiotherapy treatment can result in significant differences between planned and delivered dose [1]. In around 23% of lung cancer patients, anatomical changes such as pleural effusion, atelectasis, or a tumor shift occur at some point during the course of radiotherapy [2]. This high occurrence rate of anatomical changes (which could result in dose differences in target coverage of more than 5%), together with the complex nature of today's radiotherapy techniques, makes it essential to perform in-treatment, i.e. in vivo, verification of delivered dose to ensure treatment quality for the patient [3,4]. The electronic portal imaging device (EPID) has previously been shown to accurately and efficiently perform in vivo dose verification in 2D, 3D or even 4D [5-7].

Measured EPID doses can be compared to predicted/planned dose distributions using a gamma (γ) analysis. The result of this comparison is usually summarized in one or a few numbers, providing fast decision making based on fixed thresholds using gamma pass rate. However, this leads to loss of 2D and/or 3D spatial, dosimetric and time-resolved information. Several studies have shown previously that threshold-based methods have difficulty relating gamma pass rates to clinically used metrics such as dose volume histogram (DVH) values [8-11].

Artificial intelligence (AI) methods, more specifically machine and deep learning techniques, have been studied extensively, also for use in radiotherapy quality assurance (QA) [12-14]. These approaches use large amounts of (multidimensional) input data, and learn features from this data. Application of AI techniques to treatment verification data is promising, as the full gamma analysis result could be used instead of the condensed form. Focus has not only been on detecting treatment-related errors based on gamma analysis and corresponding gamma pass rate, but also on identifying the causes of these errors using deep learning (DL) methods [15-17].

In this study, a deep learning classification model is trained on 2D γ-maps, investigating the possibility to relate 2D γ-analysis to clinically relevant (changes in) DVH metrics for in vivo treatment verification using EPID dosimetry. This would eliminate the need for a 3D dose recalculation based on a either the planning CT, which is lengthy and time-consuming on itself, or on a cone-beam CT (CBCT), which might not always be present. Next to this, EPID dosimetry gives information on the dose delivery itself. The aim of the model was to classify the 2D γ-maps into two categories: 'error' and 'no error'. It is hypothesized that it should be possible to detect 5% 3D dose differences with this method.

2 Materials and Methods

2.1 Input data

EPID measurements from 3086 fractions of 363 lung cancer patients (380 unique treatment plans), treated with VMAT, were converted to portal dose images (PDIs) using in-house developed software [7]. Predicted transit PDIs were created based on the treatment plan and planning CT. Measured and predicted PDIs were compared per arc in a time-integrated fashion using γ-analysis with 5%/3mm criteria, resulting in 5844 2D γ-maps per set of gamma criteria. The γ-maps were clipped to -3 and +3, cropped using a 10% low dose threshold, resized to 128x128 pixels, and normalized using min/max normalization.

The full dataset was split into training (70%), validation/hyperparameter optimization (10%) and hold-out test sets (20%), with all images of one patient belonging to the same set. Next to this, 5-fold cross validation was also performed in the training and validation sets combined to evaluate model robustness.

2.2 Ground truth classification

The ground truth (GT) classification ('error' vs. 'no error') was based on DVH metrics derived from 3D Monte Carlo dose recalculations (XVMC, [18]) on daily CBCT images, including contour propagation from planning CT to CBCT using Mirada Workflow Box (Mirada Medical Ltd., Oxford, UK). Different GT classification methods (Table 1) were

implemented for both the organs-at-risk (OARs) and the clinical target volume (CTV), based on exceeding the clinical planning constraints as used during treatment planning. When this planning constraint was already exceeded in the treatment plan, the value of the DVH metric at start of treatment was used as action threshold. In this way, it is assumed that the dose should not deviate more than the planning constraint achieved. A fraction was classified in the 'error' class when one or more of the DVH metrics exceeded the specified action threshold, and in the 'no error' class when all DVH metrics were within the constraint. In Table 2, the number of fractions belonging to the 'error' and 'no error' classes for all of the GT classifications is shown.

Table 1 - Overview of the DVH metrics and their limits used in this work. Dmax values correspond to a volume of 0.03cc.

Structure	Metric	Limit
Clinical constraints OARs		
Lungs-GTV	D_{mean}	< 20 Gy
	V_{5Gy}	< 60 %
Heart	D_{mean}	< 10 Gy
	D_{max}	< 66 / 76 Gy[a]
Mediastinal envelope	D_{max}	< 66 / 76 Gy[a]
Esophagus	D_{max}	< 66 / 76 Gy[a]
Spinal cord	D_{max}	< 51.9 / 54 Gy[a]
Brachial plexus	D_{max}	< 66 / 76 Gy[a]
Absolute dose differences OARs		
Per OAR as specified above	ΔD_{mean}	> 2 Gy
	ΔD_{max}	> 5 Gy
Relative dose differences CTV		
CTV	$\Delta D_{95\%}$	> 2 %
CTV	ΔD_{mean}	> 5%
Combination CTV or OARs		
CTV	$\Delta D_{95\%}$	> 2 %
CTV	$\Delta D_{95\%}$	> 2 Gy
Per OAR as specified above	ΔD_{mean}	> 2 Gy
	ΔD_{max}	> 5 Gy

[a]*Different fractionation schemes: 24x2.75 Gy / 33x2 Gy*

2.3 Deep learning model

The γ-maps together with their corresponding GT label were used as input for convolutional neural networks (CNNs). The CNN consisted of multiple blocks of two convolutional layers and a max pooling layer. Rectified linear unit (ReLU) activation was used for all these layers. The exact CNN architecture and corresponding hyperparameters were optimized using Bayesian optimization [19]. Binary Cross Entropy (BCE) is the commonly used loss function in binary classification tasks. However, in this study, class imbalance was present and Sigmoid Focal Cross Entropy (SFCE) loss may be more suitable for binary classification in imbalanced datasets [20]. The performance of these two loss functions was compared. The Adam optimizer was used to optimize the model loss. The final fully-connected layer consisted of one single node with sigmoid activation, giving the output as a number between 0 and 1 as the probability that the input image belongs to the 'error' class. Early stopping was applied based on validation loss to prevent overfitting on the training set. Results of model training were evaluated using the area under the curve (AUC) of the precision-recall curve (AUC_PR).

Table 2 - The number of fractions per ground truth classification method belonging to the 'error' and 'no error' classes.

GT classification	# fractions in 'error' class (%)	# fractions in 'no error' class (%)
Clinical constraints OARs	1930 (62.5%)	1156 (37.5%)
Absolute dose difference OARs (ΔD_{mean} > 2Gy, ΔD_{max} > 5Gy)	1166 (37.8%)	1920 (62.2%)
Relative dose difference CTV $\Delta D_{95\%}$ > 2 %	1475 (47.8%)	1611 (52.2%)
Relative dose difference CTV ΔD_{mean} > 5 %	235 (7.6%)	2851 (92.4%)
Combination: CTV $\Delta D_{95\%}$ > 5% or CTV $\Delta D_{95\%}$ > 2Gy or OARs (ΔD_{mean} > 2Gy and ΔD_{max} > 5Gy)	1245 (40.3%)	1841 (59.7%)

3 Results

Results showed that training and validation performance of the CNN was good for the GT classification based on clinical constraints using a 5%/3mm γ-criteria, but also tended towards overfitting (Figure 1). SFCE as loss function showed better performance on the validation set compared to BCE as loss function. 5-fold cross validation results showed considerable overfitting on the training set.

Confusion matrices comparing GT DVH-classification with CNN-classification using SFCE as loss function and 5%/3mm γ-criteria are shown in Figure 2 for the training and validation sets. For the classification threshold of 0.5, it can be seen that the CNN classification results in a high number of false positives (i.e. a fraction is classified in the 'error' class, when the DVH classification is 'no error'), both for the training and the validation set. This number of false positives is lower when the classification threshold is optimized. However, still a significant number of fractions is wrongly classified.

For the other GT classifications shown in Figure 1 results showed moderate to bad performance, especially on the validation set. This shows that there is considerable overfitting of the models on the training set, leading to low AUC_PR values on the validation set.

4 Discussion

The results of this study showed that it could be possible to relate γ-maps and DVH metrics using a CNN, although there are still some limitations that need to be considered.

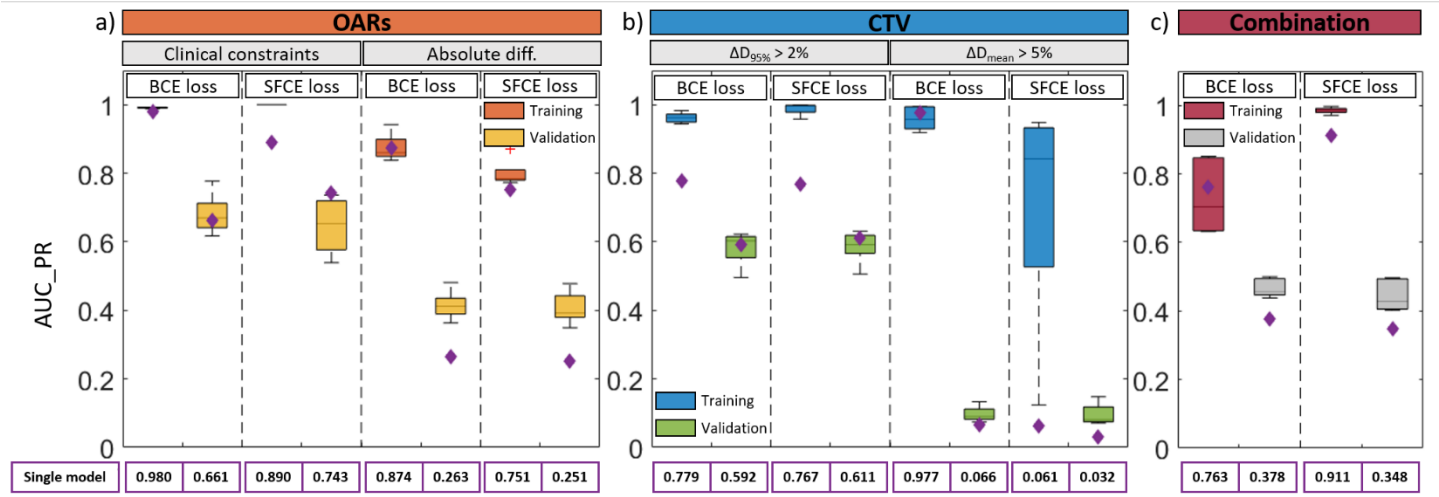

Figure 1 - Results of model performance on the training and validation set, shown here for the two different loss functions and only for the 5%/3mm γ-criteria. a) GT classification for the OARs, b) GT classification for the CTV, c) GT classification for the combination of OARs and CTV (as specified in Table 2). Model performance is presented in terms of AUC_PR for the single model as purple diamonds and for the 5-fold cross validation as boxplots.

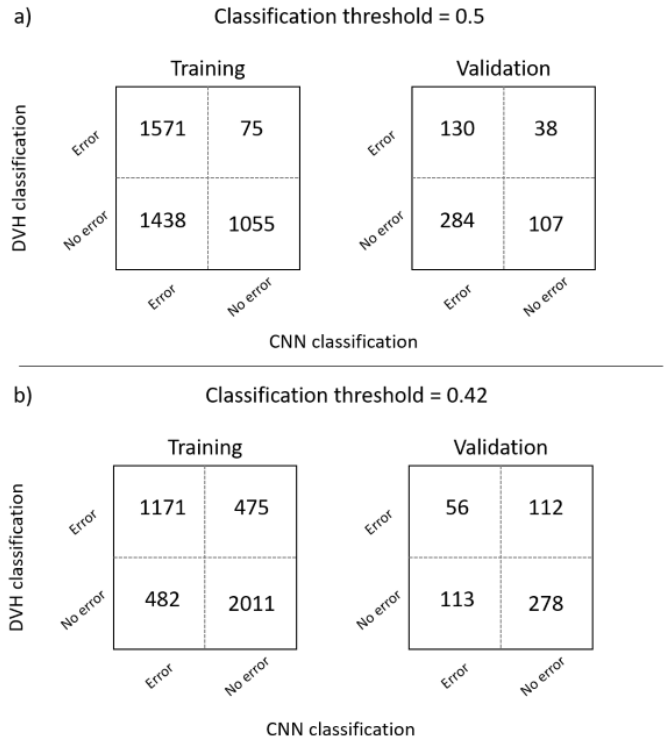

Figure 2 - Confusion matrices comparing the CNN-classification with the GT DVH-classification for a) the commonly used classification threshold 0.5 and b) an optimized classification threshold (0.42) based on equal precision and recall.

The performance of the models shown here was reasonably good on the training set, but lower on the validation set. This illustrates that overfitting on the training data occurred, even though early stopping was applied during the training process when the validation loss did not decrease any more for 20 epochs. Performance on an independent hold-out test set was not shown, but it is hypothesized that model performance would drop even further.

To prevent overfitting during model training, dropout regularization was already applied. The dropout fraction for the models shown in this study ranged between 0.1 and 0.5. This range shows also dropout fractions of relatively low numbers, indicating that the dropout as implemented currently did not improve the model training. Other methods to prevent overfitting could be considered, such as using a different, more complex network architecture.

In clinical practice, DVH metrics are commonly used to assess the dosimetric impact of anatomical changes and make clinical decisions. However, this process of decision making often remains subjective, depending on the preference of the radiation oncologist for a specific patient. In this study, several methods for GT classification into the 'error' class were implemented and tested. Using the clinical constraints appeared to be the method with the best-defined action thresholds, but a disadvantage of this approach is that large dose deviations may go undetected when the dose to a specific organ is still under the clinical constraint. Different approaches for GT classification with different thresholds were implemented in this study, e.g. relative dose differences for the clinical target volume or a combination between dose differences to the OARs and the CTV. However, these approaches did not lead to useful models compared to the hypothesis.

Next to using DVH metrics for GT classification, different approaches could be considered, such as biological metrics. Tumor control probability (TCP) and normal tissue complication probability (NTCP) might be more suitable, and it has been shown that dosimetric predictors of toxicity can be identified and can lead to clinically useful dosimetric thresholds [21].

Another limitation of this study is that the GT classification on DVH metrics is performed per fraction, whereas the PDIs are acquired per beam. Classification of these PDIs is thus also performed per beam, where each beam in one fraction received the same error/no error label. However, it could be possible that a dosimetric error would only be visible in one beam. Next to that, for VMAT arcs, the PDIs are a 2D summation over all angles used in the arc, blurring out the high dose region and penumbra. Consequently, dose differences can average out over the arc, resulting in no dose

difference in the PDI when there is a dose difference in a certain DVH metric. 3D measurements or even time-resolved EPID dosimetry might provide additional information that could improve the error classification. In a recent study, it was also shown that more simple dose comparison methods such as absolute or relative dose differences instead of gamma analysis could be a more optimal input for a deep-learning network to detect errors [22].

Multilabel classification was implemented using multiple output labels to try to further improve the CNN classification. Six of the OARs with their corresponding clinical constraints were used, and the final dense layer consisted of six nodes with sigmoid activation. However, evaluation results (not shown) were worse compared to the models reported here. There are also other deep learning approaches that might be more suitable for relatively small datasets, such as transfer learning. With this approach, a CNN that is trained on a different but large dataset, is used and only the last layers are retrained on the smaller dataset of interest. This approach has proven to be beneficial and useful for applying deep learning to small datasets [23]. This approach has been implemented in this study using a CNN trained to identify error types for lung cancer patients (evaluation results not shown), however this did not lead to higher AUC_PR scores [17]. More research is needed to study other models that could be used for transfer learning.

5 Conclusion

This study showed that applying deep learning for relating 2D γ-results to DVH metrics has potential for implementation of decision protocols in clinical practice. However, the CNN architecture implemented here is unable to result in useful models. More research is needed to prevent overfitting by looking into more complex network architectures or using different dose comparisons as input data.

Abstract Adaptive radiotherapy (ART) optimizes radiation treatment based on the changing anatomy and tumor during the treatment course. Current deep-learning prediction models do not fully utilize pre-existing ART information, which can result in a loss of physician/patient-tailored intents. To address this, we introduce a Multi-Headed U-net (MHU-net) that incorporates intents and compares it to a standard single-headed U-net (SHU-net). The MHU-net was trained to predict adaptive session dose distributions using data from the adaptive session as the primary head input and pre-plan as the secondary head input. We found high agreement between ground truth dose and MHU-net, resulting in a statistically significant reduction in MSE from 0.0048 (SHU-net) to 0.0038 (MHU-net) on 10 test patients (p-val = 0.006). In conclusion, our study demonstrates the feasibility of incorporating a pre-plan as the physician's preference for the patient to tailor the dose prediction further.

++++

1 Introduction

In the field of radiation therapy (RT) for head and neck (H&N) cancer, advancements such as intensity-modulated radiation therapy (IMRT) and Volumetric Modulated Arc Therapy (VMAT) have significantly enhanced treatment precision, creating highly conformal dose distributions on tumors [1,2]. However, these innovations often rely on plans derived from initial planning scans, overlooking factors that could accommodate structural and spatial changes during treatment. Studies have shown that patients often experience anatomical changes, encompassing factors like weight loss, muscle atrophy, or normal tissue edema, as well as tumor shrinkage, normal tissue reduction, and positional shift of certain structures throughout their treatment course [3,4]. These changes introduce uncertainties in physician-defined margins around target volumes, leading to larger irradiated volumes, heightened toxicity, and the risk of insufficient dose delivery to organs at risk, thereby diminishing treatment effectiveness and increasing the potential for side effects [5]. In response to this challenge, the innovative treatment paradigm of **Adaptive Radiotherapy** (ART) has emerged. ART is a revolutionary approach in radiation therapy, enabling the continuous adaptation of patients' treatment plans to accommodate changing anatomical conditions and reoptimizing the plan by adjusting target structures and organs-at-risk structures throughout radiation therapy [6]. This ensures accurate dose delivery to the target while minimizing radiation exposure to healthy tissues. ART adaptation provides a more personalized and effective treatment strategy, one that is specifically designed to address and adapt to the minimal changes that occur during treatment. Despite ongoing ART progress, the emergence of artificial intelligence (AI) and deep learning (DL) has been a notable development in recent years. In radiation therapy, DL-based dose prediction has garnered significant attention due to its potential to accurately predict entire dose distributions [7,8,9]. DL models can learn intricate patterns and relationships from vast data sets, allowing them to estimate radiation doses received by different areas of a patient's anatomy. However, a critical gap remains: current DL models for H&N dose prediction do not incorporate valuable pre-existing information provided by ART. This omission can result in the loss of essential physician and patient-tailored intentions, which are crucial for personalized treatment.

To address this challenge, we propose to incorporate the physician and patient-tailored intents using a Multi-Headed input U-net (MHU-net) and compare its performance with a standard Single-Headed input U-net (SHU-net) to assess the impact of these features on dose prediction accuracy and effectiveness. In leveraging these advanced architectures, we aim to bridge the gap between deep learning models and the valuable pre-existing information provided by ART. The stander U-net architecture has gained popularity in medical imaging tasks, such as dose prediction, due to its ability to capture image features at both global and local [10]. The MHU-net advances the U-net design by integrating multiple input heads, each tasked with predicting specific aspects of the dose distribution, thereby incorporating pre-existing information from ART and enabling the transmission of physician and patient-tailored intents to the next adaptive session.

2 Materials and Methods

2.1 HN cancer imaging dataset

We acquired H&N patients who were treated with ART on the Varian Ethos machine. Each plan consisted of important components such as CT scans, delineated contours of the planning target volume (PTV), 42 organ-at-risks (OARs) of interest, and the final approved plan dose. We had a total of 43 patients with 95 radiotherapy plans, which were divided into three groups: 30 patients for model training, three for validation, and 10 for testing purposes. Our dataset consisted of patient data that included both pre-plans and adaptive session plans.

2.2 Deep learning model architecture

The structural design of our model utilized the widely popular U-net network architecture as a baseline, named SHU-net. It consisted of an encoder on the left half and a decoder on the right half of its architecture. Building upon the U-Net structure with repeated 3x3x3 convolutions, rectified linear unit activations, four pooling operations, and spatial dropout at a rate of 0.1. In-depth details of our proposed MHU-net. model is depicted in Figure 1. The MHU-net incorporated the adaptive session's contours and a signed distance map of each contour as input into its primary head. Additionally, it utilized pre-plan contours, signed distance maps, and dose distribution as input into its secondary head, which then incorporated the data into the primary U-net. Finally, we utilized adaptive session data to predict the adaptive dose distribution. The MHU-net was trained to predict the adaptive session's dose distribution over 1000 epochs using an ADAM optimizer, with a learning rate of 0.001, and the mean squared error (MSE) as the loss function.

2.3 Evaluation

From these 10 patients, their ART treatment plans were withheld from training as the test dataset for the evaluation of dose prediction performance between the SHU-net and MHU-net models. SHU-net and MHU-net dose prediction was compared against the ground truth dose distribution as originally generated during the patient's course of treatment. Mean absolute percent error, as shown in equation (1), evaluated the dose differences between a model's prediction and the ground truth.

$$Mean\ Absolute\ Percent\ Error = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{D_{GT}-D_{Predicted}}{D_{Highest\ Prescibtion}}\right| * 100 \quad (1)$$

Furthermore, we conducted a detailed evaluation of the highest dose PTV, including parameters such as D95%, D98%, D99%, and homogeneity as shown in equation (2).

$$Homogeneity = \frac{D_{2\%}-D_{98\%}}{D_{50\%}} \quad (2)$$

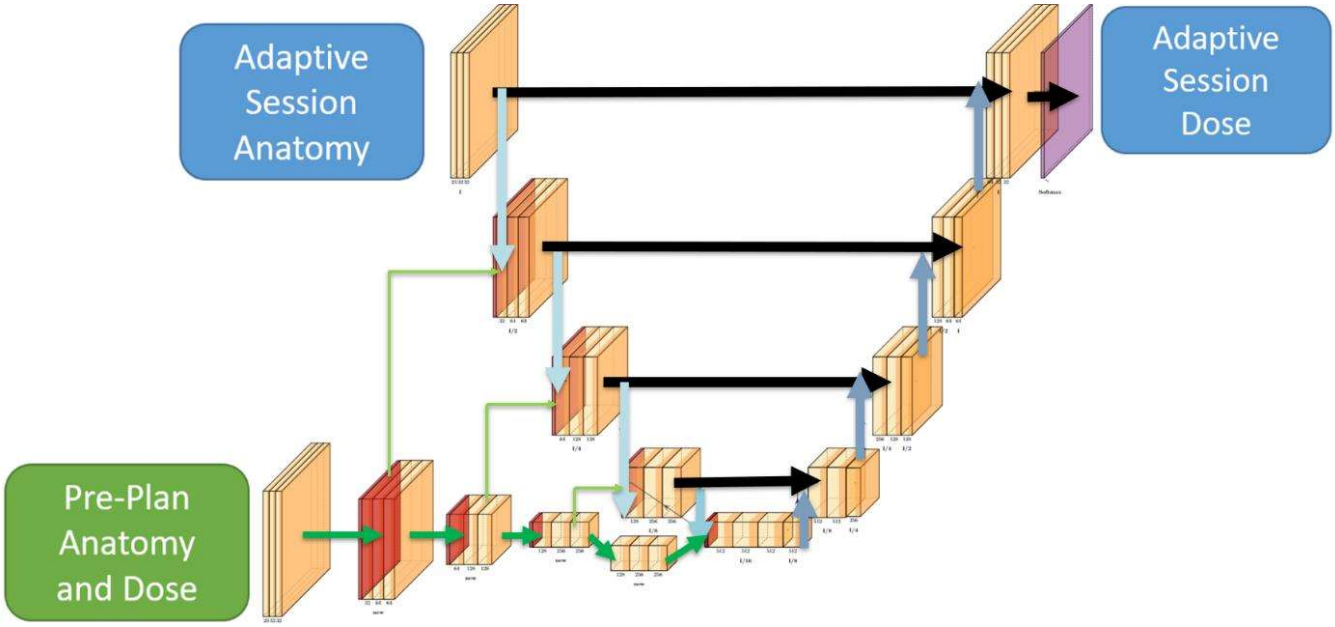

Figure 1: Multi-Headed U-net Architecture. The primary head processes adaptive session contours and signed distance maps during the contracting path to the bottleneck, indicated by light blue arrows. Simultaneously, the secondary head takes pre-plan contours, signed distance maps, and dose distribution as input, following the green arrows to the primary head and the bottleneck. The final step is to predict the adaptive session dose.

3 Results

3.1 Results of Dose Wash and Dose Volume Histogram

In Figure 2, an illustration of a dose wash from test patients is presented. The left columns display the ground truth clinical dose, while the subsequent columns exhibit the dose predictions generated by the SHU-net and the MHU-net, respectively. Upon careful analysis, it is evident that the MHU-net's predicted dose distributions closely correspond with the ground truth planned dose distributions, showcasing uniformity in various trade-offs between the PTV and OARs. Particularly noteworthy is the closer alignment observed between the predicted (dotted) and ground truth planned (solid) DVH lines for the PTV and OARs prediction in comparison to the SHU-net prediction line (dotted), as depicted in Figure 4. It is worth mentioning that the SHU-net forecasts lower doses on the inferior aspect of the brain and the left side of the shoulder compared to the MHU-net.

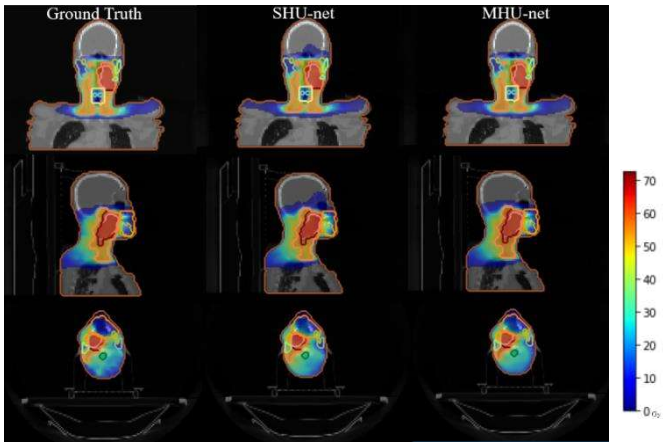

Figure 2: The dose washes of a representative patient from the test pool. The color bar represents the dosage in units of Gy.

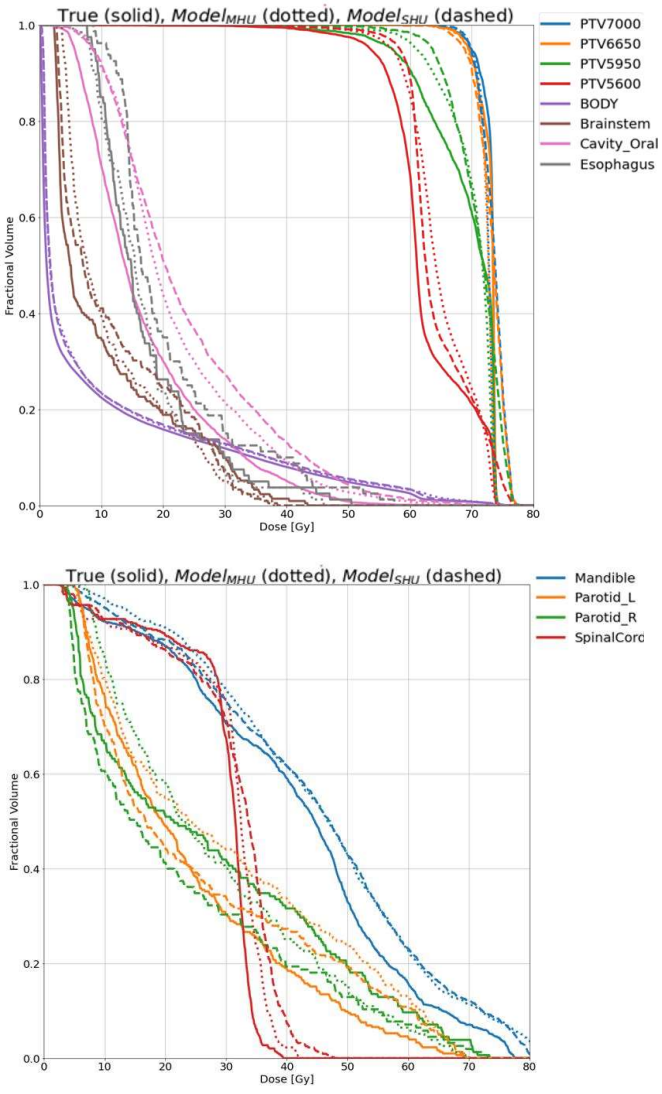

Figure 3: An example of DVH from a patient from the test data. The solid line represents the clinical ground truth dose, while the dotted and dashed lines represent the predicted dose from MHU-net, and the dashed line, respectfully.

3.2 Mean and Maximum Dose Error

According to Figure 4, the mean absolute percentage error analysis shows that out of the 11 structures examined, 8 of them demonstrated lower mean dose errors when predicted by the MHU-net (red bar) as compared to the SHU-net (blue bar). Moreover, the mean doses for these structures were within 6% of the prescription dose. This indicates a high level of accuracy and consistency in the dose prediction process. Similarly, as illustrated in Figure 3, the Absolute Percentage Error for the maximum dose ($\mathbf{D}_{max}$) shows that 8 out of the 11 structures predicted by MHU exhibited fewer errors in $\mathbf{D}_{max}$ error than those predicted by SHU models. The mean doses for these structures were within 7% of the prescription dose. This agreement between the predicted and prescribed doses highlights the effectiveness of the MHU-net in accurately estimating the radiation doses received by different regions of the patient's anatomy.

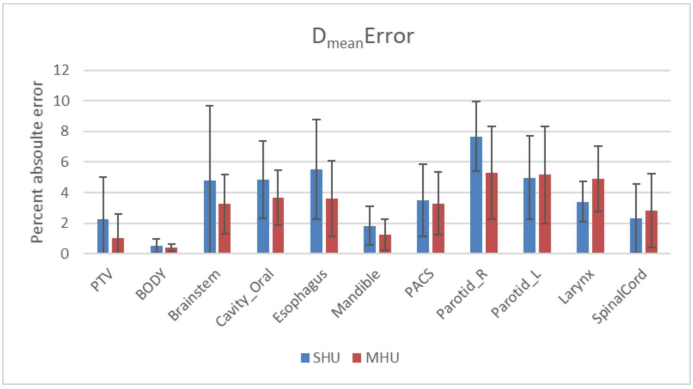

Figure 4: The absolute error of $\boldsymbol{D}_{mean}$ on the structures of interest. Error is reported as a percentage of the prescription dose

Figure 5: The absolute error of $\boldsymbol{D}_{max}$ on the structures of interest. Error is reported as a percentage of the prescription dose

Model Type	PTV D95	PTV D98	PTV D99	Homogeneity
Ground Truth	0.96±0.03	0.94±0.03	0.92±0.03	0.0013±0.00
SHU-net	0.92±0.02	0.88±0.02	0.82±0.02	0.0018±0.00
MHU-net	0.94±0.01	0.92±0.01	0.90±0.01	0.0015±0.00

Table 1: *Average PTV coverage and homogeneity for the ground truth and the prediction models.*

Table 1 shows that the MHU-net was able to achieve more similar PTV_{D95}, PTV_{D98}, and PTV_{D99} values with the ground truth than the SHU-net.

In our evaluation involving 10 test patients, we also observed a notable reduction in the mean squared error (MSE) when comparing the dose predictions of the SHU-net and the MHU-net. Specifically, the MHU-net achieved a significantly lower MSE of 0.0029 compared to the SHU-net's MSE of 0.0033, with a p-value of 0.0008 indicating statistical significance. This statistical finding also reflects a high level of agreement between the dose distributions predicted by the MHU-net and the ground truth dose.

4 Discussion

This study demonstrated a new DL-based model for 3D dose distribution prediction. To our knowledge, it has not been done with deep learning-based dose prediction for ART. The MHU-net is specifically proposed for ART, containing pre-plans accounted for the physician's treatment physician preferences and adaptive plans adjusted during treatment in response to anatomical changes for sustained treatment efficacy.

However, there are notable limitations to acknowledge. Firstly, the study's data size is constrained, involving only 43 eligible patients due to the novelty of the Varian Ethos treatment machine and ART software. This contrasts with typical deep-learning datasets, which often involve hundreds of thousands of data. Secondly, relying solely on the PTV, OARs, and CT as input data as input may constrain prediction performance. Improving the model's performance could be achieved by integrating additional information, such as various treatment modalities, beam energies, beam orientations, and field geometry. Lastly, the current dose prediction models are site-specific, necessitating restructuring and retraining for new target treatment sites with different OAR configurations. In future work, we aim to expand and enhance the model, addressing these limitations to enable implementation across multiple treatment sites.

5. Conclusion

Our proposed MHU-net demonstrates the viability of integrating a pre-plan that accounts for the physician's individualized preferences for each patient. This innovative approach goes beyond the SHU-net dose prediction model by taking into account the unique considerations and specifications set forth by the physician. By incorporating the clinician's preferences into the treatment planning process, the MHU-net enhances the personalization of dose predictions, ensuring that the proposed treatment regimen aligns more closely with the specific needs and characteristics of the patient. This personalized approach enhances treatment effectiveness, marking a significant advancement in tailoring medical care to individual patients in healthcare.

Abstract Patients undergoing radiation therapy can experience stress because of the fear of treatment. Stress causes muscles to contract, which can reduce the accuracy of the patient setup. In this study, we used biological signals to identify and artificial intelligence to predict stress during radiation therapy. Stress was calculated by analyzing biological signals measured before and during radiation therapy. We used various artificial intelligence models to verify the models optimized for stress prediction. Our findings indicate that over 90% of patients experience stress during treatment and artificial intelligence can predict this stress with over 80% accuracy. This study is pivotal for identifying patients requiring stress reduction before therapy, potentially enhancing the precision of cancer radiation therapy.

1 Introduction

A necessary procedure in radiation therapy involves the creation of an individual treatment plan to focus high-energy radiation on the tumor while sparing nearby critical organs, using simulation computed tomography images. For successful radiation therapy, the accurate positioning of the patient, identical to that in the treatment plan, is essential. If the patient's position does not match the treatment plan, the therapeutic effect is reduced and damage to normal tissues can occur [1]. Therefore, accurate beam alignment in accordance with the treatment plan to patients is critical for optimizing the therapeutic outcomes.

Accuracy of radiation treatment is influenced by both technological and human factors. Human factors, such as respiratory and gastrointestinal motion, shrinkage of the targeted tumor volume, and patient stress (anxiety) play significant roles. The inherent variability in human respiratory and digestive system movements can cause unpredictable displacements of the body and internal organs, which can be mitigated using techniques such as gating, tumor tracking, and image-guided radiation therapy. The treatment plan was modified using adaptive radiotherapy to accommodate the shrinkage of the target volume [2]. Although various methods to counteract these factors are used in daily patient treatment and are under development, there is a noticeable scarcity of research addressing the impact of patient stress on radiation therapy.

Evaluation of stress through biological signal monitoring is an emerging and pivotal field of medical research. Psychological stress triggers the sympathetic nervous system, leading to physiological changes such as increased heart rate (HR), blood pressure, breathing rate, and muscle stiffness [3]. Two of the most significant indicators in this field are photoplethysmogram (PPG) and electrocardiogram (ECG), both of which monitor changes in blood flow. Changes in blood flow are instrumental in determining heart rate variability (HRV), a key metric in stress evaluation [4]. The reliability and utility of HRV as a stress measure have been substantiated by comparison with traditional stress surveys. Moreover, the integration of HRV analysis into wearable technologies such as smartwatches, has opened new avenues for real-time, noninvasive stress monitoring [5]. Hence, HRV analysis is a promising alternative to survey-based methods that offer a more objective and continuous assessment of stress levels.

Stress in patients undergoing radiation therapy has been identified in survey studies [6]. It is observed that a majority of these patients experience heightened stress levels, particularly in the initial stages of their treatment. This underscores the need for effective stress management strategies. However, implementing universal stress reduction measures for all patients can be resource intensive and requires additional manpower and time. To address this challenge, we leveraged Artificial Intelligence (AI) techniques in conjunction with biological signal analysis to identify patients who are susceptible to stress during radiation therapy. Our approach involved training machine learning models on HRV data collected both before and during the treatment sessions. This study aimed to use before-treatment HRV data to predict the likelihood of patients experiencing significant stress during therapy sessions. This prediction enables us to tailor stress management interventions more effectively by focusing on those who need them the most.

2 Materials and Methods

2.1 Data acquisition and processing

The study protocol, including patient recruitment and data collection methods, was approved by the Institutional Review Board of the Samsung Medical Center (IRB number 2020-11-162). Prior to enrollment, written informed consent was obtained from all participants, confirming their voluntary participation and understanding of the study’s aims and processes. Our study prospectively enrolled patients who underwent radiation therapy for lung cancer. The recruitment period spanned from December 2020 to November 2023. Initially, 41 patients (123 case) were approached for participation in this study.

Data collection commenced with patients wearing a biological sensor (Laxtha, Ubpulse 360, Daejeon, Korea) upon arrival in the waiting room prior to receiving radiation

therapy. The sensor was positioned on the finger to ensure no interference during the treatment procedure. After a 10-minute acclimatization period, patients were escorted to the treatment room, where they continued to wear the sensor throughout their radiation treatment session. Upon completion of the treatment, the sensor was returned, and the collected PPG data were securely transferred to a dedicated computer system for analysis. Subsequently, the PPG data were segmented into two distinct phases for analysis: the before-treatment phase, captured while the patient was in the waiting room, and the during-treatment phase, recorded when the patient lay on the treatment couch. To account for potential HR elevations due to movement, we isolated 5 min of data following a 2-minute stabilization period in both the before- and during-treatment phases. From these phases, the HRV was computed by analyzing the intervals between successive PPG peaks. Pre-processing of the PPG data and subsequent HRV analyses were conducted using MATLAB R2020b (MATLAB, MathWorks, Natick, MA, USA) to ensure a standardized and reproducible methodology.

2.2 Stress features

Identification and accurate quantification of stress features are important for the assessment of stress levels using HRV analysis. In this study, we operationalized stress using a set of physiological markers derived from PPG signals. The second derivative of the PPG signal was used to pinpoint the heartbeat peaks, and HRV was calculated by measuring the intervals between these peaks. The selection of HRV-related stress features was based on a comprehensive literature review, identifying seven features consistently associated with physiological stress responses [7]. These features are summarized in Table 1. We employed these stress features to calculate the stress score (range: 0-100%) by observing changes before and during treatment.

Table 1. Summary of stress-related features based on heart rate variability.

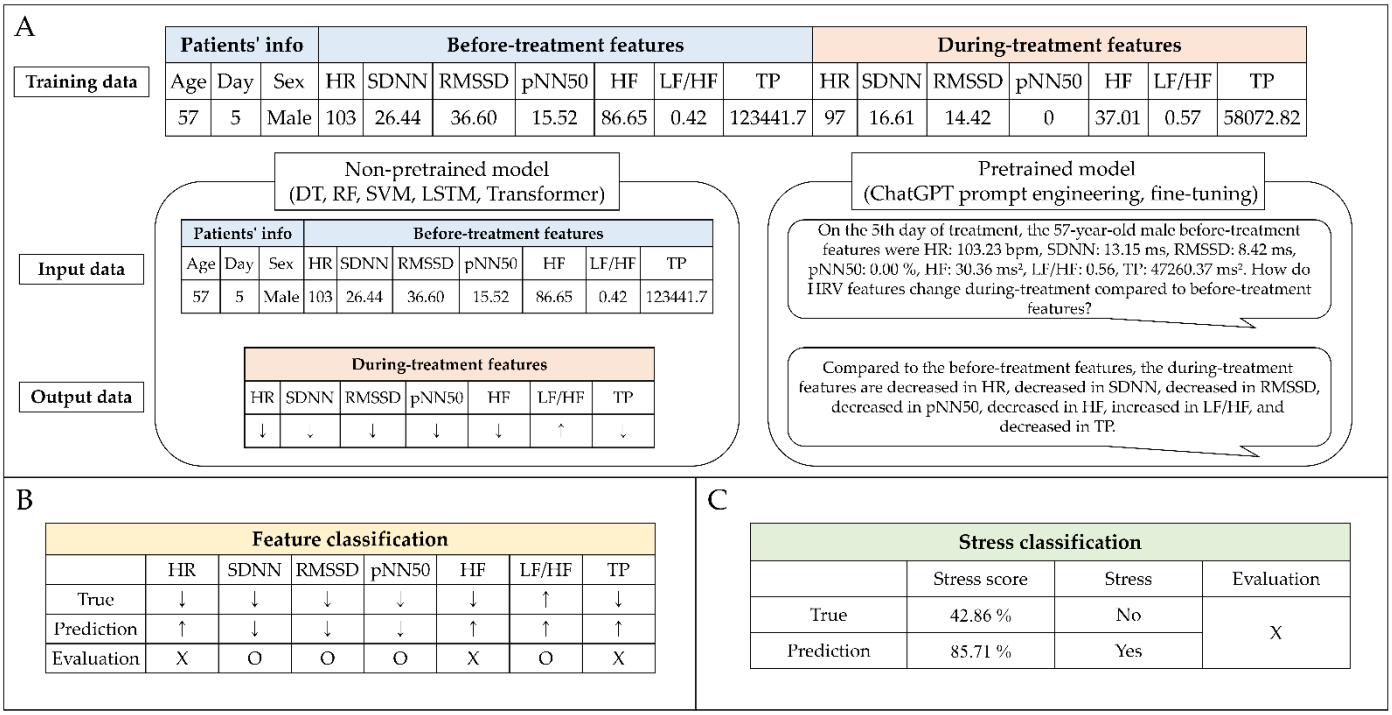
Features	Unit	Description	Stressful
HR	bpm	Average number of heart beats per minute	Increase
SDNN	ms	Standard deviation of NN intervals	Decrease
RMSSD	ms	Square root of the mean sum of squares of successive NN intervals differences	Decrease
pNN50	%	Percentage of successive NN intervals differing more than 50 ms	Decrease
HF	ms^2	Power of high-frequency range (0.15 – 0.4 Hz)	Decrease
LF/HF	ms^2	Ratio low-frequency range / high-frequency range	Increase
TP	ms^2	Total power of frequency range (0.004 – 0.4 Hz)	Decrease

2.3 Stress prediction

Predicting patient stress in the waiting room before treatment is crucial to enhance the accuracy of setting up patients for radiation treatment. This enables the early implementation of measures to reduce stress, potentially improving treatment efficacy. Non-pretrained and pretrained models were used for stress prediction. The non-pretrained model categories include decision tree (DT), random forest (RF), support vector machines (SVM), long short-term memory (LSTM), and transformer. The pre-trained models used were OpenAI's ChatGPT, which is based on a Large Language Model (LLM) and enables prompt engineering and fine-tuning. Prompt engineering involves the strategic design of input prompts to elicit the desired responses from an LLM, whereas fine-tuning refers to the process of adjusting an LLM's parameters on a specific dataset to improve its performance for particular tasks. The non-pretrained models were assessed using 10-fold cross-validation to evaluate their ability to handle three different input datasets. These datasets included treatment day, age, sex, and seven stress features identified before treatment. The model outputs were designed to classify the predicted changes in stress features during treatment (Figure 1). Subsequently, the top three input datasets from the performance of the non-pretrained models were selected for further analysis with the pretrained models. The pretrained model was evaluated against a representative one-fold out of a 10-fold cross-validation of the non-pretrained model. Therefore, the pretrained and non-pretrained models compared the results of the one-fold dataset. The pretrained models performed prompt engineering in GPT-3.5 and GPT-4.0 and fine-tuning in GPT-3.5-turbo-1106.

2.4 Evaluation

To assess the predicted stress features during treatment, we adopted two analytical approaches: feature classification (multi-label) and stress classification (binary). Feature classification utilized the raw output from our models to evaluate prediction accuracy across multiple labels. The key metrics included the Exact Match Ratio (EMR) and standard classification metrics such as accuracy, recall, precision, and F1 score, providing a holistic view of the models' performance. The feature classification result is calculated as a stress score but the stress classification is classified as "yes (> 50%)" or "no (< 50%)" based on the criterion of a stress score of 50%. The effectiveness of the stress classification was quantified using accuracy, recall, precision, and F1 score.



B

Feature classification	HR	SDNN	RMSSD	pNN50	HF	LF/HF	TP
True	↓	↓	↓	↓	↓	↑	↓
Prediction	↑	↓	↓	↓	↑	↑	↑
Evaluation	X	O	O	O	X	O	X

C

Stress classification	Stress score	Stress	Evaluation
True	42.86 %	No	X
Prediction	85.71 %	Yes

(C) The stress classification evaluation process based on 50% of the stress score calculated using the results of feature classification.

3 Results

3.1 Features classification

Datasets 6, 7, and 8, which exhibited the highest scores for recall, accuracy, and EMR, respectively, in the non-pretrained model, were selected for the pretrained model evaluation. The pretrained model was evaluated only one-fold, and for an intuitive comparison. Across the three datasets, GPT3.5 with prompt engineering, did not achieve an accuracy exceeding 0.5. In contrast, GPT4.0 outperformed GPT3.5 in all evaluation metrics. In the type 8 dataset, the fine-tuned GPT3.5-turbo-1160 model exhibited the most impressive results, whereas its performance on the type 7 dataset was comparatively lower. When focusing on the type 7 dataset, the LSTM model achieved the highest accuracy and recall. However, for the type 8 dataset, GPT4.0 with prompt engineering emerged as a superior model in terms of EMR, precision, and F1 score.

Table 2. Non-pretrained and pretrained model features classification.

Type	Model	EMR	Accuracy	Recall	Precision	F1 score
6	DT	0.000	0.637	0.727	0.635	0.672

	3.5 (F)	0.077	0.615	0.714	0.613	0.646

3.2 Stress classification

Stress classification was binary (Figure 1C). The feature classification result is calculated as a stress score but the stress classification is classified as “yes (> 50%)” or “no (< 50%)” based on the criterion of a stress score of 50%. Therefore, this differs from the feature classification results. As shown in Table 3, among the non-pretrained models, the LSTM using the type 7 dataset achieved the highest accuracy (0.846) in stress classification. For the pretrained models on the type 8 dataset, GPT4.0 with prompt engineering, demonstrated the highest accuracy at 0.769 and GPT3.5 with prompt engineering, had the highest recall at 0.800, but the lowest accuracy at 0.385. The RF and SVM models exhibited equivalent performances across the three types of datasets. The DT and transformer models were the most effective for the type 8 dataset.

Table 3. Non-pretrained and pretrained model stress classification.

Type	Model	Accu-racy	Recall	Preci-sion	F1 score
6	DT	0.615	0.375	0.429	0.400

4 Discussion

In the analysis presented in Table 2, for the type 6 and type 7 datasets, the LSTM model continued to outperform the others in terms of EMR, accuracy, and recall. However, in the type 8 dataset, both GPT4.0 and LSTM demonstrated superior performance in EMR, achieving a score of 0.231. While LSTM led to accuracy and recall, GPT4.0 excelled in precision and F1 score. GPT3.5 displayed the lowest performance across all indicators in these datasets, with GPT3.5-turbo-1160 achieving an accuracy of 0.615 for the type 8 dataset.

Considering all models, including non-pretrained and pretrained, the LSTM model demonstrated robust performance across all evaluation indices and datasets, making it the most suitable for feature classification during treatment. In scenarios where implementing a machine learning model is challenging, the pretrained GPT4.0 model, particularly with the type 8 dataset, emerged as the most appropriate choice.

Stress classification classifies "yes (> 50%)" or "no (< 50%)" based on the criterion of stress score of 50% (Table 3). In stress classification, the LSTM of the type 7 dataset classified stress effectively with an accuracy of 0.846. The RF and SVM exhibited a stability of 0.769 accuracy across all datasets. For the pretrained model, GPT4.0 showed an accuracy of 0.769 in the type 8 dataset that included all data, but in the type 7 dataset, all pretrained models failed to exceed the accuracy of 0.5. As with feature classification, LSTM was the best among all models for stress classification, with GPT4.0 being superior for the type 8 dataset. GPT4.0 is suited for predictions using diverse patient information, whereas LSTM is recommended because of its stability in scenarios with limited information. Datasets 6, 7, and 8 used for comparison in Tables 2 and 3 contain the treatment days. The treatment day is important information for stress prediction. The performance of the non-pretrained model was similar across the three dataset types. However, the pretrained model performance was the best in the type 8 dataset, which included age, sex, and treatment day, and the worst in the type 7 dataset, in which age was omitted. Stress prediction using a pre-trained model may be better when using all available patient information.

5 Conclusion

This study marks a significant advancement in cancer radiation therapy by employing AI and biological signals for stress prediction. This highlights the potential use of these tools in identifying patients who may require psychological support prior to treatment. This study suggests the need for more diverse biological signals and patient groups to enhance our understanding of the effects of stress on radiation therapy.

Abstract We evaluated if disease-free survival (DFS) of localized soft-tissue sarcoma (STS) patients can be predicted by tumor habitats based on a single voxel-wise radiomics map. The GLCM joint energy map was calculated on fat suppressed T1-weighted contrast-enhanced MRI, performed before neoadjuvant radiotherapy. Habitats were individualized based on k-means clustering method. The median relative volume of habitat 1 (RVH1, reflecting high heterogeneity) was 56.1%, and was used for dichotomization of the sample. Between 2010 and 2020, 149 soft-tissue sarcoma patients were retrospectively included. In this real-life cohort, RVH1 group was independent of MRI acquisition parameters. After a median follow-up of 46.3 months, 4-year DFS was significantly shorter in RVH1-high compared to RVH1-low group (52.5% *vs* 71.5%, p=0.029). In multivariate analysis, RVH1-high and FNCLCC grade 3 remained significantly correlated with shorter DFS (both HR=1.8, p=0.046 and p=0.033, respectively). Habitat imaging based on voxel-wise radiomics may be a valuable tool to evaluate intra-tumor heterogeneity to predict prognosis and/or to personalize treatment.

1 Introduction

Soft-tissue sarcomas (STS) are rare ubiquitous neoplasms with poor prognosis. They present important inter-tumor heterogeneity, from indolent to highly aggressive disease, but also intra-tumor heterogeneity, associating various types of tissues.

Radiomics refers to the process of extracting multiple quantitative imaging biomarkers to use them for outcomes modelling and clinical decision making. This analytical approach usually summarises tumor characteristics into various 1-dimensional (i.e. scalars) features and perform a data-driven approach for outcome prediction. Data are available using various imaging technics applied to various indications, including MRI and STS [1].

New approaches are emerging to consider spatial profiling [2]. Voxel-wise radiomics generate radiomics filtered images and could be more interpretable than 1D radiomics. On the other hand, imaging data can be used to identify tumor sub-regions ("habitats") with different biological properties.

We here propose to combine these habitat imaging and voxel-wise radiomics approach to predict disease-free survival (DFS) in localized STS patients treated by neoadjuvant RT and surgery.

2 Materials and Methods

Patients and magnetic resonance imaging

We retrospectively included all adult patients treated by normofractionated neoadjuvant RT for a localized limb or truncal STS in Centre Léon Bérard (Lyon, France) from January 2010 to November 2020. Exclusion criteria were retroperitoneal STS, bone, Ewing and Ewing-like sarcoma, desmoid tumors, experimental (neo)adjuvant treatment, metastatic disease. Since MRI were performed in various centers, we focused on the only sequence common to all patients: the fat-suppressed T1-weighted gadolinium-enhanced sequence, acquired in 2 or 3 dimensions.

Segmentation and voxel-wise radiomics extraction

Anonymized images were processed on Slicer3D® software. In MRI, magnetic field inhomogeneity and MR coils sensitivity effect can generate a low frequency intensity non-uniformity, called image bias field, that can distort images. Bias field Image bias field was corrected by the retrospective histogram based N4ITK algorithm [3]. Tumors were manually segmented (BA, 5 years of experience). Voxel-wise radiomics were then extracted after z-score normalization, with a fixed bin size of 32 and a kernel radius of 3. B-spline interpolation and nearest neighbor interpolation were used to resample images and segmentation masks, respectively, to 1 mm isotropic voxel size. Radiomics extraction was performed using Python (v3.11.2) and reference packages PyRadiomics (v3.0.1), Numpy (v1.24.2), and SimpleITK (v2.2.1).

K-means clustering-based habitats

The grey-level co-ocurrence matrix joint energy (GLCM-JEnerg) is a measure of homogeneous patterns in the image:

$$GLCM_{JointEnergy} = \sum_{i=1}^{N_g}\sum_{j=1}^{N_g}\left(p(i,j)\right)^2$$

with N_g the discrete number of intensity in the image and p(i,j) the normalized co-ocurrence matrix. We planned to focus on this 3D feature-map since it was previously described as repeatable and reproducible [4], and correlated with local recurrence in glioblastomas [5].

A k-mean clustering method was used on the GLCM-JEnerg map to separate various habitats according to their degree of local heterogeneity. For a number k of cluster (habitat) between 1 and 10, the centroids were calculated to minimize the sum of the squared Euclidean distance

differences between each value and the centroid of the cluster (*within cluster sum of square*, WCSS):

$$WCSS(k) = \sum_{j=1}^{k} \sum_{x_i \in cluster\ j} \left\| x_i - \bar{x}_j \right\|^2$$

with $\bar{x}_j$ the centroid of cluster j. The number of clusters for all maps was the optimal number of the majority, determined by the Elbow method.

The habitats were sorted by increasing centroid values (i.e. habitat 1 is the most heterogeneous one), and relative volume occupied by habitat 1 (RVH1) was recorded. The threshold used to dichotomize RVH1 was the overall cohort median value. All this clustering step was performed on MatLab (R2023b).

Clinical outcomes

Primary outcome was disease-free survival (DFS). Secondary outcomes included local recurrence-free survival (LRFS) and predictive factors of RVH1.

Statistical analyses

Categorical variables were reported as counts (percentages) and compared using Chi2 tests. Continuous variables were reported as median (interquartile range) and compared using T-tests or Welch tests (according to the normality of the distributions), or by ANOVA. Median follow-up was determined using the reverse Kaplan Meier method. Survival outcomes were estimated by the Kaplan-Meier method. Prognostic factors were explored in univariate and multivariate Cox proportional hazard models and included RVH1 and usual known factors: age ≥70 years, grade 3 according to fédération nationale des centres de lutte contre le cancer (FNCLCC), deep-seated tumor, size > 5 cm, undifferentiated pleomorphic sarcoma or myxofibrosarcoma histotypes. Two-sided p-value <0.05 was considered significant. Statistical analyses were performed using R software version 4.2.3 (R Foundation for Statistical Computing, Vienna, Austria).

3 Results

We retrospectively included 149 STS patients. Their clinical characteristics and the MRI acquisition parameters are summarized in the Table 1.

Table 1. Patients' characteristics

Characteristics	Overall (n=149)
Age	61 (48-73)
Sexe	
Male	72 (48.3)
Female	77 (51.7)

Characteristics	Overall (n=149)

Abbreviations: UPS, undifferentiated pleomorphic sarcoma; dedif./pleo., dedifferentiated/pleomorphic; FNCLCC, fédération nationale des centres de lutte contre le cancer; NAC, neoadjuvant chemotherapy; VMAT, volumetric modulated arctherapy; T1-CE, T1-weighted contrast-enhanced sequence

The optimal number k of habitats was 4 for most tumors (n=111; k=3 for n=37 and k=5 for n=1), with a median centroid of habitat 1 of 0.021 (IQR 0.016-0.029).
The median RVH1 was 56.1% (49-65) (Figure 1). The RVH1 group was not related to the MRI magnetic field strength, type of sequence, dimension of acquisitions (all p>0.96) nor to the method of fat suppression (p=0.23). It was not either related to histological subtype (p=0.09), nor FNCLCC grade 3 (p=0.2), tumor absolute volume (p=0.17) or predictive of the percentage of viable cells on surgical specimen (p=0.9).

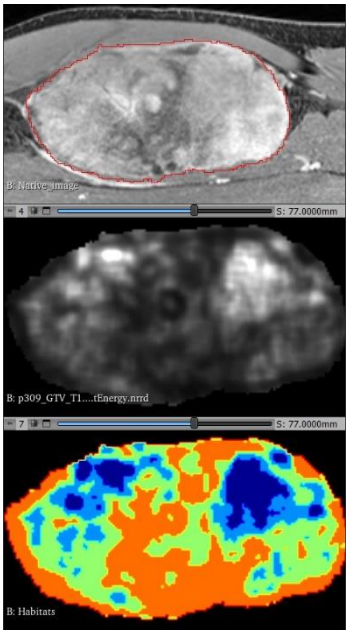

Figure 1. Native T1-weighted gadolinium enhanced Dixon-water image (up) with its GLCM -Joint Energy corresponding map (middle) and the habitat maps (down). The gross tumor volume is segmented in red. The habitat 1 to 4 are depicted from orange to dark blue, respectively.

After a median follow-up of 46.3 months (95%CI 33.1-70.1), 4-year DFS was 71.5% and 52.5% in RVH1-low and RVH1-high group, respectively (Figure 2), with 4-year LRFS of 77.3% and 65%, respectively (Figure 3). In univariate analysis, only grade 3 was significantly correlated with LRFS (HR 2.3, 95%CI 1.2-4.2, p=0.01). In both uni- and multivariate analyses, DFS was significantly related to FNCLCC grade 3 and RVH1 (HR 1.8, 95%CI 1.1-3.1, p=0.033; HR 1.8, 95%CI 1.01-3.1, p=0.046, respectively).

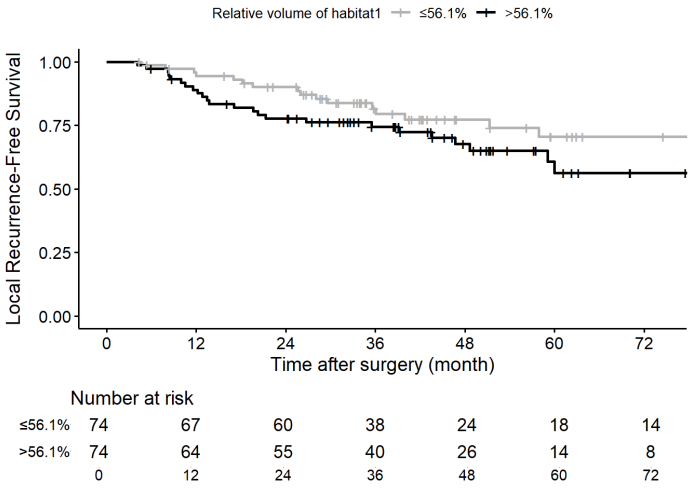

Figure 2. Local recurrence-free survival according to relative volume of habitat 1

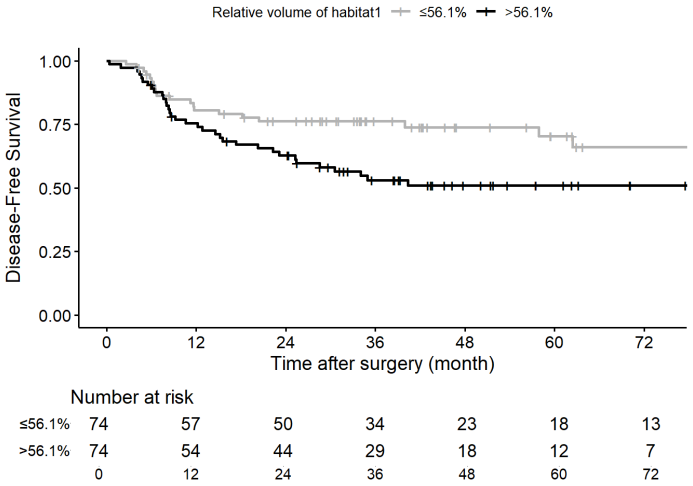

Figure 3. Disease-free survival according to relative volume of habitat 1

As a sensitivity analysis, we divided the cohort into 3 groups according to the terciles of the RVH1 distribution. The DFS tended to shorten with the increase of RVH1, with 4 year-DFS of 75% *vs* 60.9% *vs* 50.8% (Figure 4).

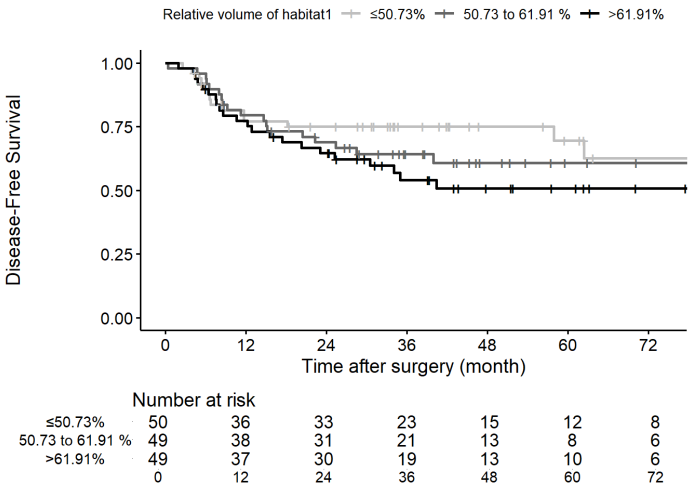

Figure 4. Disease-free survival according to relative volume of habitat 1, divided into 3 groups.

4 Discussion

We here report an original methodology of habitats imaging based on fat suppressed T1-weighted contrast-enhanced sequence voxel-wise radiomics. GLCM-JEnerg RVH1-low group present a significantly longer DFS, with a clinically meaningful difference.

This highlights the potential interest of voxel-wise radiomics either to identify tumor subclones or to predict patient prognosis.

Nevertheless, some refinements of the method may be performed. First, the repeatability of the habitats may be verified, for example by adding Rician noise in native images and process them back. As a retrospective analysis, the reproducibility of the method when performing other MR acquisitions cannot be confirmed. In contrast, an external cohort may be used to reproduce and validate the whole processes and results.

MR acquisition parameters were variable between patients and could thus introduce bias, particularly using vowel-wise radiomics [4]. Nevertheless, various steps limited this: intensity non-uniformity was corrected, native images were standardized, and a clustering was individually performed. Furthermore, the whole process was not data- but hypothesis-driven, with interpretable intermediate results, and is applied on real-world data acquired on an important cohort of patients, with sufficient follow-up, presenting rare disease managed in an expert center.

5 Conclusion

In this real-world cohort of localized STS, habitat imaging based on a single voxel-wise radiomic map was independently correlated with DFS. This kind of approach could be a valuable tool to integrate intra-tumor heterogeneity into RT personalization.

Abstract Stereotactic body radiotherapy (SBRT) for spinal metastases requires accurate target delineation to achieve optimal plan quality. However, the delineation of target volume is a labor-intensive process and subject to inter- and intra- observer variations. To address the clinical needs and improve the spine SBRT workflow, we propose a deep learning-driven framework for the auto-localization and delineation of the target volume for spine SBRT, using multi-modal imaging. Consisting of a vertebrae segmentation network and a target volume segmentation network, the proposed workflow can localize the lesion on images based on clinical chart diagnosis, and further generate clinical target volumes (CTV) with a Dice score of 0.86 on the independent testing set. Additionally, this framework is supported by a comprehensive web platform, allowing efficient patient database management and user interactions such as review and revise. Our proposed framework can be a promising tool to streamline the spine SBRT treatment workflow.

1 Introduction

The spine is the most common site for bony metastases, with up to 40% of cancer patients developing spinal metastases[1]. As cancer patients' life expectancy increases, so does the incidence of spinal metastases, making their management increasingly challenging and demanding[2]. Spine stereotactic body radiotherapy (SBRT) has emerged as a promising treatment regimen, delivering highly conformal radiation to spinal lesions while minimizing exposure to surrounding healthy tissue. Rapidly adopted for spine metastases management[3], SBRT has demonstrates high local control with minimal neural or systemic toxicity[4,5].

Like other radiotherapy (RT) regimens, spine SBRT requires a potent tumoricidal dose for effective tumor control, balanced against minimizing tissue-damaging doses to reduce complications in organs at risk (OARs), such as radiation myelopathy and vertebral compression fractures (VCFs). In current practice, creating an optimal treatment plan for spine SBRT is particularly challenging due to the close proximity of the spinal cord and the overlapping of the vertebrae with the target area. Precise target volume delineation is therefore an essential step in achieving a s high-quality treatment plan.

To aid in this process, consensus guidelines for spine SBRT target volume have been published to standardize the target delineation[6]. Yet, the manual process of defining treatment target volumes remains a time-consuming and laborious task, heavily reliant on the clinician's expertise. This process is prone to considerable variations among different clinicians, as several studies have shown common intra- and inter-observer variations in defining target volumes for spine SBRT[7-8]. The complex structure of the spine and the large variability in patient anatomy add to the difficulty in accurately localizing and delineating the target volume. Multi-modal imaging including CT and MRIs are often utilized together to provide sufficient information about the lesion target. After the localization of the gross tumor volume (GTV), clinical target volume (CTV) can be subsequently contoured by incorporating different anatomical regions (such as vertebral body, pedicles, spinous process, etc.) based on the location of the GTV per consensus guidelines.

With advancements in artificial intelligence (AI) technology, particularly in mathematical algorithms and computing technologies, AI has had a transformative impact on the field of radiation therapy[9-10]. However, despite

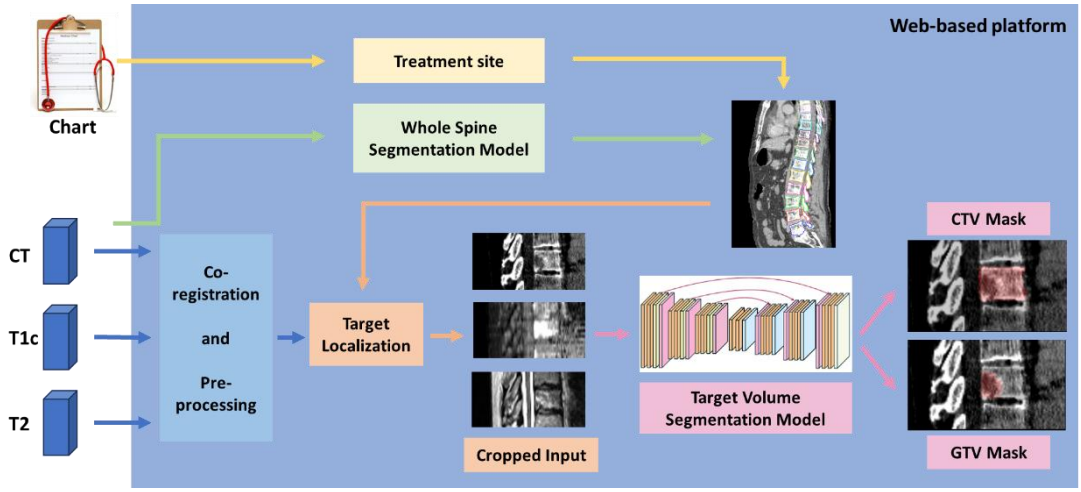

Figure 1 The overall design of the proposed framework for spine SBRT treatment target localization and delineation.

that various studies have been proposed on automating spine segmentation, they primarily focus on vertebrae segmentation of the entire spine and are not yet directly applicable to clinical spine SBRT workflow[11-12]. The automation of target volume localization and delineation remains an urgent need to improve the spine SBRT treatment workflow.

In this study, we propose a deep learning (DL)-driven framework to address the clinical need. The proposed framework not only enables AI-based vertebrae segmentation and labeling as well as GTV, CTV localization and delineation, but also maintains a comprehensive database for managing spine SBRT DicomRT data. In additional, this proposed framework is supported by a web-based platform to enable user interaction to facilitate clinical workflow.

2 Materials and Methods

The patient data used in this study were retrospectively collected from our institutional CyberKnife spine database. Only patients with spinal metastasis limited to one vertebral level and located at thoracic or lumbar spine are selected in this study. CTVs and GTVs that were contoured by physicians per consensus guidelines are used as ground truth in the study. Initially, a total of 48 spine SBRT patients were collected. Forty-two of these 48 patients met the inclusion criterion with a total of 56 treatment site. We further randomly divided these 56 cases into 3 groups: 40 for the DL model training, 8 for model validation and 8 for independent testing. The data stratification ensures that multiple treatment sites of one patient remain in the same group.

Figure 1 demonstrates the design of our proposed framework that can be summarized into three steps: 1) Spine segmentation and labeling, 2) target localization, and 3) Target volume segmentation. For each case, the corresponding framework input consists of CT, T1ce (T1 contrast enhanced), and T2 MRIs. The MRI images are co-registered and resampled into the same resolution and spatial coordinate as the CT.

In the first step, after importing the multi-modal images, the whole spine will be segmented from the input CT images using a TotalSeg-based DL model embedded in the framework platform[13]. Specifically, detailed spine vertebrae are auto segmented and labeled according to the spine anatomy.

Next, in the target localization step, the diagnosis regarding which vertebra the lesion is located at is then retrieved from clinical charts, e.g. “T03”. Then the corresponding vertebra mask generated from the above whole spine segmentation process will be used to localize the volume of interest (VOI) and to crop the multi-modal images into smaller crops with the size of 120×118×60 centered at the targeted vertebra, utilizing the center of mass (CoM) of the corresponding vertebra. The crop size is the same among all cases and is chosen to enclose the entire target vertebra with small margins added in all direction.

In the final step, the cropped multi-modal images are used as the 3-channel input to our segmentation model, which uses a 3D nnU-Net as the backbone, to generate the GTV and CTV segmentation simultaneously[14]. The model consists of a contracting path for context capture, featuring successive layers of 3D convolutions and pooling, where feature channels increase with each layer. A bottleneck connects to an expanding path for precise localization, which includes 3D up convolutions and concatenations with corresponding layers from the contracting path. This design, with skip connections between down-sampling and up-sampling layers, ensures detailed feature mapping.

The experiments were implemented using the Pytorch library with Python environment on Windows 11 64x, Intel Xeon processor CPU with 64 GB RAM, and NVIDIA GeForce RTX 3090 GPU. The proposed model parameters are optimized for 250 epochs through minimizing the Dice loss function (formula 1), which compared the prediction with manually contoured masks. Other model parameters and configurations, e.g., batch size, are determined using the nn-UNet framework. The validation set was used for tuning the model hyperparameters, while the independent testing set is a holdout set that is not involved in training at all to test the final model performance.

$$loss = 1 - \frac{2\sum_i^k P_i G_i}{\sum_i^k (P_i)^2 + \sum_i^k (G_i)^2} \quad (1)$$

P_i and G_i represent the predicted segmentation and ground truth manual contour with K voxels, respectively.

The entire framework is supported by a platform with web-based interface under our institutional network[15], as shown in the figure 2. Once importing the data from the web-browser, the platform will automatically execute the following procedures. In addition, the platform enables the visualization of the entire process and allows the user interaction for modification and inspection, meanwhile maintaining a patient database for improved data management.

Figure 2 The web-based interface of the proposed Spine SBRT data management and target delineation framework.

3 Results

We evaluate the performance of our proposed target localization and segmentation framework on both the validation set and the independent testing set using multi-modal images. The averaged Dice similarity coefficient (DSC), and the averaged 95th percentile Hausdorff

distance (HD95) are used to quantitatively assess the segmentation performance of our model. DSC is computed to measure the degree of overlap between the model prediction and the ground truth CTV masks (formula 2). In addition, HD95 (formula 3) measures the greatest value of all the distances from a point on model's segmentation output to the closest point on the ground truth contour set.

$$DSC = \frac{2|P \cap G|}{|P| + |G|} \quad (2)$$

$$HD = \max\left(h(S_P, S_G), h(S_G, S_P)\right) \quad (3)$$

$$h(S_P, S_G) = max_{p_P \in S_P} min_{p_G \in S_G} \|p_P - p_G\| \quad (4)$$

P and G represent the predicted segmentation and the ground truth volumes, respectively. S_P represents the surface of the predicted CTV segmentation, and the S_G represents the surface of the ground truth CTV contour. The terms p_P and p_G are the points in contour surfaces S_P and S_G, respectively. The DSC and HD95 of all 8 independent testing cases are listed in the table 1.

Table 1 Dice score and 95th percentile Hausdorff distance (HD95) of the segmentation results on the independent testing set.

Testing	GTV		CTV	
Case	DSC	HD95 (mm)	DSC	HD95 (mm)
1	0.20	20.06	0.88	4.03
2	0.63	5.12	0.89	6.63
3	0.76	4.19	0.89	2.93
4	0.61	3.15	0.92	2.00
5	0.76	2.93	0.92	2.23
6	0.65	6.91	0.90	2.00
7	0.08	38.25	0.79	6.82
8	0.29	15.13	0.70	12.85
Mean	0.50	11.97	0.86	4.93

Ablation studies on the impact of imaging modalities are also investigated by varying the input channels from all 3 modality (CT, T1ce and T2) to one channel only (CT). The mean DSC and HD95 scores of both the validation set and testing set are listed in the table 2.

Table 2 Mean Dice score (DSC) and 95th percentile Hausdorff distance (HD95) of the segmentation results with varied imput modalities.

Model	GTV				CTV			
	Val		Test		Test		Val	
	DSC	HD 95	DSC	HD 95	DSC	HD 95	DSC	HD 95
CT, T1ce, T2	0.43	13.14	**0.50**	**11.97**	**0.85**	**4.17**	**0.86**	**4.93**
CT, T1ce	**0.49**	**10.07**	0.47	13.30	0.85	4.48	0.86	5.47
CT	0.36	13.62	0.46	16.15	0.83	5.00	0.80	7.82

4 Discussion

Automatic delineation of spine SBRT target volumes can greatly alleviate the workload for neurosurgeons and radiation oncologists. Presently, these professionals are tasked with the manual delineation of treatment target volumes that involves reviewing multiple imaging modalities in tandem for each patient. Additionally, automated processes offer the advantage of greater consistency in target volume determination. By adhering to same clinical guidelines, these methods can minimize the intra- and inter-observer variability that typically arises from human interpretation, thereby enhancing the overall quality of treatment. In the current spine SBRT practice, GTV is the intact lesion, and CTV is derived from the intact lesion following the consensus guideline[6]. However, currently there is no available tool for the fully automated spine target volume delineation.

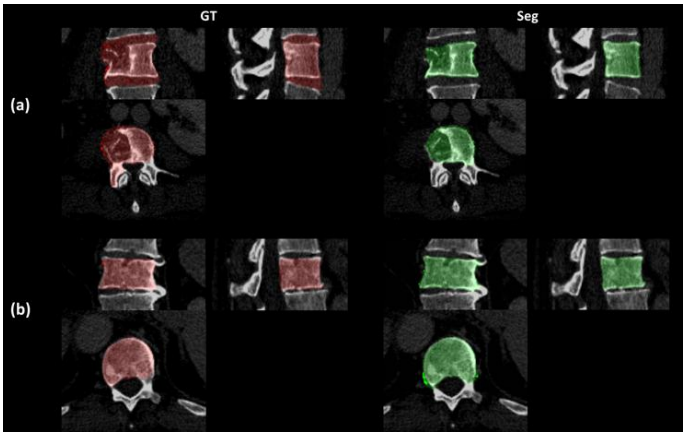

Figure 3 Examples of the CTV segmentation (Seg, in green) results comparing with the ground truth (GT, in red) contour on CT images.

Our proposed framework aims to streamline the spine SBRT treatment workflow by automating target localization and delineation facilitated by whole spine vertebrae segmentation and labeling. It is designed to mimic physicians' contouring practice to localize target position first then followed with a DL model to segment out the CTV by learning the rule-based expansion, to maximize the agreement between the model's prediction and current clinical contouring guidelines. In addition, the web-based platform interface design and the database management further improves the efficiency of the proposed framework. As shown from table 1, though with limited training data, the results on the unseen testing set suggest high agreement between the model prediction and physicians' manual CTV contours, with an averaged DSC and HD95 of 0.86 and 4.93 mm, respectively, indicating the promising performance of the proposed framework. On the other hand, the GTV segmentation accuracy is relative inferior, which is mainly caused by two limitations: 1) unlike CTVs that are usually defined by the rules, GTVs can vary a lot while our dataset is too small to learn such variations; 2) The quality and resolution of MRIs in this study is not optimal, which can greatly influence the GTV accuracy. Figure 3.b displays an example of the segmentation and the ground truth (the testing case #1) It can be found that the auto-segmentation agrees well with the manual contour. We also plot the worse testing case (case #8) in the figure 3.a. From the images we can see that in this case the ground truth CTV has a relatively rare expansion exceeding the vertebral body. Due to the lack of

samples of this type in the training data, the model couldn't learn this special CTV expansion and inclusion rule.

We also investigated the use of different imaging modalities in the spine SBRT CTV/GTV segmentation. From table 2 we can tell that, the use of T1c MRI can greatly help to improve the target delineation accuracy, while the contribution from T2 MRI images is relatively small. Our results agree with the current clinical practice, where T1c and CT images are often utilized for identify the lesion while T2 is usually used for spinal cord identification.

Additionally, the importance of target localization was also investigated. As shown in the figure 4.a, we shifted the target localization to include an extra adjacent vertebra in the model input for a testing case. Since CTV is usually derived from the lesion following certain inclusion rules, and the lesion in this case is very small, including one extra vertebra confused the model to generate a wrong CTV segmentation (in red) in the adjacent vertebra. The ground truth CTV mask is displayed in blue for comparison. Instead, the same patient but with the correct target localization, the DL model can easily generate accurate CTV segmentation (red mask in the figure 4.b) that agrees well with the ground truth.

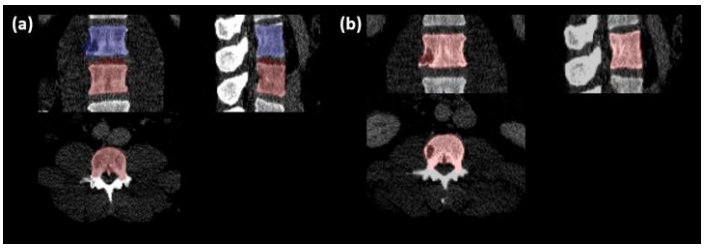

Figure 4 The impact of inaccurate target localization in the CTV detection and segmentation accuracy.

As a preliminary study, our work still holds several limitations. First, the data size of this study is very limited, which can greatly restrict the model ability. Currently, we are expanding the dataset to further improve the performance. Secondly, in the currently framework, lesion vertebra location was manually fed into the platform by extracting the key words from the clinical diagnosis chart following the institutional naming convention (e.g. "T03"), to enable the localization of the target in the CT and MRI images. As the ongoing work, we are automating this step with natural language processing (NLP) to further streamline the proposed framework.

5 Conclusion

In this study, we proposed a deep learning-driven framework to enable the automatic localization and delineation of the GTV and CTV in spine SBRT using multi-modal imaging. The preliminary results demonstrated promising result for the accurate target volume delineation. In addition, the framework is supported by a comprehensive web platform offering whole spine and OARs segmentation and efficient data management. It can be a promising tool to streamline the current spine SBRT workflow.

Safeguarding Clinical AI-Based Auto-Segmentation: Open-Source Models as Quality Assurance Against Catastrophic Failures

Daniel Alexander, PhD[1] and Rafe McBeth, PhD[1]

[1]Department of Radiation Oncology University of Pennsylvania, Philadelphia, PA

Abstract This purpose of this work is to propose the use of an open source whole body CT segmentation model as a secondary independent check for validating outputs from a commercial auto-segmentation tool in radiation therapy planning. Evaluating uncertainty and comparing contours in 52 prostate cancer cases, we observe robust overall reliability with notable challenges in rectum contouring. Agreement is strong between the independent and clinical models for bladder and femoral heads (>0.9 DSC for >97% of patients), with moderate performance for prostate. Advocating for an automated secondary model check during contour generation, we emphasize the need for a verification of model output for the continued quality assurance of the planning workflow, aiming to enhance accuracy and confidence in AI-assisted radiation therapy planning.

1 Introduction

Anatomical delineation of organs-at-risk (OARs) on a volumetric image is a critical step in the workflow of generating treatment plans in radiation therapy. Conventionally this task is performed by physicians or trained treatment planners and is a time-intensive process. With the recent rise in popularity in the use of deep learning-based auto-segmentation solutions to reduce the time and resource burden on clinical staff, as well as to improve the consistency and standardization of clinical contouring, there is a need for robust verification of the output of these deep learning models.

It is understood that variability in contours is one of the largest sources of uncertainty in radiation therapy, due to both intra- and inter-observer variability, as well as contouring error[1, 2]. There have been proposed methods to perform quality assurance for traditional human-driven OAR contouring processes primarily by comparing clinical segmentations against a historical knowledge base [3, 4]. With the rise in AI-based tools in radiation therapy, including auto-segmentation, there have been separate suggestions for corresponding quality assurance methods [5, 6]. In this study, we suggest an open source whole body CT segmentation model based on the popular nnU-Net architecture, TotalSegmentator, to function as a secondary, independent model to cross-check the output of a commercial deep learning-based auto-segmentation tool. [7, 8]. Similar to secondary, independent dose calculation algorithms used in clinical practice to identify gross errors in monitor unit calculations, we believe that independent deep learning models trained on unrelated datasets can be used as a second check on clinically-deployed AI solutions to serve a similar purpose.

2 Methods

Planning images and structure sets for a cohort of 52 patients who underwent external beam radiation therapy for prostate cancer at out institution were anonymously exported from our treatment planning system database for contour analysis and inference. All planning CTs for this cohort had been submitted to our commercial auto-segmentation tool (ART-Plan, Therapanacea, Paris, France) as part of the standard clinical workflow, and these structure sets were exported alongside the planning CTs in DICOM format. All DICOM data was converted into NifTi format to facilitate inference by the pre-trained TotalSegmentator model and analysis. Five clinical structures were identified to evaluate the performance of the independent model: bladder, rectum, prostate, and right and left femoral heads.

2.1 Assessing prediction uncertainty

In order to evaluate the uncertainty in contour predictions from TotalSegmentator, the CT data for each patient was manipulated via translations along each axis of +4 and +8 voxels. Theses translated image volumes were submitted to the pre-trained model along with the original image volume, and resulting predictions were processed with the reversed translations of -4 and -8 voxels along each axis, respectively. This resulted in seven unique predictions for each structure per patient. Each of the predictions from the translated image volumes was compared against the prediction from the original image volume by calculating Dice similarity coefficients (DSC) for each pair. Additionally, in order to assess the uncertainty in the model output as a function of anatomical direction, a composite prediction was formed by summing the binary masks from the seven unique predictions, and the gradients along the x, y, and z-dimensions were calculated as shown in Figure 1. For each dimension, line profiles were evaluated through each point in the plane perpendicular to the gradient direction, the positive and negative peaks were identified, and the peak heights and widths were aggregated. The average width of the positive and negative peaks were interpreted as uncertainty in the border of the prediction along that axis; for example, for peak gradient widths along the z-axis, positive and negative average peak widths corresponded to uncertainty in superior and inferior borders, respectively.

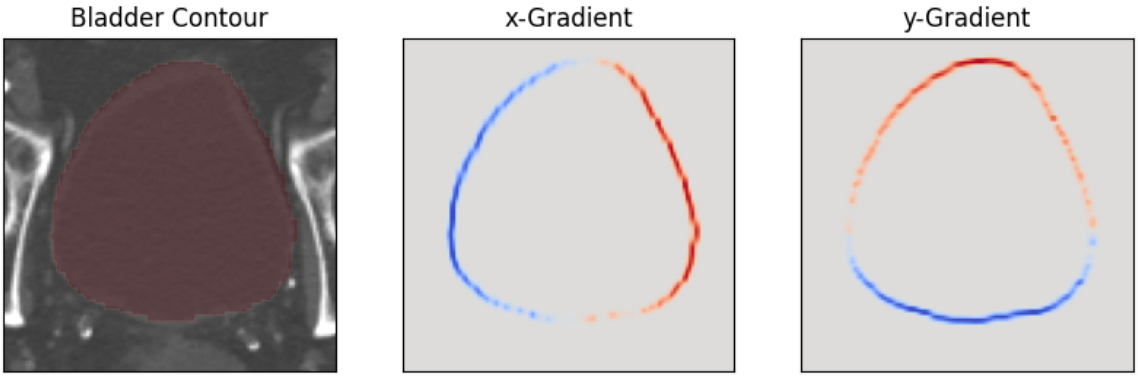

Figure 1: Analysis of composite mask gradients along different axis. Left: Bladder contour in red overlaid on CT image slice. Center: Resulting x-gradient of composite bladder prediction. Right: Resulting y-gradient of composite bladder prediction.

2.2 Comparison of clinical and independent contours

Baseline predictions on original planning image volumes from the independent model were compared with the clinical structures generated by the commercial system for the five structures listed above. DSC and Hausdorff distance metrics were calculated between the structure pairs for each patient, and aggregate data was analyzed.

3 Results

3.1 Prediction uncertainty

Table 1 shows the mean and standard deviation of the DSSC values for each structure, averaged across the patient cohort.

Structure	Average Mean	Average Std Dev
Bladder	0.987696	0.004095
Femur_Head_L	0.981661	0.006421
Femur_Head_R	0.981555	0.006311
Prostate	0.965240	0.009722
Rectum	0.960647	0.013215

Table 1: Average Mean and Standard Deviation Across All Patients for Each Structure.

The worst performing structure across seven independent predictions was the rectum contour, while the best performing was bladder; however, all structures were fairly stable at DSC > 0.95 and a standard deviation of < 1.5%. Furthermore, Table 2 shows the gradient widths, a surrogate for prediction uncertainty, along each anatomical direction for the five evaluated contours. Similarly, the rectum shows the greatest uncertainty overall.

3.2 Inter-system contour comparison

Figure 2 highlights a comparison of the contours produced by the clinically deployed auto-segmentation tool and the independent secondary model. Calculated Hausdorff distances for the evaluated contours were 36.9 ± 29.6, 11.3 ± 3.8, 3.0 ± 1.0, 3.0 ± 0.7, and 5.3 ± 2.5 mm for the rectum, prostate, right femoral head, left femoral head, and bladder, respectively (Median ± IQR). Corresponding DSC values were 0.66 ± 0.15, 0.76 ± 0.07, 0.97 ± 0.01, 0.97 ± 0.01, and 0.96 ± 0.02, respectively. For the bladder and femoral heads, the success rate was >97% for a 0.9 DSC criteria, while the prostate contours has worse agreement, with a 0.65 criteria yielding a 95% success rate. Again, the rectum comparison showed the worst agreement with only 86% of patient contours meeting a DSC threshold of 0.5.

4 Discussion

The uncertainty quantification performed on the TotalSegmentator predictions highlights the fairly robust reliability of the model. However, due to the somewhat arbitrary nature of the labels produced based on the paradigm in the training data, especially with the rectum structure, there continued to be disagreements with the clinical autocontouring tool. Clinical deployment of a pre-trained secondary model would necessitate thoughtful postprocessing of the output to align with the clinical standards in place.

We propose a suggested workflow to enhance the clinical integration of a "second check" quality assurance approach for AI based contouring. In this envisioned workflow, a database of benchmark metrics would be established to determine action and tolerance levels for contour agreement based on statistical process control [9]. After deployment, the secondary model would be automatically invoked at the time of clinical contour generation. The contours produced by the commercial deep learning-based auto-segmentation tool would be simultaneously cross-verified by the independent model and evaluated in the context of the preestablished action level. If necessary, the contours would then be made available to the planner and physicist for visual examination prior to the planning phase. This proactive approach aims to catch potential inaccuracies and uncertainties early in the workflow, providing an additional layer of assurance and reinforcing the collaborative role of clinicians in the AI-assisted

Structure	Left	Right	Anterior	Posterior	Superior	Inferior
Bladder	2.046	2.021	2.103	2.143	2.296	2.271
Femur_Head_L	2.217	2.431	2.197	2.287	2.549	2.620
Femur_Head_R	2.490	2.207	2.197	2.262	2.504	2.601
Prostate	1.975	1.978	2.046	2.022	2.064	2.149
Rectum	2.400	2.320	2.232	2.350	3.162	2.719

Table 2: Average width (in voxels) of peaks in the gradients of the composite masks for each structure, related to uncertainty in the prediction.

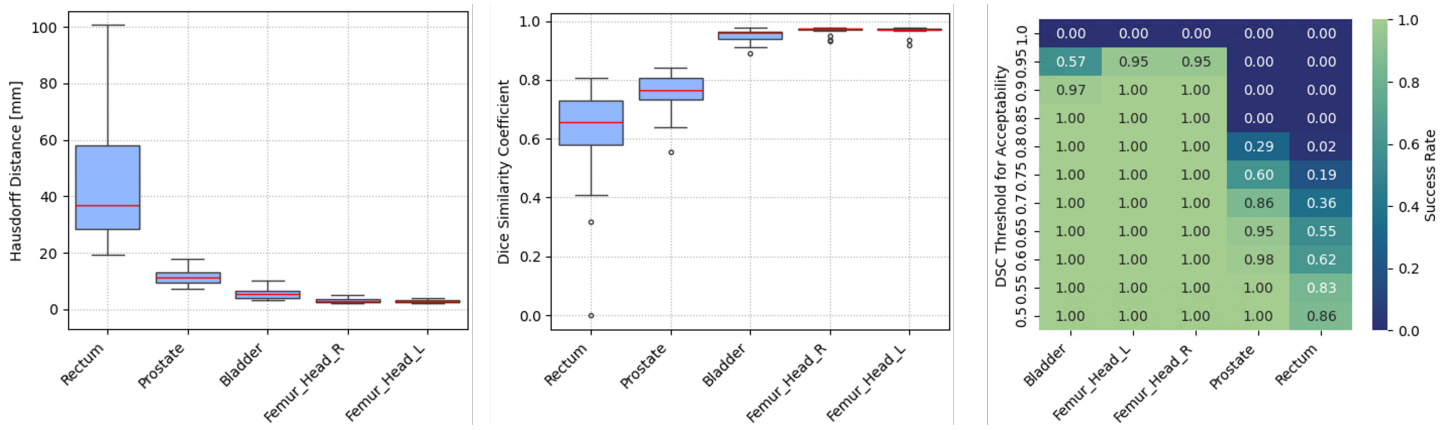

Figure 2: Quantitative comparison of contours generated from a clinically deployed AI autocontouring tool and an open source secondary independent model. Left: Distribution of Hausdorff distances across the patient cohort for each structure. Center: Distribution of DSC values across the patient cohort for each structure. Right: Success rates for each structure, defined for a given structure as the fraction of patients for which the DSC between the two structure predictions is above the threshold of acceptability.

radiation therapy planning process.

5 Conclusion

This study addresses the critical need for robust verification in the context of deep learning-based auto-segmentation solutions for radiation therapy planning. With the increasing reliance on AI tools to streamline and standardize the contouring process, a secondary independent model can serve as an cross-check on the output of an otherwise automated tool. The comprehensive evaluation conducted on a cohort of 52 prostate cancer patients provides insights into both the strengths and challenges of this approach.

The assessment of prediction uncertainty through manipulation of CT data and subsequent analysis of model outputs reveals a generally robust reliability of the model. Despite its overall performance, discrepancies highlight the nuanced nature of aligning model outputs with clinical standards. This emphasizes the importance of thoughtful postprocessing when deploying pre-trained secondary models in a clinical setting.

In conclusion, our study contributes to the evolving landscape of AI applications in radiation therapy by introducing a potential verification strategy. The proposed workflow and insights into prediction uncertainty provide a foundation for further refinement and implementation of AI-driven contouring solutions, with the goal of ultimately reliability of radiation therapy planning in the era of deep learning.

Abstract Accurate superficial target segmentation on a CT scan is challenging task, since the 2D segmentations must accurately follow the 3D surface curvatures projected onto orthogonal planes. For radiation oncologists this is a considerable time investment.
We present a technique to automatically segment a target from a wire placed on the patient's skin using a CT scan. This method furthermore allows for automatic beam and couch angle determination as well as placement of the treatment plan reference point as defined by fiducial markers.
Multiple wire materials were considered (Al, Cu, Sn) to define the CTV borders on the skin surface; from these, Sn proved to be superior with respect to detectability on CT.
A phantom study was performed to assess the properties of the wires. The performance of the detection and segmentation algorithm were tested and evaluated on 25 patients. The algorithm correctly detected all fiducial makers, wires and other objects.

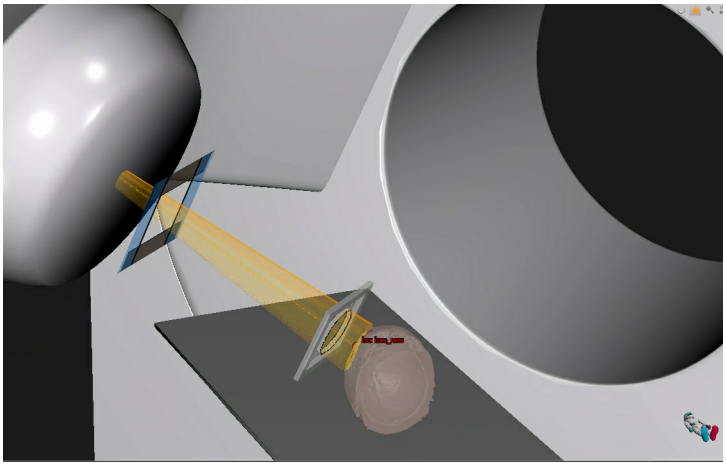

Figure 1: Example of an automatically determined optimal beam and couch angle.

1 Introduction

Electron radiotherapy is an established treatment for non melanoma skin cancer [1]. In recent years, Monte Carlo electron planning has become widely available to accurately calculate dose for electron treatments.
The transition from classic, water tank measurement based, isodose atlases to the current (eMC) practice has a considerable impact on the clinical workflow. In the classical workflow, the radiation oncologist defines the visible target area (either the gross target volume (GTV) or clinical target volume (CTV)) on the skin of the patient using a marker. This area is then used to select the inlay for the electron applicator, either from existing templates or customized through casting for the electron applicator. The beam and couch angles are then defined visually by approximating the beam direction with the projected normal of the target. Due to the difficulty of defining these angles visually, the setup angles can vary per treatment fraction.
Treatment planning using eMC requires high quality Computed Tomography (CT) image data to accurately calculate the dose for the specific anatomy of the patient. The radiation oncologist places a wire on the skin to define the CTV boundary, so the CTV at the surface is visible at the CT. However, accurate segmentation of superficial target volumes on a CT is often challenging and time-consuming for radiation oncologists, who have to segment the CTV on 2D planes while adhering to the 3D skin surface curvatures projected onto the orthogonal planes. Moreover, these CT images often show poor contrast between target and healthy tissues, which increases the difficulty of accurate target segmentation.
In this work, we developed a method to automatically determine the treatment area, starting with a wire around the visible lesion. Using this method, we were able to accurately determine the reference point in the CT dataset, as defined by fiducial markers. Furthermore, using the detected wire on the CT, we could easily determine the optimal beam and couch angle for the treatment.

2 Materials and Methods

2.1 Wire properties

Multiple wires were first tested for robust detectability on a CT scan. The wires should be non-toxic for the human skin and should be easily shaped by the radiation oncologist so to follow the often, highly irregular target surfaces, e.g. in the nasal region.
Copper (Cu), aluminium (Al) and tin (Sn) were considered candidates. Table 1 shows the properties of the wires that were measured. CT scans were obtained with 1 mm thick slices with matrices of 512^2 or 1024^2 pixels. Since a large fraction of non melanoma skin radiotherapy patients have lesions on the skull, the wire should show sufficient contrast with high density bone tissue.
We developed a anthropomorphic skull phantom to test the contrast of the wires. High density plaster ($\pm$ 1500 HU)

Material	Z	Density (g/cm^3)	Diameters (mm)	
Al	13	2.70	0.56	0.90
Cu	29	8.96	0.50	1.06
Sn	50	7.26	0.30	0.50

Table 1: Wires of multiple densities and atomic number were considered. For each material two diameters were used. Note the approximate doubling of atomic number.

mimicked cortical bone ($\pm$ 1300 HU). A thin layer of silicone casting rubber ($\pm$ 140 HU), represented surrounding skin tissue ($\pm$ 100 HU). The contrast of the wire with respect to bone tissue was determined using equation 1

$$\text{contrast} = \frac{I_{\text{wire}} - I_{\text{skull}}}{I_{\text{skull}}}. \tag{1}$$

Artefacts were visually assessed.

2.2 Wire detection

A stepped, region growing wire detection algorithm was integrated in the treatment planning system (TPS, RayStation 12A, RaySearch, Sweden) using Python 3.8. As a standard procedure, the external contour of the patient is outlined on the CT in the TPS. A stepwise, region growing algorithm proved to be compatible with the functionality of the TPS. An initial lookup volume for the wire extended isotropically 2 mm inside and 20 mm outside the external contour.
In the lookup volume, the highest densities ($>$ 2300 HU) were contoured using the gray level threshold functionality of the TPS. An isotropic expansion of this structure of 5 mm formed a next lookup volume. In this volume a threshold of 1800 HU generated an expansion for the wire. The new structure was also limited to 2 mm within the external contour. In the last step, a 3 mm expansion of the resulting structure served as a lookup volume for voxels with a density $>$ 1150 HU. This resulting volume was limited within 2 mm of the external contour. A final expansion and contraction of 6 mm closed remaining small holes.
The stepped, region growing threshold algorithm identified all high metal objects near the skin surface, such as fiducial markers, wires and other objects (e.g. metallic dental implants). Each object has to contain voxels with a density $>$ 2300. Non metal object do not contain densities in the order of 2000 HU. Consequently, the stepped detection process prevented the high density cortical bone to be misidentified as metallic structure, while still identifying connected voxels with a lower density, because of the partial volume effect, as part of the high density structure.
The single high density structure needed to be split in separate parts, with one metalic item each. The high density structure (near the skin) was transformed to a triangle mesh. In this representation connected indices of the triangle points form the separate parts of the structure and can be split using this connections.

Categorie	V_{mesh} [cm^3]	V_{filled}	Z-position [cm]
Fiducial marker	< 0.03	> 0.7	$-0.5 < Z < 0.5$
Wire	-	< 0.1	-
Other object	-	-	-

Table 2: Criteria to assign a part of the high density structure to a category.

Finally, the parts were divided in three categories. To categorize parts, we made use of the concept of filled volume, V_{filled}) (equation 2). Where r_{max} is the maximum distance to the Center of Mass (COM) of all points belonging to a connected part.

$$\begin{aligned} V_{\text{filled}} &= \frac{V_{\text{mesh}}}{\frac{4}{3}\pi r_{max}^3} \\ &\text{where} \\ V_{\text{mesh}} &= \sum_{t \in T} \frac{\mathbf{o}_t \cdot (\mathbf{v}_{t,1} \times \mathbf{v}_{t,2})}{6}. \end{aligned} \tag{2}$$

T represents the set of triangles. The vector from the first point of triangle t to the origin is represented by $\mathbf{o}_t$ and the vectors from the first point to the two other points by $\mathbf{v}_{t,1}$ and $\mathbf{v}_{t,2}$. In table 2 the criteria for the assignment to a category are defined.

2.3 Isocenter, beam and couch angle

The points of the triangle mesh representation of the wire served as input for the calculation of the gantry and couch angle. First, a plane was fitted through the points using the least–squares method as shown in equation 3

$$\begin{aligned} ax + by + c = z \rightarrow Ax = B \\ \begin{bmatrix} a \\ b \\ c \end{bmatrix} = \mathbf{n} = \left(A^T A\right)^{-1} A^T B. \end{aligned} \tag{3}$$

The vector $\mathbf{n}$ defines the normal to the fitted plane and was expressed as a beam and couch angle by expressing the vector in spherical coordinates, correcting for the patient scan position. Two solutions were found; the solution that had a couch angle between 100° and 260° was selected.
Subsequently, the COM of the wire was set as the entrance point of the beam. The isocenter was identified and placed on the surface of the patient by searching for a drop in HU values, resulting in a source skin distance of 100 cm. The HU values were taken by the outward pointing $\mathbf{n}$, crossing the COM. A threshold of -250 HU was taken, where a value of 0 was assigned if below the threshold and 1 if above. The surface of the patient was identified as the furthest gradient step. Figure 1 shows an example of an automatically determined isocenter (where the center of the beam crosses), beam and couch angle.

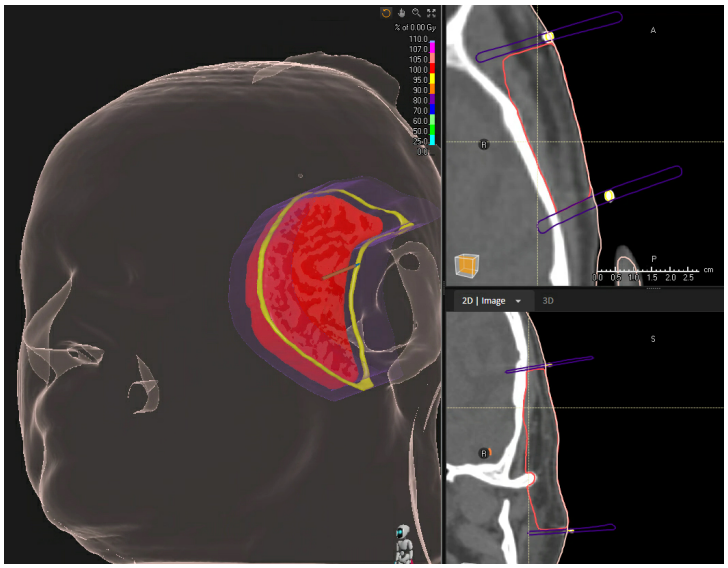

Figure 2: The wire (yellow) is expanded (purple) in the beam direction (arrow) and marks the lateral border of the CTV (red). The CTV depth is prescribed at 1 cm, limited to bony structures.

Finally, the reference point could be determined by taking the COM of the fiducial markers. The first detected fiducial marker was taken as the reference point. In case of two fiducial markers, the most anterior marker defined the lateral position, and the most posterior determined the height. With three located fiducial markers, the mean of the two closest in height defined the height, the other lateral position. The average of all markers was taken as the inline position.

2.4 Target segmentation

The radiation oncologist defined the CTV on the skin by placing the wire around the lesion. The wire was segmented using the algorithm of paragraph 2.2. Together with the optimised beam and couch angles the wire contour served as input for target segmentation.
An expansion of the wire in the direction of the beam marked the surface border of the target area. The radiation oncologist prescribed the depth of the target, eventually limited by organs at risk (OAR). Some OARs such as bone and eyes can be automatically segmented by the TPS. Using standard TPS functionality (margin operations), the CTV was obtained. An example of the target definition is shown in figure 2.

3 Results

The phantom study on Al, Cu and Sn showed that Al did not exceed the density of (cortical) bone, rendering it ineligible for further study. Cu and Sn showed good contrast in the phantom study.
The algorithm developed was tested on 25 patients treated previously at our clinic. All objects were correctly categorized by the algorithm (table 3). Cu wires were occasionally incorrectly identified as two parts (Patients 5, 7, 12 and 17). All Sn wires detected were closed.

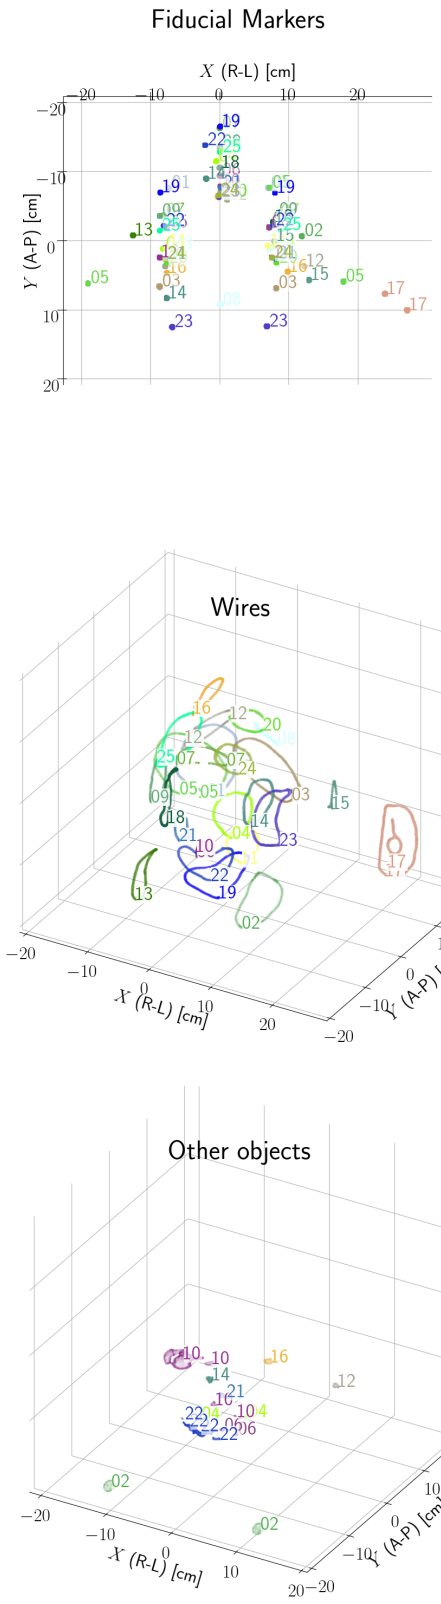

Figure 3: The algorithm correctly detected all fiducial makers, wires and other objects in the set of 25 cases.

Patient	Material	Number of objects detected			Other object type
		Wires	Fiducial markers	Other objects	
1	Cu	1	3	-	
2	Cu	1	1	2	Support structure
3	Cu	1	3	-	
4	Sn	1	3	2	Dental
5	Cu	2	3	-	
6	Cu	1	3	2	Dental
7	Cu	2	3	-	
8	Cu	1	3	-	
9	Cu	1	3	-	
10	Cu	1	3	4	Dental
11	Cu	1	3	-	
12	Cu	2	3	1	Dental
13	Sn	1	1	-	
14	Sn	1	2	1	Dental
15	Cu	1	2	-	
16	Sn	1	3	1	Dental
17	Cu	2	2	-	
18	Sn	1	2	-	
19	Sn	1	3	-	
20	Sn	1	3	-	
21	Sn	1	3	1	Dental
22	Sn	1	3	4	Dental
23	Cu	1	3	-	
24	Sn	1	3	-	
25	Sn	1	3	-	

Table 3: Number of objects identified in each category; the majority of the other objects identified dental

Objects that were not wire or fiducial marker were mostly mostly dental. In one case, the TPS included the couch and supporting structures in the external contour. Parts of this support were categorised as other, metallic, object.
In figure 3 all categorised objects are shown. The target segmentation of the CTV gave consistent results. In some cases the depth of the CTV was adjusted according to anatomical information. In all 25 patient scans, the reference point was correctly identified.

4 Discussion

The introduction of eMC dose calculation has greatly changed the treatment planning and delivery of electron radiotherapy for superficial lesions.Target definition on a CT scan has become more precise but less straightforward. We presented a method to automatically segment the target. This method takes intuitively the beam as a starting point and generates a target region in the direction of the beam. The proposed algorithm proved to be reliable in all 25 clinical situations.
Cu showed limitations as a closed wire was split into two parts in 4 of 14 cases. Sn proved to be the optimal material for the wire detection and segmentation of the CTV. Besides the excellent detectability on CT, the material can easily be shaped to conform to complex geometries of the CTV. Sn wire is easily available for limited cost.

The automatic detection and segmentation process creates CTV contours where the radiation oncologist can evaluate on and adjust where necessary. This saves considerable time in the clinical workflow process, which enables a more efficient workflow. The next step of this work will evaluate the accuracy of the CTVs created by this process with input from our radiation oncologists.
The presented auto segmentation methodology and algorithm can be extended to automate the definition and segmentation of a standard or patient specific bolus on the CT image. Methods to design [2] and construct [3] a patient specific bolus have been earlier proposed.

5 Conclusion

We have presented a robust method to automatically and accurately detect the wires and segment the CTV for electron radiotherapy. Optimal beam and couch angles are determined using our algorithm. The Sn wire performs better than Cu wire on its detectability on a CT.

Abstract Segmentation of flaps plays a pivotal role in the treatment planning of radiotherapy for patients with head and neck cancer. Accurate and robust flap segmentation could significantly enhance the accuracy and safety of radiotherapy. In this work, a comparative study was carried out using two distinct models for fully automated medical image segmentation: the nnUNet framework, leveraging the U-Net convolutional neural network architectures, and MedSAM, founded on transformers. Both model were previously trained and validated using a well-curated GORTEC (Groupe d'Oncologie Radiothérapie Tête Et Cou) prospective multicentric cohort. The present work focuses on the external validation of trained models in a "real-life" external cohort. As it was already observed in the previous study, the nnUNet outperformed MedSAM (Mean Dice score of 55 versus 74). The performance of nnUNet was lower than it was in the test set of the previous study , although the drop in performance is mostly due to the fact that the method works well on a majority of cases but completely fails in some studies that suffer from artifacts or with flaps with previously unseen or rare locations/characteristics. Our future work will focus on improving the performance of the segmentation in these cases.

1 Introduction

Head and neck cancer (HNC) constitutes a complex oncological domain where therapeutic interventions, particularly radiation therapy (RT), require accuracy and robustness to reach an optimal balance between therapeutic efficacy and sparing of healthy tissues in organs at risk (OAR). The efficacy of RT is contingent upon the accurate delineation of anatomical structures. Flaps, comprising diverse tissues within the intricate head and neck region, exhibit inherent morphological intricacies, therefore posing a challenge for conventional segmentation methodologies applied to Computed Tomography (CT) three-dimensional (3D) images.

The requirements for accurate and robust flap segmentation is underscored by its direct impact on the comprehensive analysis of dose-volume effects, thereby influencing treatment planning and outcome prognostication. Traditional segmentation paradigms manifest inadequacies in addressing the intricate morphological variations characterizing flaps, prompting the exploration of advanced computational methods, particularly those rooted in Deep Learning (DL) frameworks.

The application of DL is widespread in the field of medical imaging, particularly in the context of RT planning. Defining target volumes and identifying OAR during RT planning is a complex task, given that the native anatomy undergoes modifications due to tumor resection, resulting in significant tissue defects and post-operative changes such as inflammation, edema, fibrosis, and the presence of surgical clips.

For an accurate assessment of the causality of radiation-induced deterioration in the functional outcomes of reconstructive flap surgery, it is imperative to achieve fully automatic flap delineation. This process aims to address issues such as flap atrophy and fibrosis. However, the delineation of flaps in CT 3D images poses a novel, challenging, and time-consuming task for radiation oncologists.

Recent advancements in DL have demonstrated superior performance in the segmentation of complex 3D images compared to traditional computer vision techniques [1]. While segmentation models are increasingly prevalent in the analysis of CT or magnetic resonance imaging (MRI) scans, their primary application has been in discriminating the presence or absence of tumors or cancers [2].

This study endeavors to contribute to the field by presenting segmentation and evaluation techniques specifically tailored for flap analysis in the context of reconstructive surgery and RT. The focus is on addressing the challenges associated with flap delineation and evaluating the performance of the proposed techniques.

2 Materials and Methods

2.1 Datasets

Two distinct datasets were relied upon. The first one served the dual purpose of training and testing our segmentation models. It contained DICOM-RT data (CT images and manual contours) pertaining to poRT planning, sourced from a GORTEC (Groupe d'Oncologie Radiothérapie Tête Et Cou)) prospective study. A total of 152 patients, recruited across 33 centers between 2019 and 2021, were included in the study, with the exclusion of 4 patients due to the missing CT slices. The remaining 148 patients' CT and RT structure sets encompassed tumor volumes and OAR information. The delineation of ground truth flap contours adhered to established guidelines [3] and was conducted on Raysearch station

v8.0. Importantly, the contouring process was executed independently by two experts, who were blinded to patient characteristics and outcomes.
The second imaging dataset exclusively served as an external testing set, for evaluating the generalization capabilities of the models. This dataset comprised poRT planning DICOM-RT data sourced from Amiens CHU, involving 70 patients. Similar to the first dataset, the creation of ground truth flap contours followed the delineation guidelines [3] and was performed on Raysearch station v8.0. The contouring process in this instance was also conducted independently by two experts unaware of patient characteristics and outcomes during the procedure. Because this dataset was sourced from routine clinical practice data, it can be considered a "real life" dataset, in contrast to the more curated data of the first dataset, collected in a prospective study.

2.2 nnUNet Segmentation Model

The nnU-Net framework was employed for the training of a pre-configured generic U-Net [4] on our first (GORTEC) dataset [5]. A random partitioning of the dataset into training and test sets was performed using an 80/20 split, resulting in 120 patients for training and 28 patients for testing. All images were uniformly resampled to a voxel size of $1.17\times1.17\times2mm^3$, selected as the median voxel size within the dataset. Resampling was carried out using 3rd-order spline interpolation for images and nearest-neighbor interpolation for Ground Truth masks.
Data augmentation techniques encompassed the application of nnU-Net augmentation methods, including random flips, affine transformations (rotation, translation, and/or scaling applied to the volume), elastic deformation (deformation along a grid mesh) of both CT scans and segmentation maps, brightness and contrast adjustments, as well as image quality reduction.
Standard parameters of the nnUnet framework were utilized.

2.3 MedSAM Segmentation Model

The Medical Segment Anything Model (MedSAM) [6]is derived from the open-source Segment Anything Model (SAM) [7], developed by Meta AI. MedSAM is applied to medical image segmentation. It adeptly processes both two-dimensional (2D) and three-dimensional (3D) images, with the caveat that 3D images are processed as independent 2D slices.
In our efforts to fine-tune MedSAM for the specific task of delineating flaps in CT images, we adhered to the network architecture delineated in SAM [7]. This architecture comprises an image encoder and a mask decoder. The image encoder [8] utilizes positional encoding [9] to map the input image into a high-dimensional image embedding space. Following this, the mask decoder integrates the image embedding and prompt features through cross-attention [10].
The network employed in our investigation is built upon the transformer architecture [10], incorporating a Vision Transformer (ViT)-derived image encoder designed to extract features from images. Additionally, a mask decoder was implemented to generate segmentation outcomes and confidence scores, making use of the image embedding and output token. Striking a balance between segmentation efficacy and computational efficiency, we opted for the foundational ViT model as the image encoder.
During the data pre-processing phase, the dataset was partitioned with the same split as for the nnU-Net training and evaluation, relying on an 80/20 split ratio, resulting in distinct training and test sets encompassing 120 and 28 patients, respectively. The initialization of the model involved employing the pre-trained MedSAM model in conjunction with the ViT-Base model. All trainable parameters within the image encoder and mask decoder underwent updates throughout the training process.
The chosen loss function constituted an unweighted summation of Dice loss and cross-entropy loss, a combination proven to exhibit robustness across diverse segmentation tasks [11]. Optimization of the network was achieved through the implementation of the AdamW optimizer [12], configured with parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$, an initial learning rate set at $1e^{-4}$, and a weight decay of 0.01. The training regimen utilized a batch size of 160, and data augmentation was omitted. Employing Quadro P400 GPUs, the model underwent training for 2000 epochs, with the final model selected based on the last checkpoint.

2.4 Evaluation

Both trained models were then applied without any fine-tuning or changes in the parameters, on the second dataset from the CHU Amiens. Quantitative evaluation of performance was reported using the mean and median Dice score, as well as individual patient scores. In addition, the behavior of the algorithm with respect to image characteristics, such as the size and location of flaps, or the presence of metal artifacts, was qualitatively assessed.

3 Results

This section will present both quantitative and qualitative outcomes for the comparative assessment of MedSAM and nnUNet models in the context of automated flap segmentation.

3.1 Quantitative results

It is important to emphasize that both models were exclusively trained using the first dataset and evaluated the second dataset as an external validation set. In the initial training and evaluation of both models on the first dataset, the nnU-Net outperformed the MedSAM model (0.74 vs 0.55 mean Dice

and 0.87 vs 0.63 median Dice). In assessing the generalizability of segmentation models, the mean and median Dice scores, based on the external Amiens dataset, are presented in Table 1. MedSAM demonstrated a mean Dice coefficient of 0.35, whereas nnUNet exhibited a higher mean Dice coefficient of 0.62. Furthermore, nnUNet surpassed MedSAM in terms of the median Dice coefficient, with values of 0.66 and 0.37 respectively. Both methods exhibited a decrease of performance when applied to this new "real life" dataset (from mean Dice of 0.74 to 0.62 and median Dice from 0.87 to 0.66).

Model	mean DSC	median DSC
nnUNet	0.62	0.66
MedSAM	0.35	0.37

Table 1: Dice scores of nnU-Net and MedSAM on Amiens dataset.

MedSAM yielded an average DSC with a mean and median value of 0.35 and 0.37, respectively. This performance was deemed inadequate in comparison to the outcomes achieved by nnN-Unet. An examination of the MedSAM results exposed significant variations, with certain images exhibiting satisfactory delineation (DSC: 0.55-0.75), while others displayed inaccuracies (DSC < 0.10-0.20). This discrepancy suggests that the absence of 3D modeling particularly penalized the efficacy of MedSAM in the challenging task of 3D flap delineation. Figure 1 describes the observed behavior, illustrating the distribution of Dice scores calculated for each of the 70 patients (the entire Amiens dataset) according to the nnUNet and MedSAM models.

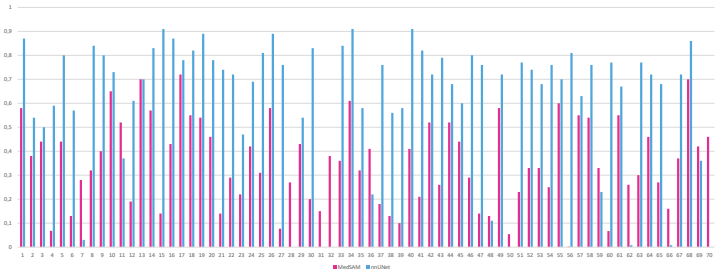

Figure 1: Distribution of Dice scores for the entire Amiens dataset according to nnUNet (blue) and MedSAM (pink) models

3.2 Qualitative results

Similarly as for the behavior of the algorithms in the first dataset, some variability was also observed in the performance, as a majority of cases were well segmented and a minority displayed non-satisfactory delineation or complete failures, which could be mostly attributed to the rare size/location of the flap and/or the presence of moderate to severe artifacts as illustrated in Figure 2.
The results depicted in Figure 3, present consecutives slices

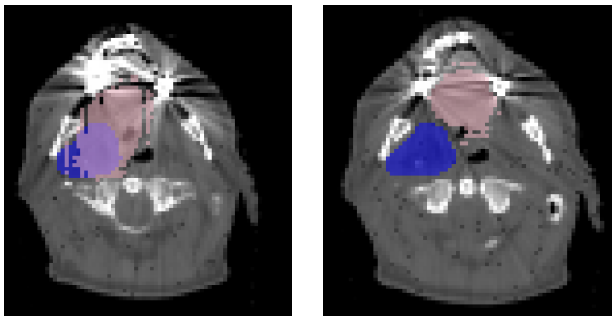

Figure 2: Example of segmentation results on training dataset (two consecutive slices) produced by MedSAM model in the presence of metal artifacts.

from one patient, showcase the segmentation outcomes generated by the nnUNet and MedSAM models.

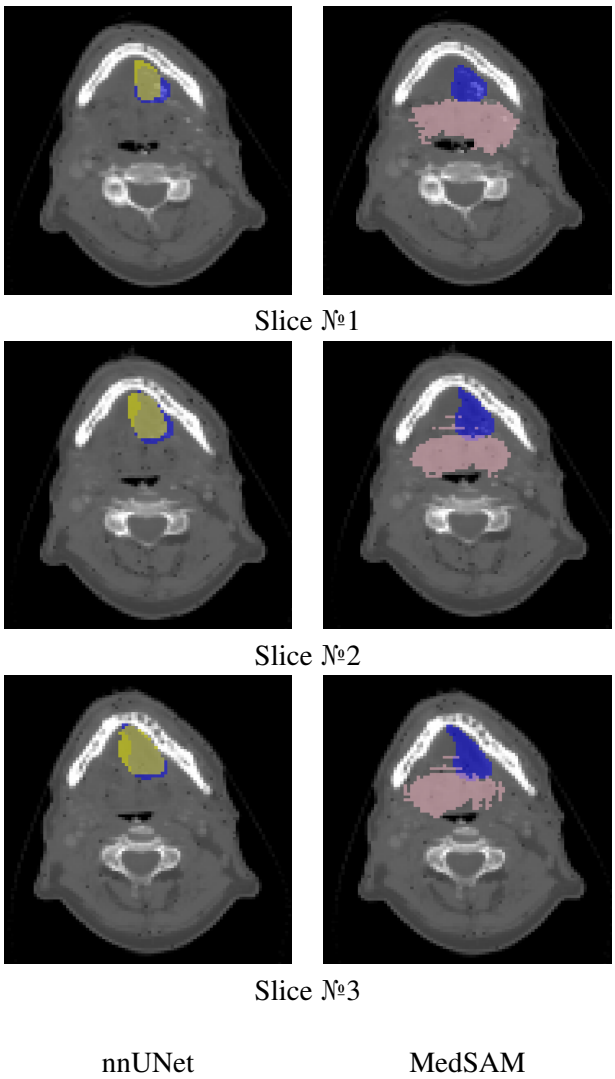

Figure 3: Example of segmentation results produced by nnU-Net & MedSAM models on consecutive slices (Ground truth in blue, nnUNet segmentation in yellow and MedSAM segmentation in pink).

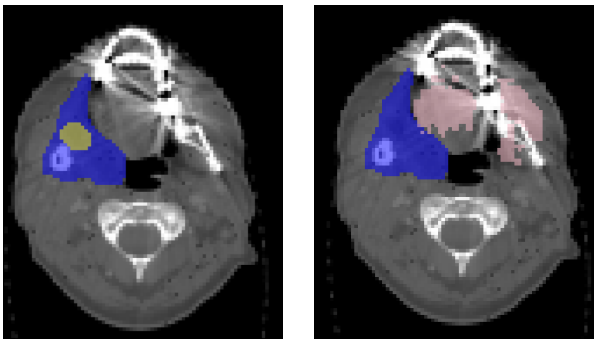
In these representations, the ground truth is denoted in blue, nnU-Net segmentation in yellow, and MedSAM segmentation in pink. The visual evidence highlights the superior

performance of nnU-Net over MedSAM in the context of flap segmentation. The segmentation produced by nnU-Net exhibited a closer alignment with the ground truth compared to MedSAM, indicating a higher degree of concordance between nnU-Net's segmentation output and the actual delineation of structures.
The discerned generalization performance of nnUNet and MedSAM in the context of flap segmentation, particularly when confronted with dental metal artifacts, is visually illustrated by Figure 4.



nnUNet MedSAM

Figure 4: Example of segmentation results on Amiens dataset (slice 17) produced by nnUNet and MedSAM models in the presence of metal artifacts.

4 Discussion

nnU-net is specifically designed for medical image segmentation tasks, utilizing a contracting and expanding path to capture and refine features from medical images. It typically achieves higher accuracy in medical image segmentation tasks compared to SAM. SAM, with its general-purpose nature, can be applied to various tasks, including image segmentation, natural language processing, and code generation. It provides class-specific outputs, allowing it to label each segment with a corresponding class.
Our results confirm the previous findings that nnU-Net strongly outperforms MedSAM for automatic flap segmentation in CT images of postoperative HNC RT patients. However, we also found that the performance of the algorithm substantially decreased in this new "real life" evaluation dataset. However, this trend was not systematic in all the 70 cases, as 48 out of 70 had Dice scores between 0.6 and 0.9. The lower mean and median scores are therefore due to more cases with complete failures (flap not detected or confused with another structure, or due to metal artifacts).

5 Conclusion

Our external validation in a new, "real life" cohort of 70 patients, suggest the previously trained nnU-Net model performs with satisfactory accuracy in a majority of cases. However, there are, as it was the case for the training/validation step in the multicentric prospective study, some patients for which the method is unable to properly detect and/or delineate the flaps, either because the flaps is at a rare location or because of the presence of strong artefacts. Regarding the comparison between nnU-Net and MedSAM, our new evaluation confirms the superiority of nnU-Net, MedSAM being unable to properly account for the 3D nature of the data and to take into consideration the information between adjacent 2D slices processed independently. Our future work will focus on improving the performance on rare locations/characteristics of flaps and dealing with cases that present moderate or severe artifacts.

Abstract Prostate cancer is the most common non-skin cancer for men. Despite of early diagnosis and intervention, the recurrence rate remains high after primary treatment. It was reported that, following external beam radiotherapy (EBRT), local recurrence is mostly dose-dependent and most frequently occur at the site of the dominant intraprostatic lesion (DIL). Dose escalation to the DIL via simultaneous integrated boost (SIB) may improve local tumor control. However, accurate delineation of DIL based on on-board MR images poses a great challenge for MRI guided prostate adaptive therapy. In this work, we propose an algorithm of edge enhancement confidence based on multimodal images, to simultaneously utilize the DIL position information of pre-treatment PET images and the alignment information derived from daily MR images, to accurately identify DIL areas. The effectiveness of the framework was evaluated on prostate cancer patients treated with SBRT on a low field MRI system . The obtained DIL confidence images, account for daily motion on daily MR images improving the accuracy and robustness oftarget delineation and dose escalation for adaptive radiotherapy.

1 Introduction

Prostate cancer(PC) is the most common non-skin cancer for men, representing 7.3% of all new cancers globally[1]. Approximately one in six men will be diagnosed with prostate cancer during their lifetime, and about one in 36 will die of prostate cancer, with an estimated 268,490 cases diagnosed in the United States in 2021[2, 3]. Despite early intervention, the recurrence rate of approximately 20-50% after primary treatment[4]. Following external beam radiotherapy (EBRT), local recurrence is most commonly observed in the dominant intraprostatic lesion (DIL) site[5]. Many clinical studies have demonstrated that dose escalation to the DIL via simultaneous integrated boost (SIB) may improve local tumor control[6].

However, accurate delineation of DIL poses a great challenge in computed tomography(CT). Many studies have used functional imaging to delineate DIL, such as single photon emission computed tomography, positron emission tomography/computed tomography(PET/CT), and Magnetic Resonance Imaging(MRI).PET has high specificity in identifying DILs and benign areas and has high sensitivity in identifying some very small DILs.

In recent years, MR-guided adaptive radiotherapy has developed rapidly, MR guided RT (MRgRT) has superior soft tissue contrast during image guidance or treatment planning. MRI-guided radiation therapy systems, ie, Viewray and Unity[7, 8], allow for MR imaging while patients in treatment position, thereby promoting precise dose delivery within the target area for adaptive radiotherapy. Although daily MR imaging can promote the difference between DIL and benign areas, accurate DIL delineation without PET images presents a major challenge.

Many studies have proposed semi-automatic segmentation algorithms[9]. Compared with automatic segmentation algorithms through neural networks, semi-automatic segmentation can introduce prior knowledge and does not require training. In addition to binary segmentation results, confidence can often be given. Sinop and Grady proposed a common framework based on semi-automatic segmentation algorithms. include graph cuts, and random walk algorithms for interactive segmentation[10]. However, these algorithms are not well adapted to 3D medical images and multi-modal scenes.

To solve the problem of accurately identifying DIL areas during the adaptation radiotherapy, we propose an automated framework based on multimodal reference images, which allows us to simultaneously utilize the DIL position information of offline PET images and the motion information of daily MR images, thereby Accurately identify DIL areas.

2 Materials and Methods

We propose a framework to calculate ROI confidence based on pre-treatment PET and daily MRI. The ROI confidence algorithm is adapted from the algorithm proposed by Liu and Li et al[11]. The original algorithm requires manual designation for a rough trimap, marking extremely few foreground voxels, many background voxels, and a large unknown region. Our adapted algorithm is designed to streamline the adaptive radiotherapy workflow. We implement an automatic confidence algorithm and achieved completely automatically through PET without requiring the manual designation of a rough trimap. Our proposed workflow is illustrated in Figure 1.

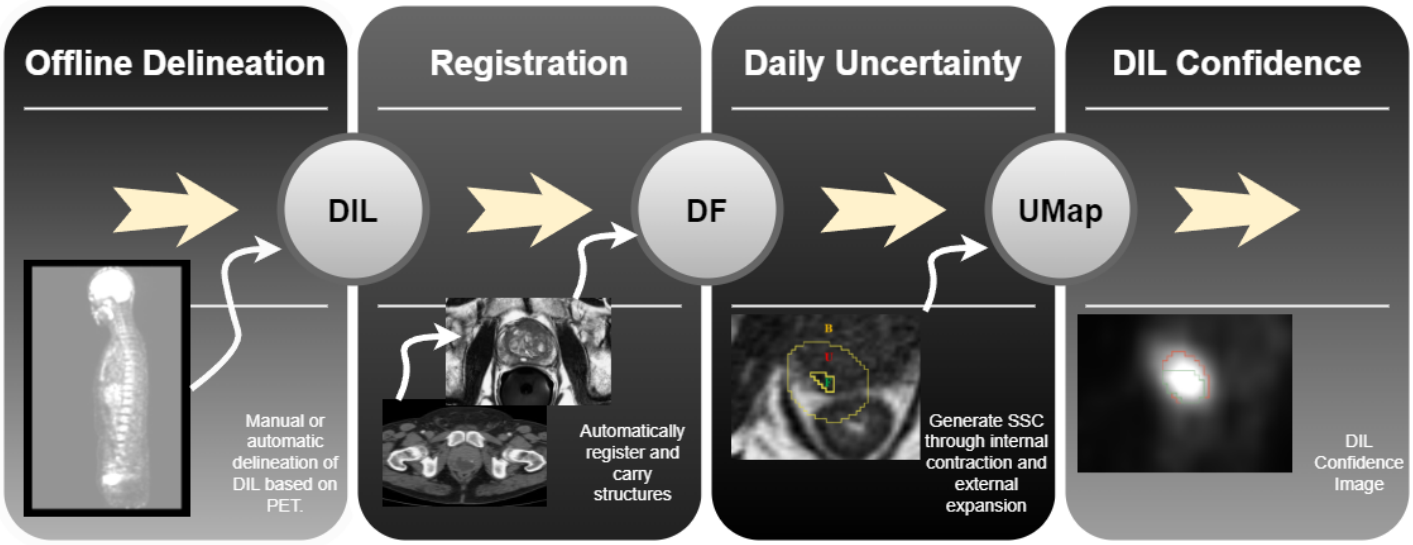

Figure 1: Framework of generating accurate DIL structure confidence based on multimodal images.

Specifically, on the patient's pre-treatment PET/CT images, the prostate structure on the CT is automatically delineated through an automated AI-segmentation tool Manteia AC. The DIL area is automatically segmented through the threshold in the corresponding PET area.

The segmented DIL structure is contracted and expanded by 50% in size in 3-dimension space. The contracted structure is defined as a certain area, and the shell formed by the expanded structure and the contracted structure is defined as an uncertain area. Defined areas in such a way as to cover possible motion in adaptive radiotherapy and the sum of certain and uncertain areas is defined as a structure with solution confidence (SSC). The confidence in the determined area is set to 1, the uncertain area is set to 0.1, and the rest is set to 0.

In the process of adaptive radiotherapy, the MRI of the day is obtained, and the pretreatment CT is deformed to the MRI of the day through deformable registration to obtain the deformation field. The SSC is superimposed on the daily MRI through the deformation field. After registration, the area with a confidence level of 1 in the SSC is positioned as a reference point in the algorithm, and the confidence level of the area with a confidence level of 0 is calculated by calculating the correlation matrix between 3-dimensional multi-modal pixels. The final DIL confidence images were determined based on offline PET and MRI.

We verified the effectiveness of the algorithm on retrospective prostate cancer patients treated on a low-field MR treatment system. Each patient underwent a pre-treatment PET-CT scan and daily MR scans before each treatment fraction.

3 Results

Figure 2(a) illustrates a typical patient of the registration results of CT and MR. Except for the large changes in the skin, the bony structures are completely aligned.

Figure 2(b) shows registration of PET to onboard MRIs. 2(c) DIL confidence image fusion MR. 2(d). DIL confidence image fusion PET.

Calculation speed is very important for adaptive radiotherapy. The calculation of a 3D multi-modal correlation matrix is very time-consuming. However, in the optimized algorithm, the confidence image calculation time of a typical patient is 2.13 seconds.

4 Discussion

We propose a framework that can automatically run and solve DIL confidence images. This framework allows input of pre-treatment PET/CT and DIL structure, as well as daily MRI, to solve the confidence image of DIL structure through a multi-modal 3D correlation matrix. The proposed framework shows promising to accurately delineate the DIL area for prostate adaptive radiotherapy, enabling safer for dose escalation to the DIL via SIB treatment delivery.

The proposed framework is novel in the following aspects. Compared with traditional semi-automatic segmentation algorithms, the proposed framework automates scaling the pre-treatment PET, which doesn't require manual intervention. Compared with deep learning-based algorithms, the framework does not require a large amount of data for training.

5 Conclusion

We propose a framework of utilizing multimodal images, based on pre-treatment PET and onboard treatment MRs, to accurately delineate DIL with confidence. The proposed framework enables the accuracy and reliability of dose escalation to the DIL for online prostate SBRT adaptive radiotherapy.

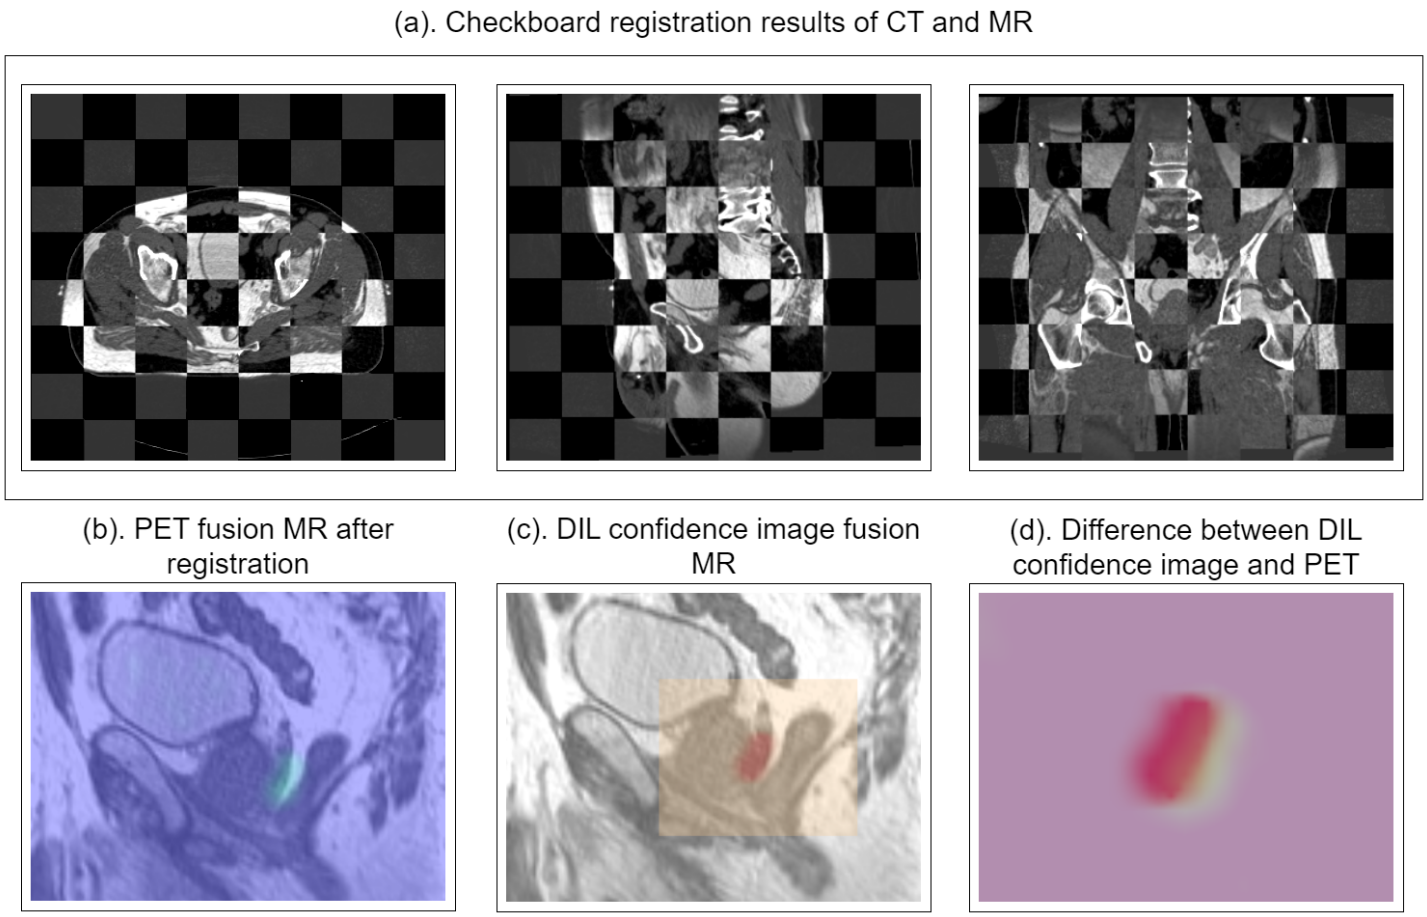

Figure 2: Multimodal calculation of DIL structure confidence results. (a). The registration result is a checkerboard pattern, from left to right, the horizontal plane, the sagittal plane, and the coronal plane. (b). PET fusion MR. The green area is PET. (c). DIL confidence image fusion MR. The red area is the DIL confidence, and the darker the red, the higher the confidence level. (d). Abstract Medical image segmentation plays a crucial role in clinical imaging services, with automatic segmentation techniques being pivotal for enhancing diagnostic accuracy and saving time. Despite their importance, current auto-segmentation methods exhibit suboptimal accuracy, marked by a significant gap between automated results and the ground truth. Traditional methods rely heavily on the image data alone, while clinicians typically utilize additional contextual information beyond the images for accurate contouring of targets and organs. To bridge this gap, our study introduces an innovative approach that incorporates clinical inputs into the auto-segmentation model. We collected clinical data that could potentially alter the segmentation, translated it into meaningful text, and employed a transformer-based text encoder to convert these texts into distinct vectors. These vectors effectively scale the features in our auto-segmentation model, allowing it to incorporate and benefit from multi-modal clinical information. This methodology significantly enhances segmentation quality, as demonstrated in our application of prostate segmentation for radiation therapy, where the delineation of prostate target involves integrating further clinical findings and physician preferences. Our experiments focused on five key factors that influence the segmentation of prostate targets for radiation therapy, with results showing that our proposed method not only outperforms the baseline model lacking clinical input but also surpasses current state-of-the-art methods. This advancement in auto-segmentation technology holds the potential to revolutionize diagnostic processes, offering a more accurate and efficient tool for clinicians.

1 Introduction

Medical image segmentation is a critical task that classifies pixels to identify specific regions within medical images. While clinicians can perform segmentation manually, this process is time-consuming and requires specialized training. Hence, automatic segmentation has been proposed, particularly for CT and MRI images[1]. Although automatic segmentation is already used in various clinical applications, most methods still rely solely on image data.

Recent advancements in natural language processing[2, 3], notably the development of CLIP[4], have been significant. CLIP can embed text and image inputs into a shared vector space, potentially revolutionizing medical image auto-segmentation, which often requires information beyond the images themselves.

To enhance medical image segmentation using additional modalities, we propose a framework that utilizes both image and supplementary information. With variables identified as influential to the segmentation task, our process begins by collecting the data and translating the variables into concise, informative sentences. These sentences are then encoded using a transformer-based text encoder, producing a unique vector embedding for each input. Incorporating this encoded information into a standard image-based segmentation model, we achieve improved segmentation results.

We evaluated our method in a radiation oncology application: prostate segmentation for prostate cancer patients. Five variables were considered for their potential impact on segmentation during radiotherapy[5, 6]: slice thickness, IV contrast, spacer, physician, and MRI. These variables were converted into text, encoded by a pre-trained language model into a vector space, and then normalized and sampled for integration into the segmentation network. The sampled vectors scale features at multiple levels within the neural network, merging the text embedding with image features. This process culminates in decoding the hybrid image-text features to achieve segmentation.

Our method significantly outperforms the baseline neural network without text inputs, addressing the challenge of data scarcity that limits the efficacy of learning-based auto-segmentation. Typically, hundreds to thousands of images are required to train a deep neural network for medical image auto-segmentation. Insufficient data can severely compromise model accuracy. By integrating text data with image data, our method provides richer information, enhancing segmentation accuracy. We also present a controlled text analysis demonstrating how each variable influences segmentation model behavior.

In summary, our contributions are:

- A novel segmentation framework that incorporates medical inputs from multiple modalities into image-based segmentation.
- Validation of our method in prostate radiotherapy, demonstrating superior performance compared to baseline methods.
- Efficacy of our approach in multiple down-sampled datasets, showing optimal performance with limited data availability.

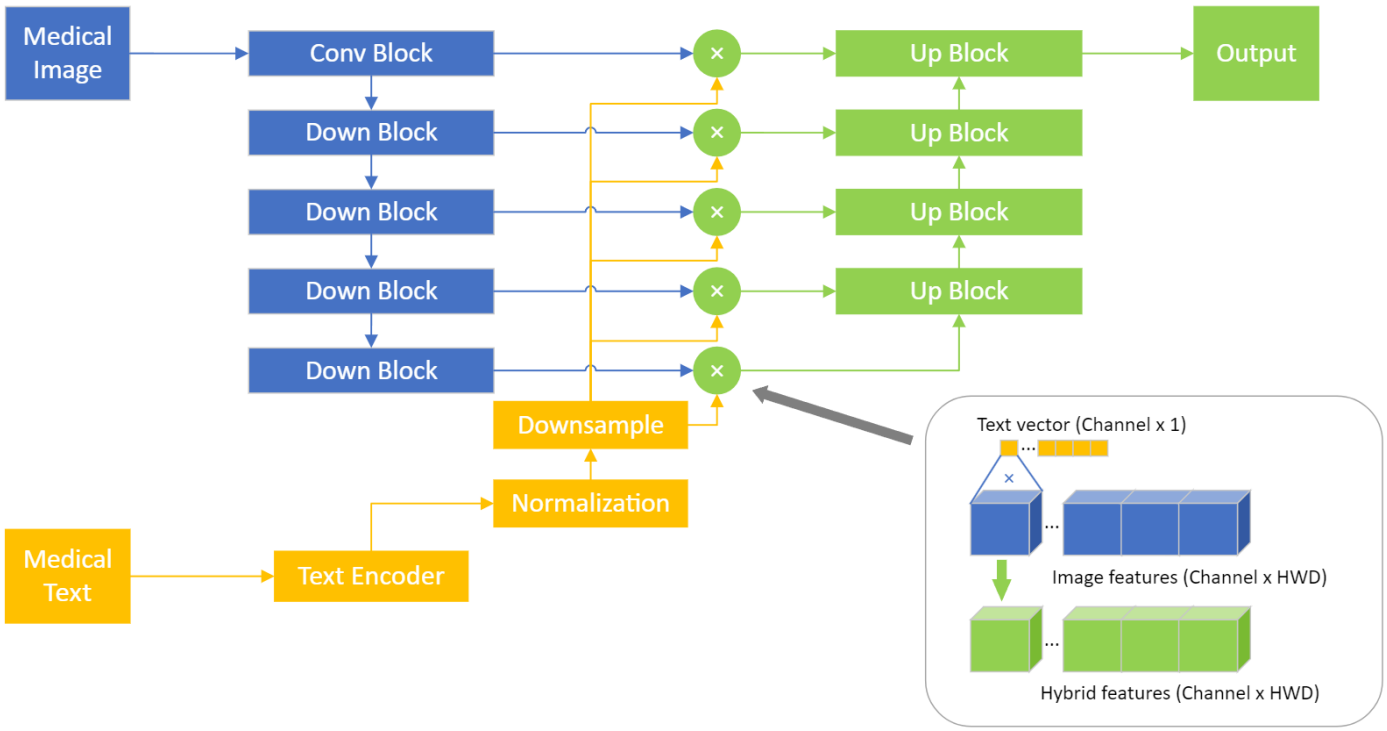

Figure 1: The proposed framework and details.

2 Materials and Methods

Joint framework of image and text input The proposed framework, as illustrated in Figure 1, operates on two primary inputs: a medical image and accompanying medical text. The medical image could be a standard CT or MRI image; in radiation oncology, 3D CT images are typically utilized for treatment planning. These images are processed using a U-Net image encoder, producing encoded image features across five different resolutions.

The second input is medical text. Clinical inputs are often initially in non-textual formats, necessitating translation into text. This process requires a deep understanding of clinical data to ensure that the resultant text is both distinct for different variables and amenable to encoding by a standard text encoder. Once we obtain well-translated text, it is encoded using a text encoder like the CLIP text encoder. The CLIP model, pretrained on a diverse range of internet datasets including medical data, is well-suited for encoding general medical-related texts. It converts each word of a sentence into a token, resulting in a token series that mirrors the sentence's length. This series is then transformed into a 512-value 1-D vector.

To integrate this vector into the deep learning network effectively, we normalize it to a mean of 0 and a standard deviation of 1. This normalization is crucial for stabilizing the training process, as it reduces variability in model accuracy across training sessions. Subsequently, the text vector undergoes down-sampling to align its dimensions with those of the image features. This involves applying stacked down-sampling layers and collecting the output of each layer. Each down-sampled text vector is then utilized to scale an image feature of a corresponding size, as depicted in Figure 1.B. The resultant scaled features, embodying both image and text characteristics, are decoded using a standard U-Net decoder to achieve the final segmentation.

The model is trained using cross-entropy and Dice loss, employing an Adam optimizer with an initial learning rate of 10^{-5}.

Application of prostate segmentation

In this section, we detail the implementation of our proposed framework in a prostate segmentation task. Current automatic segmentation tools for the prostate predominantly rely on image findings, yet their effectiveness has been shown to diminish over time. A recent study revealed a decline in pixel accuracy for newer patient images. This degradation in model performance is attributed to various time-sensitive variables that either alter the image or affect prostate segmentation. Five variables, in particular, are noted for their significant impact on model accuracy:

- **CT Slice Thickness**: Changes in CT slice thickness can alter the perceived prostate volume in pixel terms. A 3 mm slice thickness, for instance, reduces the number of slices containing the prostate.
- **Intravenous Contrast**: This contrast agent, injected venously, enhances body fluid contrast. It particularly increases urinary contrast in the bladder, clarifying the boundaries between the prostate and bladder.
- **MRI Imaging** When available, MRI images of the prostate region are used for more accurate delineation.

Variable	Values	Translation
CT slice thickness	1.5 mm, 2 mm,3 mm	The CT image slice thickness is 1.5/2/3 mm.
MRI availability	Yes, No	The patient has an/no MRI image.
Intravenous contrast	Yes, No	The patient has a normal/higher contrast in bladder.
Spacer hydrogel	Spacer regular, Spacer VUE, No	The patient has a no/an invisible/visible spacer hydrogel.
Physician	A, B, C, D, E, F, G, H, I, J	The prostate is contoured by physician X.

Table 1: The 5 variables of prostate segmentation and their possible values and translation.

Studies suggest that prostate delineation based on MRI is generally smaller than that based solely on CT.

- **Spacer Hydrogel**: This absorbable hydrogel, injected before imaging, comes in two types: Spacer VUE, which is visible in CT scans, and Spacer Regular, which is less visible. Their presence can affect the imaging of the prostate.
- **Physician Contouring**: Physicians contour the prostate using institutional guidelines and personal preferences, leading to delineations that reflect various personal styles.

We incorporated these five variables into the prostate delineation process, guiding our framework's segmentation approach. Each variable was translated into sentences summarizing its effect on prostate segmentation, as outlined in Table 1. These sentences were then inputted into the text encoder of our framework.
For practical application, we collected a clinical dataset of 729 patients from a cancer hospital.

3 Results

3.1 CLIP-UNet has a higher performance than U-Net

We compared our proposed model with a baseline model and a state-of-the-art (SOTA) method for medical image segmentation. The results are presented in Table 2, where five models were tested on the same test set comprising 82 patients. MIS-FM, a foundational model for medical image segmentation, was trained on the same training set. U-Net (16) represents a typical 3D U-Net with 16 initial channels. Given that 3D models are substantially larger than 2D models, the model size can be a limiting factor in some research environments. A 16-channel model provides a balanced trade-off between size, speed, and performance. Similarly, U-Net (32) is a 3D U-Net with 32 initial channels, equivalent to the full-scale model described in the original paper. The last two columns detail our proposed method: CLIP-UNet with 16 and 32 initial channels, corresponding to the U-Net configurations.
CLIP-UNet demonstrated significantly higher accuracy compared to both the 16-channel and 32-channel U-Net models. It also surpassed MIS-FM in terms of accuracy. Particularly,

Model/Performance	Test Dice	Model Size
MIS-FM	84.02%	526 MB
U-Net (16)	83.43%	12.7 MB
U-Net (32)	84.43%	50.6 MB
CLIP-UNet (16)	86.20%	12.7 MB
CLIP-UNet (32)	86.40%	50.6 MB

Table 2: Performance of proposed framework, baseline model and SOTA method

CLIP-UNet with 16 initial channels outperforms U-Net by a large margin of 2.77%. Additionally, the text input for CLIP-UNet can be pre-encoded before testing, as there is a limited variety of texts. Once all possible texts are encoded, the text encoder within the model becomes unnecessary; only the encoded text embeddings are needed. Consequently, the model size of CLIP-UNet matches that of the corresponding U-Nets with the same channel count. Furthermore, the computational cost of CLIP-UNet during inference is also comparable to that of U-Net.

3.2 CLIP-UNet is better than U-Net with fewer data

The proposed segmentation framework utilizes a greater number of medical inputs compared to the baseline U-Net, given the same number of patients. Consequently, CLIP-UNet shows promise for achieving superior performance even with a smaller patient cohort for training. In our experiment, we created multiple sub-datasets from the full dataset, training both CLIP-UNet and U-Net on each. The findings are detailed in Table 3. The complete dataset comprised 729 training patients, with the Dice scores for CLIP-UNet (32) and U-Net (32) being 86.49 and 84.43, respectively. Subsequently, we randomly selected 700 patients from the original 729 to form a training subset, applying both models to this subset. This process was repeated by further sampling down to 600, and progressively to 100 patients, each time training both models anew. The evaluation set of 98 patients and the test set of 82 patients remained constant across all models. The Dice scores for models trained on both the complete dataset and the subsets are presented in Table 3.
As the volume of training data decreases, CLIP-UNet demonstrates remarkable resilience against performance decline. Notably, with as few as 300 training cases, CLIP-UNet's

Training data size	U-Net	CLIP-UNet
100	71.86	74.70
200	81.32	78.69
300	80.91	84.48
400	82.19	85.08
500	82.87	85.90
600	84.99	86.15
700	84.36	86.34
729	84.43	86.40

Table 3: Performance of CLIP-UNet and U-Net with different number of training patients. The result is the tested Dice score in percents.

performance still holds at 84.48%, surpassing that of U-Net trained on the full dataset. This outcome suggests that the paired medical text provides substantial guidance for accurate prostate segmentation.

3.3 Analysis of variables with controlled text guidance

This experiment evaluates the trained CLIP-UNet (32) using the complete training dataset, but with controlled texts during testing phase only. We manipulated each variable to indicate its correctness, for instance, altering the statement from "The patient has an MRI image." to "The patient has no MRI image." To transition each variable from correct to incorrect, we altered them to their subsequent possible value, such as changing 'Physician D' to 'Physician E', or 'invisible spacer' to 'visible spacer'. We analyzed each variable in two scenarios: one where a single variable was incorrect while the others were correct, and another where a single variable was correct while the others were incorrect. These variations were tested with the CLIP-UNet (32) on a test set comprising 82 patients.

We use the CLIP-UNet with accurate text input as a baseline and compares all other test results against it. It is observed that the UNet's performance is 1.97% inferior to that of the CLIP-UNet. Furthermore, when all variables are incorrect, the CLIP-UNet's accuracy decreases by 2.56% compared to when variables are correct. This suggests that the improved accuracy of the CLIP-UNet is heavily reliant on the accuracy of the variables in the texts. Comparing the baseline to scenarios with a single incorrect variable, it appears that Slice Thickness, IV Contrast, and Physician information exert a minor influence on the test results, suggesting these variables might be less critical. However, even with all other variables being incorrect, correct Slice Thickness improved accuracy from -2.56% to -2.18%. Likewise, accurate physician information enhanced accuracy from -2.56% to -2.36% under the same conditions. The impact of IV Contrast on accuracy was minimal, regardless of the correctness of other variables.

4 Discussion & Conclusion

Medical image segmentation is a longstanding and multifaceted topic, with numerous applications and methodologies. Since the rise of Convolutional Neural Networks (CNNs) in the 2010s, they have become the predominant architecture in most automated segmentation models for medical imaging. However, other segmentation methods, such as those based on image registration, continue to be widely used in clinical settings. Despite their effectiveness, both CNNs and image registration methods primarily focus on image input alone. This approach differs from how physicians typically delineate clinical targets, which often involves considering additional clinical information from medical systems or diagnostic findings to achieve accurate segmentation of the desired quality. Consequently, integrating clinical inputs beyond mere imaging into automated segmentation is increasingly favored by clinicians. Leveraging recent advances in machine learning, we have incorporated various clinical inputs into an auto-segmentation model based on CNNs.

Our proposed model demonstrates higher accuracy compared to baseline CNN models, yielding segmentation results that more closely align with the gold standard. Furthermore, the model performs well even with limited data resources, a common limitation for traditional segmentation models. Uniquely, our model tailors its output segmentation based on the provided clinical inputs, allowing clinicians to adjust the results adaptively according to different requirements, such as the preferences of the approving physician. This high level of accuracy and adaptability promises an enhanced auto-segmentation experience for clinicians.

Abstract

Purpose: To investigate the effect of the global electron cutoff energy (ECUT) on the calculation accuracy of Monte Carlo (MC) based Treatment Planning. Systematic studies on heterogeneous phantoms are done to determine how ECUT affects the dose uncertainty and consequently the dose volume histogram (DVH) and dose mass histogram (DMH).

Methods: Square phantoms made of different density materials are included in this study. Dose calculations (6MV-IMRT with two beams) are performed using the MCSIM code with the same number of histories and two different ECUT settings (521 keV and 700 keV). Dose DVH and DMH are calculated using MCSHOW code.

Results: The uncertainty on the average dose calculated for low density region (0.001 g/cm^3) is about 2% with ECUT=521 keV and 9% with ECUT=700 keV, respectively. For regions with densities of 0.3 g/cm^3, the uncertainty is about 1% in both 521 keV and 700 keV calculations. We observe differences up to 20% in the Total Target - DVH between 521 keV and 700 keV while the DMH values differed by less than 5% between the two ECUT settings.

Conclusions: DVHs for targets including large (about 40%) low-density regions may be significantly affected by the ECUT value used with the Monte Carlo algorithm. In contrast, DMH is not affected by high ECUT in the treatment plan evaluation, and thus we can use high ECUT and DMH to improve the efficiency and accuracy of Monte Carlo based Treatment Planning.

1 Introduction

Previous studies [1,2,3] have been reported the influence of uncertainties on DVH. The (ECUT) equal to 700 keV is generally accepted as an adequate parameter for MC dose plan calculations. The use of 700 keV versus 521 keV reduces the time of dose calculation, however, it can affect the calculation accuracy of Monte Carlo Treatment Planning. In particular, the accuracy of dose values calculated in low density regions may be very sensitive to the ECUT parameter. Since the DVH histograms are built by the sum of voxel doses of the given volume, the uncertainties of dose values will affect the DVHs, and consequently may affect the evaluation of the plan.

In the present work we aim to study the effect of ECUT on the calculation accuracy of Monte Carlo Treatment Planning. Systematic studies on heterogeneous phantoms were done to determine quantitatively, how ECUT affects the dose uncertainty [4,5] and consequently the DVH and DMH.

2 Material and Methods

Monte Carlo dose calculations are performed in tissue-like material phantoms to investigate the combining effect of density and electron transport parameter (ECUT) on DVH and DMH.

Four square phantoms of different densities are designed, and dose calculations are performed for each phantom using MCSIM code [4,5] and two different ECUTS, 521 keV and 700 keV. Each phantom (*see Figure 1*) with dimensions of 10x10x10 cm^3 includes one target and the target itself has two components (T1 and T2) with equal dimensions of 4x4x4 cm^3. T2 is made of the same tissue-like material with density (1 g/cm^3) in the four different phantoms while T1 is made of air material but different density (0.001 g/cm^3, 0.1 g/cm^3,0.2 g/cm^3 and 0.3 g/cm^3) in each phantom.

6MV-IMRT dose calculations are performed for each phantom using the same number of histories (ten million) and the same simulation parameters except ECUT.

MCSHOW [6] was used to display isodose distributions on top of the phantom and plot the DVHs for T1, T2 and total target (T1+T2). MCSHOW includes a new feature which allows to plot DMH for T1, T2 and total target (T1+T2).

		Phantom 1 Density 0.001	Phantom 2 Density 0.1	Phantom 3 Density 0.2	Phantom 4 Density 0.3
	Volume (cc)	Mass (gm)	Mass (gm)	Mass (gm)	Mass (gm)

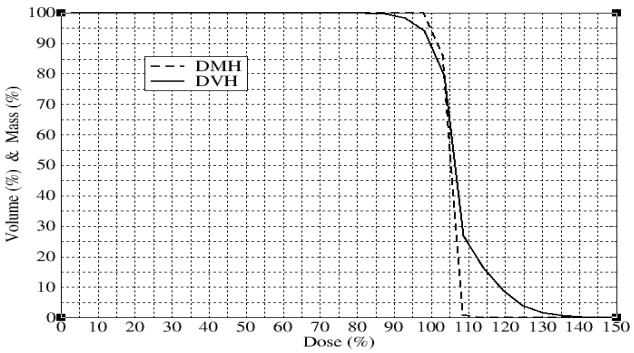

Figure 2: DVH and DMH calculated for the air-like density phantom and ECUT=700 keV

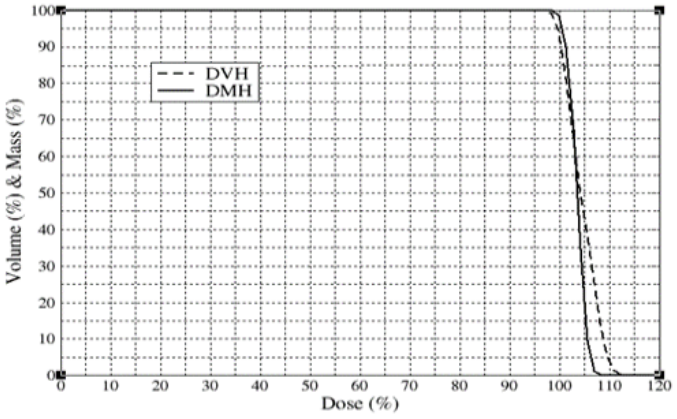

Figure 3: DVH and DMH calculated for the air-like density phantom and ECUT=521 keV

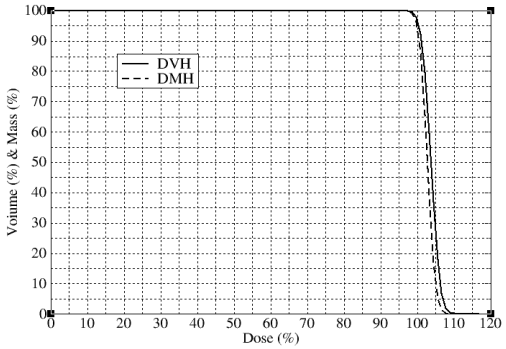

Figure 4a,b: DVH and DMH calculated for the phantom with density of 0.1 g/cm^3 a) upper: ECUT=700 keV and b) lower: ECUT=521 keV

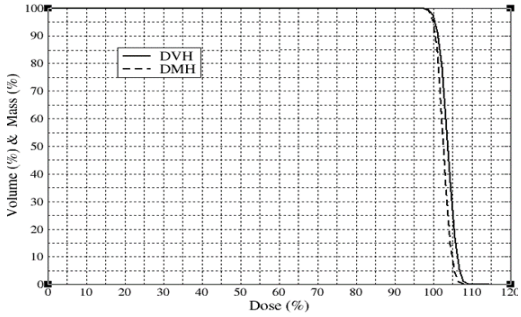

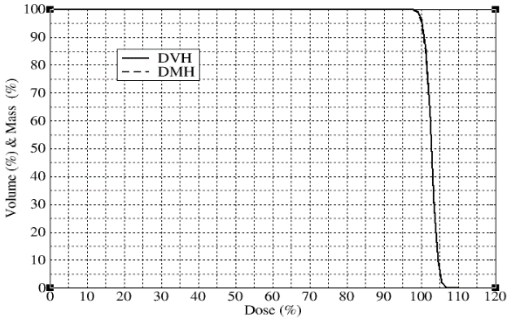

Figure 5a,b: DVH and DMH calculated for the phantom with density of 0.3 g/cm^3 a)upper: ECUT=700 keV b) lower: ECUT=521 keV

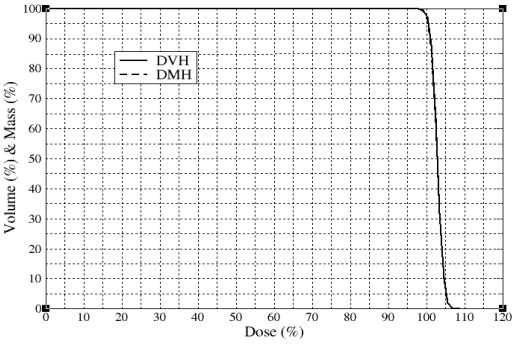

4 Discussion

In above Tables, we see that the uncertainty on the average dose values calculated for T1 (0.001 g/cm^3) is about 2% for calculation with ECUT=521 keV and 9% for that with ECUT=700 keV. Increasing the density of T1 to 0.3 g/cm^3 decreases the uncertainty to about 1% in both 521 keV and 700 keV calculations. Table 1a) shows that the uncertainty on the values of $D_{average}$ obtained by 700 keV calculation for the Total Target of air-like density phantom is about 5% while those values for 521 keV calculation (see Table 1b) have an uncertainty lower than 2%. The dramatic effect of the density on the uncertainty of the maximum dose is shown in both tables. And this effect is strongly accentuated by ECUT. Varying ECUT from 521 to 700 keV increases the uncertainty on maximum dose (air tissue phantom) by about 55%.

Figure 2 shows the comparison of DVH and DMH calculated for the air-like density phantom and ECUT=700 keV. The value of DVH-maximum dose is about 10% lower than prescribed dose while the minimum dose is about 20% greater than prescribed dose. In contrast, the DMH plot exhibits good shape.

The DVH and DMH plots determined in 521 keV calculation are presented in Fig 3. In the upper region of the plot, we do not observe differences between DVH and DMH. However, in the lower region (for less than 50% of the volume) differences up to 5% are observed between the two plots. Our results indicate that DVH may not be the good solution for the low-density regions even when the calculation is done with ECUT equal to 521 keV.

In Figures 4 a) and b), we see that differences between DVH and DMH calculated for the phantom with density of 0.1 g/cm^3 are not significant for both cases, 700 keV and 521 keV calculation. Figure 5 a) and b) show that DVH and DMH plots match perfectly.

5 Conclusion

Our results indicate that the ECUT value does not affect the DVH plotted from Monte Carlo dose distributions calculated in regions with density equal or greater than 0.3 g/cm^3.
DVHs for targets including large (about 40%) low-density regions may be significantly affected by the ECUT value used with the Monte Carlo algorithm. In contrast, DMH is not affected by high ECUT in the treatment plan evaluation, and thus we can use high ECUT and DMH to improve the efficiency and accuracy of Monte Carlo based Treatment Planning. Based on the results of the present work, real clinical cases were selected and included in the ongoing studies.

Massachusetts General Hospital (MGH), Boston MA 02114, USA

Abstract GMC [gímık] is a one-variable Monte Carlo dose algorithm for proton therapy. Its accuracy and performance were presented at the ICCR in Melbourne in 2013. Here, we present the current state of GMC after porting to a GPU architecture. Elevated from the original version, we demonstrate the impressive speed gain while conserving the system's accuracy. Features now include dose-averaged LET and BioDose computations, support for PBS and SOBP fields, as well as RBE modeling based on the McNamara model with arbitrary alpha-beta ratios. The DICOM data processing and loading steps for transparent integration in the clinical workflow take the major part of the total running time, while the computation runs in order of seconds, regardless of patient size, number of beams, prescription, etc. A live demo may be performed.

1 Introduction

GMC [gímık] was first introduced at the XVII International Conference on the use of Computers in Radiation therapy in Melbourne in 2013 [1]. At the time, this one-variable Monte Carlo dose algorithm was implemented on a CPU and shown to provide fast and accurate dose calculation for proton therapy beams, with the promise of exponential speed gain through porting on the GPU architecture [2].
The code has been ported to a GPU implementation and now includes dose-averaged LET_d, BioDose [3], and RBE based on the MacNamara model [4] with default alpha-beta ratios of 2 and 10 – one can also specify any other arbitrary alpha-beta ratio value. Here, we report on the accuracy and performance of this updated GMC version.

2 Materials and Methods

GMC is designed de-novo to reproduce clinical proton physics observables, including dose (to water) and LET_d, and to reduce the computational and physics models to their minimum.
A set of simple plans was generated directly in our treatment planning system (TPS), Astroid [4] which is based on a pencil beam algorithm for dose calculations [5]. These were intended to test the accuracy of the physics observables at the macro level. Clinical patient plans were then recomputed given various parameters (a subset is provided in Table 1) for verification purposes. The timing of the various operations (data loading, data preparation, computations, data presentation, and saving) was aggregated for performance evaluation.
Computations were performed on an individual Dell Precision 7820 workstation with an Intel Xeon P family I7 processor and an NVIDIA RTX A5000 GPU card (Ampere architecture-based with 24GB GDDR6 memory).

3 Results

Physical expectations and GMC calculations show excellent agreement at the macro level, i.e. single energy depth dose and scattering power [6]. This is then demonstrated by recomputing a 1-liter 2-GyRBE reference dose sphere, which is provided in Figure 1.

In Figure 2, we further illustrate the accuracy of the BioDose calculation – which depends on dose and LET_d – based on the same reference sphere simulation.

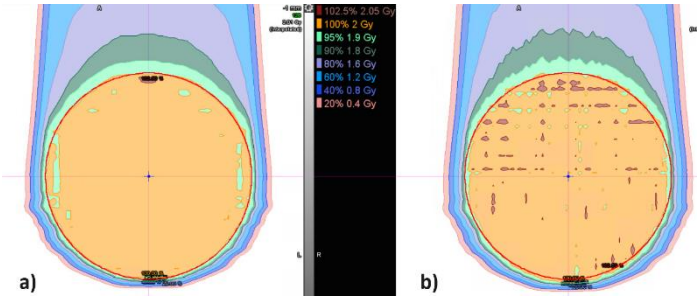

Figure 1: Dose distribution for a 1-liter 2-GyRBE reference dose sphere a) generated in Astroid and b) recomputed in GMC.

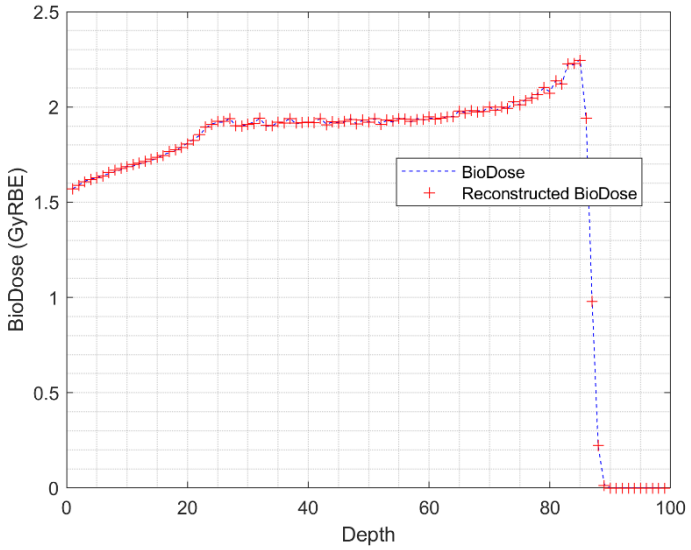

Figure 2: The GMC output BioDose cube is compared to the reconstruction from the base quantities: (Dose/1.1) × (1 + LET × 0.03).

Overall, excellent agreement is observed in terms of both dose distribution and dose-volume histograms for the clinical patient plans. An arbitrarily chosen patient case is depicted in Figure 3, comparing Astroid and GMC. In this CSI case, a slight underdose of the target is observed around the brain due to the improved scattering modelization with the Monte Carlo engine.

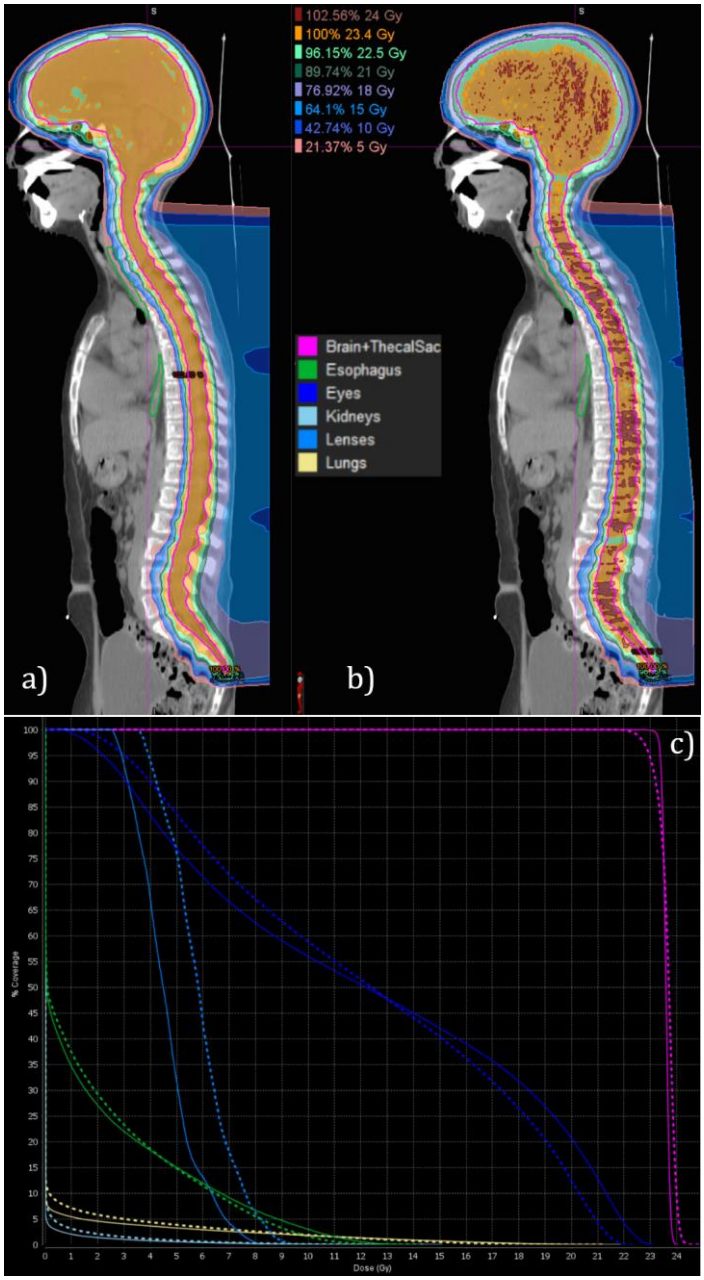

Figure 3: Dose distributions for a CSI plan a) generated in Astroid and b) recomputed in GMC. The dose-volume histograms are provided for both computation in panel c – Astroid (solid lines) vs GMC (dash lines). This plan is based on a common 1.8 GyRBE dose per fraction, it uses five large fields with apertures and thick range shifters. It consists of a total of 615×1e^9 protons.

Table 1 provides the total GMC running time, which includes all the steps from data retrieval to data saving, for a subset of six representative patient cases. Computation-only (proton transport and post-processing) timing is also provided. The computations here included the auxiliary quantities (LET_d, BioDose, and RBE).

Table 1: GMC simulation run times for a subset of Astroid clinical patient plans representative of the planning parameters used in the clinic. All computations (and total) times include the auxiliary quantities (LETd, BioDose, and $RBE_{a/b=2 \text{ or } 10}$).

Treatment site	Planning parameters	Number of protons (Gp)	Total time (s)	Computation time (s)
Breast	1 Field, large size, 8 cm RS, No AP, highly hypo-fractionated	838	7.2	3.5
Brain	4 fields, small size, 3 cm RS, No AP	31	6.9	2.3
Clival	4 fields, small size, 8 cm RS, AP	77	6.8	3.1
CSI	5 fields, large size, 8 cm RS, AP	615	16.5	8.5
Prostate	4 fields, small size, no RS, AP	133	7.7	2.6
Shoulder	2 fields, medium size, 8 cm RS, AP, Metal rod	286	7.1	3.4

RS = range shifter, AP = apertures, Gp = 1e^9 protons, “large” field size refers to an open snout > 20 cm, and “small” fields are < 10 cm.

4 Discussion

In this work, excellent dosimetric accuracy is observed between the TPS and GMC. Here, we do not compare it against a general Monte Carlo engine. These are time-consuming and may take days to complete, especially as the number of treatment fields and the field size increase [6]. The CPU version of GMC was benchmarked against GEANT4/TOPAS in the past [1-2]. Similarly, many studies at our institution involved our various proton TPS (which all used the same pencil beam algorithm) and comparisons based on TOPAS [8-10]. Future TOPAS comparisons against GMC will be generated.

Future work involves the automation of plan recalculations as new proton DICOM plans are detected in our Picture Archiving and Communication System (PACS). This will be performed using a dedicated server with four NVIDIA RTX A5000 paired through NVLink Bridge for improved speed. All the dose computations in this work were based on an individual workstation; recomputation speeds and parallel plan processing are expected to improve further using the dedicated server.

In this work, dose computational times were provided inclusive of auxiliary quantities; the rational for this is the growing interest in using these variables in the general planning paradigm. However, it would be faster and less resource-intensive to perform the dose calculation only. This could be of interest for online adaptive planning.

5 Conclusion

GMC has been ported to a GPU architecture. It retains the original accuracy while adding novel features and exhibiting an incredible speed gain. Future work will involve improving integration for online adaptive therapy systems and pursuing open licensing to distribute the code for general use by the proton community.

Assessing neutron-induced carcinogenesis risk in high-energy radiation therapy: a Monte Carlo and track structure study using realistic neutron spectra and DNA damage clusters

Sachin Dev[1], Felix Mathew[1], and John Kildea[1]

[1]Department of Oncology, McGill University Health Centre, McGill University, Canada

Abstract High-energy photon radiation therapy (> 8 MeV) can lead to unintended patient exposure to secondary photoneutrons, posing a risk for iatrogenic cancers. Existing studies to evaluate the potential of photoneutrons to induce carcinogenesis have been performed solely with flat neutron spectra irradiating the ICRU-4 sphere. Therefore, to replicate a real-world cell irradiation scenario, our study is modeling an in-vitro cell irradiation geometry irradiated with realistic photoneutron spectra encountered in high-energy external-beam photon radiotherapy and aims to evaluate the resulting neutron-beam RBE. As a first step, we have quantified the secondary particle spectra in the ICRU-4 sphere for monoenergetic neutron beams of initial energies 1 keV, 1 MeV, and 10 MeV. An in-house nuclear DNA model and an algorithm for recording clustered DNA damage will be used to calculate DNA damage yields. The neutron RBE obtained from the simulation will be validated by performing in-vitro irradiations of B-lymphoblastoid cells with a 6 MV photon beam used as reference radiation and with the photoneutron spectra arising from a 15 MV linac.

1 Introduction

The use of ionizing radiation offers great benefits to society. However, radiation may be detrimental to human health. The use of radiation thus entails an associated non-zero risk. The unwanted photoneutron exposure to patients during high-energy (> 8 MeV) radiation therapy is one such example of a risk associated with the use of radiation [1, 2]. This unavoidable exposure of secondary neutrons can potentially cause patients to develop iatrogenic secondary cancers later in life [3]. The risk for inducing stochastic effects associated with neutrons is energy dependent and relatively higher in magnitude as compared to other types of radiation. The energy dependence of neutron-induced stochastic effects is typically quantified by neutron radiation weighting factors (w_R) provided by International Commission on Radiological Protection (ICRP 2003, 2007) [4, 5] and the neutron quality factors (Q) published by the United States Regulatory Commission (US NRC 2021) [6]. Although the factors w_R and Q follow similar energy dependence trends qualitatively, their magnitudes are highly discrepant. The wide variety of neutron RBE data used to derive the weighting and quality factor potentially explains this discrepancy. This study is an expansion of our Neutron-Induced Carcinogenic Effects (NICE) research group's efforts to trace the biophysical origin of neutron RBE [2, 7, 8, 9, 10]. Recent studies [11, 12] have used Monte Carlo simulation frameworks to investigate neutron RBE using neutron-induced DNA damage lesions with flat neutron spectra composed of multiple mono-energetic beams. However, we aim to use realistic neutron spectra measured previously by our group [2]. In the future, we aim to validate the RBE values obtained from Monte Carlo simulations with in vitro experiments. In this work, we describe how we obtained secondary species spectra in the ICRU-4 sphere when irradiated with monoenergetic neutron beams of initial energies 1 keV, 1 MeV, and 10 MeV. Simulations were repeated with different versions of the TOPAS Monte Carlo framework [13] and the obtained spectra were validated against the corresponding versions of Geant4 [14].

2 Materials and Methods

The four-component soft tissue-equivalent sphere recommended by the International Commission on Radiation Units and Measurements (ICRU) for use in radiation safety and dosimetry applications was modeled in TOPAS v3.6. The ICRU-4 sphere is 30 cm in diameter and made up of hydrogen, carbon, nitrogen, and oxygen. The ICRU-4 sphere approximates a human adult torso. Three scoring volumes of radius 1.5 cm each and made up of the same ICRU-4 material were centered along a single axis at radial distances of 0 cm, 7.5 cm, and 13.5 cm from the sphere's center, consistent with the previous study by our group [8] performed in Geant4. These scoring volumes have been referred to as inner, intermediate, and outer scoring volumes, respectively. The ICRU-4 sphere was irradiated with monoenergetic neutrons with initial kinetic energy of 1 keV, 1 MeV, and 10 MeV originating from a source positioned on the surface of the ICRU sphere.

The Lawrence Livermore data libraries, which include information for photons [15], electrons [16], and atomic relaxation [17], were employed to manage electromagnetic processes. Default models were integrated to address reactions of lesser dosimetric significance, such as free neutron decay (G4DecayPhysics) and the decay of radioactive isotopes (G4RadioactiveDecayPhysics). Hadronic elastic scattering and inelastic processes (fission, scattering, neutron capture) were described using Geant4 ParticleHP models. An extension was developed in TOPAS to correctly simulate the transport of thermal neutrons below 4 eV. An additional G4NeutronHPThermalScattering model was incorporated in the TOPAS extension which simulates thermal neutron (0 eV -> 4 eV) transportation. To make the G4NeutronHPThermalScattering data set work, the elemental hydrogen in the ICRU sphere was replaced by the

element Hydrogen in Water (TS_H_of_Water) by redefining it using elemental composition and the natural abundance of its isotopes. All the simulations were performed on Digital Research Alliance of Canada clusters for 10^9 histories. The spectra of each secondary species (protons, deuterons, alphas, carbon nuclei, nitrogen nuclei, oxygen nuclei, and gammas) produced were recorded for each monoenergetic neutron energy. The TOPAS v3.6 generated secondary species spectra were compared with Geant4 v10.06p03. All the plots were generated in the ROOT [18] data analysis framework.

After obtaining the secondary species spectra in the ICRU-4 sphere with monoenergetic neutron irradiation and matching the spectra with those in the Lund et al study [8], the next step is to simulate in vitro experimental geometry in TOPAS. Our group has measured photoneutron spectra arising from a 15 MV linac at different locations in the radiotherapy bunker [2]. The realistic photoneutron spectra will be used to irradiate in vitro geometry computationally and obtain secondary species spectra.

Our lab has built a geometric nuclear DNA model of a single cell using the TOPAS-nBio [19] framework and it is available under an open-source license [9]. The model consists of nucleotide base pairs created using six spheres to represent two nitrogenous bases, two deoxyribose molecules, and two phosphate groups. The nucleus has been constructed as a cubic grid to make the model computationally efficient. The nucleus-sized volume has 6.3 Gbp of DNA at a density of 13.3 Mbp/um^3 making it consistent with human nuclei. Our single-cell model will be stochastically exposed to secondary particle spectra at different dose levels: 0.0 Gy, 0.5 Gy, 1.5 Gy, and 3.0 Gy. The IAEA phase space files [20] will be used in TOPAS to simulate 6 MV linac beams and generate the transport of secondary particles and thus irradiate our single-cell model to different dose levels mentioned above.

The photoneutron RBE obtained from Monte Carlo simulations will be validated against an RBE value estimated experimentally. We are currently exposing human B-lymphoblastoid cells to three doses of 0.5 Gy, 1.5 Gy, and 3.0 Gy to 6 MV photons in vitro along with sham irradiation to 0.0 Gy. A linac is used to deliver the doses at a dose rate of 600 MU/min. We aim to perform in vitro cell irradiations with photoneutrons originating from 15 MV linac.

3 Results

The initial spectra of secondary gammas and charged particles were collected in all three scoring volumes of the ICRU-4 sphere for 1 keV, 1 MeV, and 10 MeV neutron sources. Figure 1 shows the secondary charged particle spectra produced in the inner scoring volume with a 1 MeV neutron source. In Figure 2, we present a comparison of electron spectra produced within the inner scorer by a 1 MeV neutron source. In this analysis, we used the "Pre-Step point" object of the Geant4 framework that allowed us to retrieve information about the particle, such as its kinetic energy, position, and direction, at the moment before it moves to the next point in the trajectory.

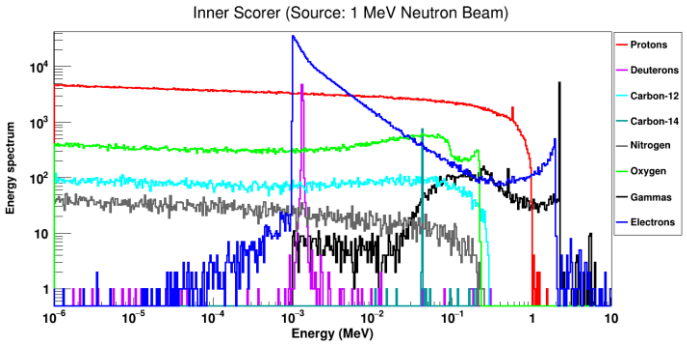

Figure 1: Secondary charged particle spectra in inner scoring volume obtained by 1 MeV neutron source in Topas v3.6

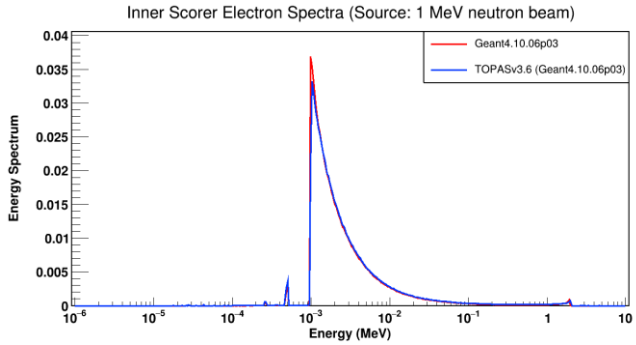

Figure 2. The electron spectra within the inner scoring volume, generated by a 1 MeV neutron source, are compared between Topas v3.6 and Geant4 v10.06.p03.

4 Discussion

For all incident monoenergetic neutron beams of 1 keV, 1 MeV, and 10 MeV, a strong agreement was observed in the secondary particle spectra produced in all three scoring volumes of the ICRU-4 sphere with Geant4 v10.06.p03. In this study, TOPAS v3.6 was used for simulations, which is a wrapper of Geant4 v10.06.p03. However, Lund et al [8] performed simulations in a different version of Geant4: v10.04.p02, yet all spectra obtained in TOPAS v3.6 matched well with Lund et al study [8] except for electrons and secondary gamma due to improved cross-sections for electromagnetic processes in Geant4 v10.06.p03. In addition, the simulations were also repeated with TOPAS v3.9 and corresponding Geant4.10.07p03, and a good agreement between the two was observed. The thermal neutron transportation physics lists were not prebuilt in TOPAS so an extension was developed using G4NeutronHPThermalScattering dataset to correctly simulate thermal neutron transportations. An important limitation of our single-cell model is that it considers the direct and indirect DNA damage induced by radiation only but does not apply cell repair models. Our research group is

currently developing an update to our custom DNA model by incorporating cell repair kinematics. We aim to expand this study by analyzing the impact of repair models on resulting neutron RBE.

5 Conclusion

We have generated secondary particle species produced by monoenergetic neutrons of initial energies 1 keV, 1 MeV, and 10 MeV by simulating the ICRU-4 sphere in TOPAS. We have developed an extension in TOPAS for correct simulation of thermal neutron transportation for the first time thus contributing to advance the capabilities of the TOPAS simulation application. Repeated simulations with different versions of TOPAS code and matching the results with corresponding Geant4 versions demonstrated the robustness of both our methodology and results. In the future, we aim to calculate realistic photoneutron RBE using our simulation application and validate it experimentally.

Abstract Fundamentally understanding biological responses to ionizing radiation is of crucial importance. Mechanistic modeling by microscopic Monte Carlo (MC) simulation of the radiation physics and chemistry process triggered by radiation, as well as the process to generate initial DNA damages, plays an important role. However, such simulation is often very time consuming, limited the scope of simulation affordable. Our group has been developing open-source high performance microscopic MC simulation package – gMicroMC based on Graphical Processing Units (GPU). This paper summarizes our recent progress in recent developments in modeling the radiation transport process and DNA damage calculations for various DNA structures. To demonstrate the utility of this tool, we also present two example applications, namely radical production in electron FLASH irradiation, and relative biological effectiveness (RBE) of heavy ions calculated by considering DNA damage of various complexities.

1 Introduction

DNA damages and lesions are the primary lethal factors for radiation induced cell death. Of these, DNA double strand breaks (DSBs) play a key role. Recent developments from experiments by electrophresis and foci detection reveal the importance and complexity on the relationship between DNA damages and cell death. Besides the number of damage sites, the size and complexity also matter. Therefore, it is fundamental to understand the distribution of DNA damages after irradiation, especially considering that the damages are modulated by various factors of irradiation, e.g. dose, dose rate, linear energy transfer (LET) etc.

Monte Carlo (MC) simulation has been widely used in medical physics field due to its faithful description of radiation physics process and environmental conditions. The extension of conventional macroscopic MC simulation, e.g. for dose calculation purpose, into microscopic simulation, e.g. at micrometer or nanometer scale, including the particle transportation and chemical reaction, becomes an essential tool to model the DNA damage immediately (e.g. not accounting damage repairs) induced by ionizing radiation at sub-cellular levels. There is a continuous effort in developing such packages [1–3]. Along with the tool development for simulations, the modeling of DNA structure becomes more and more delicate to dig out more subtle yet basic perspectives into radiation damages. For instance, the change from a simple cylinder sensitive volume to detailed multi-scale DNA structure in a cell nucleus enables the modeling of the effect of histone proteins or a transformation from base damage to sugar damage.

A major hurdle faced by microscopic MC simulation with fine DNA structure modeling is low efficiency. Factors accounting for this challenge include, but are not limited to, the complex radiation physics and chemistry process to model, the many-body simulation problem in the radiation-chemical stage, the long chemical stage over multiple orders of magnitude in time, and the complex DNA geometry. Due to limitation in computation, suboptimal modeling setups have been employed, impeding resulting accuracy. For years, our group has been striving to develop high-performance MC packages with the use of Graphical Processing Units (GPU). We designed and optimized proper data structure and parallelism algorithms that fit the logic of GPU. Specifically, we developed a method to voxelize the space and sort particles based on their voxel index [4], thereby reducing the burden in tracking mutual interactions in the many-body radiation chemistry simulation. We built a DNA model for lymphocyte cell nucleus and the framework to transport electrons and decay of excited water molecules, which gave rise to the first version of gMicroMC [5]. Since then, this package has been maintained by our group and publicly shared to the research community *. We later added the function to explicitly consider oxygen molecules [6] and the support for proton and heavy ions in a concurrent transport framework of radicals and DNA structure[7]. The application of gMicroMC has enabled studies such as understanding oxygen depletion in FLASH condition [8] and modeling of relative biological effect (RBE) of carbon ions [9].

In this manuscript, we present the advancements in the gMicroMC package, highlighting our recent developments. We also provide illustrative examples demonstrating its utility in modeling DNA damages, thereby enhancing radiobiology modeling. We hope that this paper will introduce this versatile tool to the broader research community.

2 Materials and Methods

2.1 gMicroMC simulation process

The simulation was divided into four stages. In the physical stage, gMicroMC transports primary particles and secondary

*https://github.com/utaresearch/gMicroMC

electrons , recording positions and types of ionized and excited water molecules. In the physico-chemical stage, it computes the de-excitation process of these water molecules through predefined channels and probabilities, generating the initial distribution of radicals. After that, the simulation in the chemical stage diffuses these radicals and checks mutual reactions among them, as well as with DNA structure and other molecules, e.g. oxygen, in a step-by-step manner. Finally, searching along the DNA chain is performed for DNA damages of various complexities based on the DNA damages created in the first three stages. The advantage of gMicroMC is the high computational efficiency realized via GPU parallelization and GPU-friendly parallel simulation algorithms in all the four stages.

2.1.1 Transport simulation of radiation physics and chemistry process

Physical stages The physics processes modeled in gMicroMC were summarized in Table 1. We focused on the transport of charged particles. For photon irradiation, we initiated the simulation from the generated secondary electrons. The medium was considered to be water. For heavy ions, all cross sections with water were scaled based on those of proton's, $\frac{d\sigma_{ion}}{dW}(E_k) = Z^2 \times \frac{d\sigma_{proton}}{dW}(E_k/A)$, where W is the energy transfer, E_k, Z and A are the kinetic energy, charge and atomic mass, respectively. For more details of the modeling, users can refer to our previous publications [5, 7]. One thing worth pointing out is that the package was not designed for transporting particles over several centimeters. Hence, we ignored some processes that have marginal effect on transportation in micrometer scale, for instance the elastic process of proton. Due to the heavy mass of proton, the deflection angle is tiny for the length scale of interest. We validated the simulation of the physical stage by computing physics quantities, e.g. LET and secondary electron spectrum, and comparing with published data.

Physico-chemical and chemical stages After the physical stage, the excited and ionized water molecules generated a series of radicals based on a defined list of paths. In the chemical stage, the basic simulation for radicals' diffusion and chemical reactions was conducted in a step-by-step manner. For each time step, the radicals diffused freely while the reaction was determined by the distances between radicals

Table 1: Physics process between different particles and water in gMicroMC.

Process	Electron	Proton	Heavy ion
Ionization	Yes	Yes	Yes
Excitation	Yes	Yes	Yes
Elastic	Yes	No	No
Dissociative	Yes	No	No
Charge effect	No	Yes	Yes

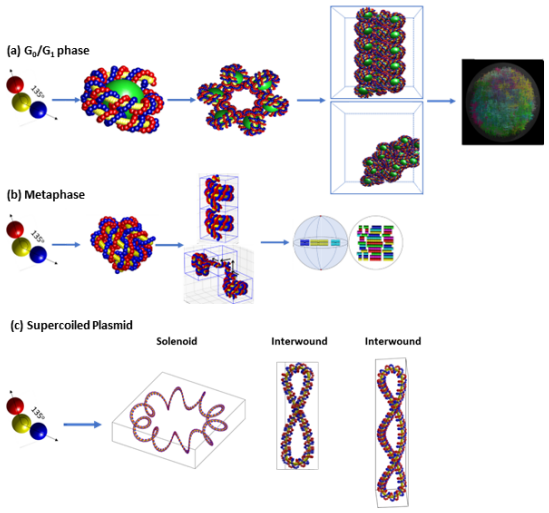

Figure 1: Illustration of different DNA models.(a) Lymphocyte cell nucleus model at G0/G1 phase, (b) meta phase, (c) supercoil plasmid model. Both the solenoid type with writhing number 10 and interwound type with writhing number 1 and 2 are displayed.

[4]. Due to the advantages of GPU's processing power, we afforded to include the presence of DNA in the chemical stage, where reactions between radicals and DNA were modeled explicitly. This increased the simulation realism, for instance the considerations of scavenge effect of DNA structure.

2.1.2 DNA models

gMicroMC currently includes two DNA models of lymphocyte cell nucleus. One is for G0/G1 phase and the other one is for meta-phase. The model for the G0/G1 phase considered the multi-scale nature of DNA packing in a cell nucleus of a sphere with 11 micrometer diameter (Fig. 1(a)). It partitioned the cell nucleus space into voxels of 55 nanometer, and filled each voxel with one of the two types of building blocks, namely the one connecting the opposite faces and the other one connecting adjacent faces. The connection path among voxels were designed by a thermal relaxation process of 46 chromosome structures. For each of the two building blocks, it was constructed by considering the hierarchical DNA structure containing chromatin fiber unit, nucleosome and base pairs. Under this multi-scale structure, 6.2 GBp DNA were packed into the the cell nucleus model.

The meta-phase DNA structure (Fig. 1(b)) used the same idea of multi-level structure. Yet, they differed in the definition of building blocks and the way to arrange them. The dimension of repeating unit was 11 nanometers and it constituted rod-shaped chromatid segment of 730 nm in diameter and 460 nm in height. The arrangement of these chromatid segments followed the coarse-grained polymer physics to match experimental Hi–C data.

Besides the two cell nucleus DNA models, we also provided a supercoiled plasmid DNA model (Fig. 1(c)). Although it is simple, it has the unique potential to allow benchmarking simulation results with experimental results, since experiments

can be performed using plasmid DNAs in a controllable fashion. We implemented both the solenoid and interwound type of folding. The elemental structure was the base pairs with the distance between adjacent base pair 0.34 nm. With different writhing number, different structure could be generated. Fig. 1(c) showed the supercoided DNA models with writhing number of 10, 1 and 2. The number of base pairs were 2050, 246, 416, respectively.

2.1.3 DNA damage calculation

The transport of the radiation physics and chemistry process generated a number of DNA damage sites along the DNA chain, directly by the charged particles' energy deposition, or indirectly by radicals' reactions with DNA sites. After damages sites were generated, we analyzed the geometrical locations of these damages to identify Single Strand Breaks, DSB and damages of higher complexities.

2.2 Example use cases

With the comprehensive developments, we presented in this section two examples to demonstrate the utility of gMicroMC.

The first example was the calculation of radical production in electron FLASH therapy realized using an electron beam of a medical linear accelerator. Specifically, we simulated the presence of electron tracks to a volume of interest within a RF pulse with a duration of 1 μs for instantaneous dose rates of 10^6 and 10^8 Gy/s. We simulated the entire radiation physics and chemistry process with oxygen in the environment explicitly considered, hence allowing us to study the dependence of radical yield on oxygen concentration.

The second example calculation was RBE modeling in heavy ion irradiation. This example included DNA damage simulation to demonstrate the utility of this function. The core component was to define a variable to measure the radiation effect and to be linked with biological endpoint of cell survival fraction (SF). As mentioned previously, both the size and complexity of DSB contributes to the biological effects. We hence defined the number of lethal DSBs (LDSBs) as a weighted sum of DSBs of various complexities $N_{\text{lethal}} = \sum_i \omega_i N_i$ where ω_i was the weight and N_i the count of ith DSB type. The weights were determined via fitting to experimental data. With this definition, we computed DNA damages of various complexities under the reference Co60 beam and various heavy ions including helium, carbon, and neon. Under the assumption of the existence of a universal survival model $SF(N_{\text{lethal}})$ over different types of irradiation, using known experimental SF data $SF_j(D_j)$, where D_j is the dose of jth type of irradiation, and the computed data $N_i = k_{i,j} D_j$, where $k_{i,j}$ is ratio between the number of the ith DSB complexity parameter and dose, we were able to derive N_{lethal} expression, and hence computing $SF(N_{\text{lethal}})$. With this function, RBE was obtained by computing the quotient of dose of x-ray and heavy ions to reach the given level of N_{lethal} corresponding to the endpoint $SF = 0.1$.

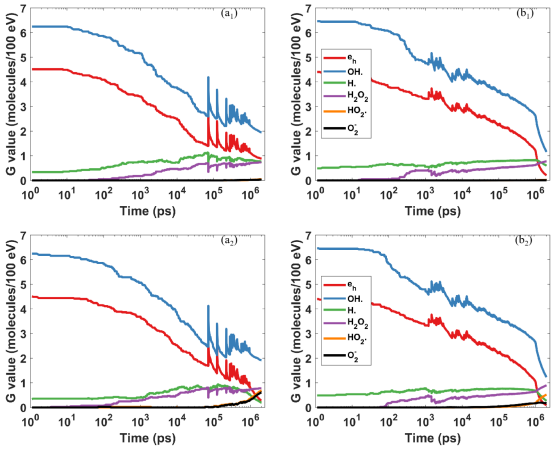

Figure 2: Comparison of the chemical yields under different dose rates of FLASH radiation with (a) 10^6 Gy/s and (b) 10^8 Gy/s. Top and bottom rows represent 0.1% (hypoxia) and 3% (physoxia).

3 Results

3.1 Computational efficiency

gMicroMC running on one GPU card is generally about 100 times faster than the CPU-based package in various simulation tasks we performed. For a test on transportation with one 750 keV electron executed on one Nvidia Titan Xp GPU (1.58GHz) and single core of Intel i7-6850K CPU (3.6GHz), the acceleration factor was 32 and 539 for physics stage and chemical stage, respectively. gMicroMC completes DNA damage pattern search in a few seconds.

3.2 Radical production in electron FLASH therapy

We presented the comparison of radical yields of under different dose rates in Fig. 2. The spikes were caused by injection of electrons within the pulse. As the instantaneous dose rate increased to a high level of 10^8 Gy/s, radical production process, as well as oxygen consumption, were significantly altered due to the spatial and temporal overlap of radicals and the mutual reactions among them.

3.3 RBE modeling in heavy ion irradiation

Fig. 3 presents the fitted N_{lethal} as a function of dose in Co60 beam and helium beam. Using this N_{lethal} quantity as a function of dose for different radiation types, we obtained the SF function of helium, carbon and neon beams with different energies and hence LETs, as presented in the top row of Fig. 4. This further allowed to compute RBE for different LETs shown in the bottom row.

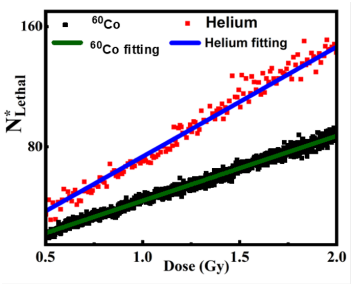

Figure 3: N_{lethal} as a function of dose for helium ions and ^{60}Co.

4 Discussion

The simulation of radical production in FLASH radiation demonstrated the power of our tool, as well as the insights regarding radical yields modulated by dose rate and oxygen environment. A more relevant question is DNA damages in these conditions, which are currently under exploration in our group. While DNA damages are generally related to radical numbers, the presence of DNA structures, e.g. histone protein, may lead to scavenging effects, complicating the dependence of DNA damage number and complexity on dose rate. More importantly, using the simple supercoil DNA, the simulation results can be compared with experimental results, providing insights to the understanding of FLASH effects.

The calculation of RBE via N_{lethal} offered a framework to model SF based on biologically relevant quantities. It hence bypass the need to empirically connect SF model parameters, e.g. α and β in the linear-quadratic model, with physics quantities such as dose, dose rate, and LET. The dependence of N_{lethal} on these quantities is naturally accounted by the microscopic MC simulation. The fundamental assumption in modeling SF and RBE is that DSBs of various complexities governs the cell survival behaviors. From the cell perspective, the biological process in response to DNA damages, e.g. the repair process, should be related to DSBs of various complexities, but it is expected that cell does not know, and react differently to, the type of radiation causeing the damages. Hence, even the process from initial DNA damages to the endpoint of cell survival is complex, we expect that there is

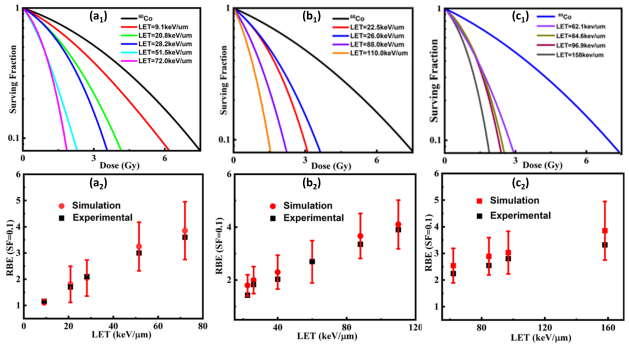

Figure 4: Simulated SF curves (top row) and RBE values (bottom row) for (a) helium, (b) carbon and (c) neon ions for V79 cells.

a universal function linking DNA damages to the endpoint. The term "universal" is in the sense that it is applicable to various radiation types. It is this assumption that allowed us to calculate SF using the same framework for various types of heavy ions and x-ray, and hence computing RBE. Yet it is possible that the universal function from DNA damages to cell survival is not only dependent on the single variable of N_{lethal}, but rather on each types of DSB N_i. In this case, a more complex function form is needed. However, due to scarcity of available data, we would run into the risk of overfitting. Hence, we chose to consider a single variable approach in this study and hope a linear combination of DSB of different complexities can capture the major behavior of the model.

5 Conclusion

This paper summarized the recent development of gMicroMC and presented two example applications. The versatile functions of microscopic MC simulation and radio-biological modeling of DNA structure and damages could benefit the research community in providing mechanistic prospective to understand the radiation damages to DNA.

Abstract

In this study, Geant4 simulations were used to evaluate the infinityArc (iArc) radiosurgery system currently under development. This new system is equipped with a robotic arm that allows for the precise and safe movement of the equipment's head around the patient while delivering the beam. The radiation from 22 ^{60}Co sources passes through a collimation system towards the isocenter. To meet FDA approval standards, a comprehensive study protocol utilizing Geant4 simulations has been established, adhering to IEC 60601-2-11:2013 and NCRP 102 guidelines which are defining performance criteria to be achieved. Monte Carlo simulations were used to calculate the dose distribution in a spherical water phantom and to assess leakage radiation around the equipment's head. The dose profiles and isodose curves will be compared with physical measurements once the prototype is completed. Preliminary results suggest the efficacy of the shielding geometry. Nevertheless, further simulations and in-depth investigations are required to further characterize the system.

1 Introduction

The iArc is a novel radiosurgery system currently under development by a company founded by a group of experts, including medical physicists, engineers, and entrepreneurs dedicated to addressing global health inequalities. This new system will be used to treat functional brain disorders such as trigeminal neuralgia, arteriovenous malformations, vascular malformations, as well as benign and malignant intracranial and extracranial tumors.

The device consists of 22 ^{60}Co sources arranged in a cylindrical head. Gamma ray beams converge through a collimator system to the isocenter, where the target volume should be positioned. There are two collimation systems: the primary collimator with a fixed aperture and the secondary collimator with a variable aperture. The system is designed to rotate the treatment head around the patient at a constant distance from the isocenter.

In order to obtain FDA approval, a study protocol using Geant4 as a simulation tool has been established. The protocol, based on the IEC 60601-2-11:2013 standard and NCRP 102 report, outlines the steps to be followed and the criteria that the new system must meet to secure approval. The IEC 60601-2-11:2013 standard sets safety and essential performance requirements for gamma beam radiotherapy equipment, including multi-source stereotactic radiotherapy [1]. Manufacturers must comply with these requirements in the design and construction of such equipment. The NCRP 102 report provides recommendations regarding the design, performance, and optimal use of medical imaging and therapy systems utilizing medical X-rays, electron beams, and gamma rays for energies up to 50 MeV [2].

2 Materials and Methods

2.1 Monte Carlo simulation

The head of the iArc system was modeled with Geant4, a C++ based toolkit that employs the Monte Carlo method [3]. Geant4 is designed for high-energy physics and is also applicable to low-energy ranges, allowing its utilization in the medical field [4]. In this study, Geant4 version 11.1.0 (December 2022) was used. The system was dosimetrically characterized by assessing the dose distribution (dose profile and isodose) in a spherical water phantom. The dose profiles and isodose curves will be compared later with physical measurements, once the prototype is functional. In addition to dose profiles in a water phantom, the radiation leakage around the system head was evaluated.

2.1 IEC 60601-2-11 and NCRP 102 report

This study is based on a protocol that outlines the steps to follow and establishes the performance criteria to be achieved. The criteria are defined based on the standard 60601-2-11 and the NCRP 102 report.

These standards specify that the ratio of the dose at the isocenter to the dose at the surface of a 16 cm water phantom centered on the radiation isocenter should be greater than 30.

The assessment of leakage radiation at the system's head requires conducting several tests. In this paper, we will present two of the four tests to be performed:

- **IEC 60601-2-11 Compliance: Beam-on Stray Radiation (Clause 201.10.2.5.2.2)**: The shielding should sufficiently reduce stray radiation, ensuring that the dose rate at any point 1 m from the center of ^{60}Co sources is $\leq$ 0.5% of the maximum absorbed dose rate on the radiation beam axis at a 1 m distance.
- **IEC 60601-2-11 Compliance: Beam-Off Isocenter Dose Rate Assessment:** The beam-off dose rate should be less than 2% of the beam-on dose rate for the smallest secondary collimator size.

2.2 Dose distribution

In Geant4, three fundamental steps were considered: creating the physical geometry, defining the possible physical events, and finally execute the simulation process.

Each source in the system is enclosed within a steel bushing assembly. The configuration of the cobalt source is the same as the one used by Romano et al. (2007) [5]. In our study, the initial positions of photons were uniformly sampled within a cylinder with a diameter of 2.54 mm and a length of 20 mm. To achieve a reasonable computation time, the direction of photons was sampled within a cylinder with an angular distribution $\Delta\theta$ of 10°. Romano et al. (2007) indicated in their study that restricting the photon propagation does not have a significant effect on the final results.

The radiation emitted by each ^{60}Co source is collimated by a cylindrical primary and secondary collimator made of tungsten. The secondary collimator is available in three different configurations that provide three different dimensions of the beam diameter at the isocenter (4, 8 and 14 mm).

At 480 mm from the center of the sources is the spherical water phantom with a diameter of 160 mm, simulating the patient's head. To simulate a treatment of the patient's head, the system must rotate by 30 degrees around the x-axis in a clockwise (Figure 1) direction. Subsequently, we conduct a simulation for each angle, totaling 360 simulations to replicate the rotational movements performed during a surgical intervention. The summation of the entire set of static simulations yields the final dose distributions.

A cube with a side length of 105 mm was placed at the center to calculate the total absorbed dose at the end of the simulation. It is divided into 105 x 105 x 105 cubic voxels of 1 mm^3, where the deposited dose is recorded.

The standard electromagnetic processes were employed as the physics list in Geant4. A detailed description of physical processes can be found in Geant4 [6]. The particle production cut, expressed by Geant4 as a range of particles in the material, was set to 0.1 mm for the entire system.

A total of 1.584×10^{13} primary particles were generated for different configurations of the secondary collimator. The simulation was partitioned into 360 independent tasks, each with distinct seeds, on a Linux cluster to shorten the overall simulation duration.

2.3 Leakage radiation

The method employed for this part of the study is similar to the one described earlier, with a few exceptions. Table 1 outlines the specificities of this section.

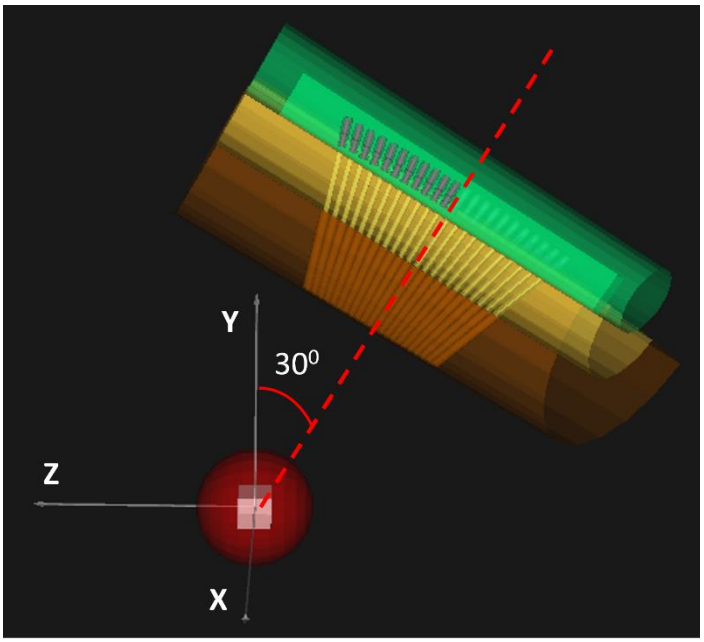

Figure 1: The iArc radiosugery system treatment head. The treatment head is in the (y,z) plane. The spherical water phantom is shown in red. The cubic detector is located at the center of the phantom.

Table 1:Detector configurations

	Particularities
Beam-Off Isocenter Dose Rate Assessment	Primary particles exhibit full isotropic angular distribution.
Beam-on Stray Radiation (Clause 201.10.2.5.2.2)	A central detector and 14 strategically positioned detectors within the water phantom. Primary particles exhibit full isotropic angular distribution.

3 Results

The results presented in this section are preliminary findings from the simulations conducted. Despite their preliminary nature, these results hold significant importance as they offer an initial understanding and assessment of the studied system.

3.1 Dose profile and isodose

For all collimator configurations, we obtained relative dose profiles along the x, y, and z axes, as well as isodose curves in the sagittal, coronal, and axial planes. We run 1 simulation per angle, for a total of 360 simulations per

collimator size, and then merged the results of these runs. The y-axis dose profile is identical to the x-axis as expected from the symmetry of the system. Figures 2-5 show the relative dose profiles and isodose curve.

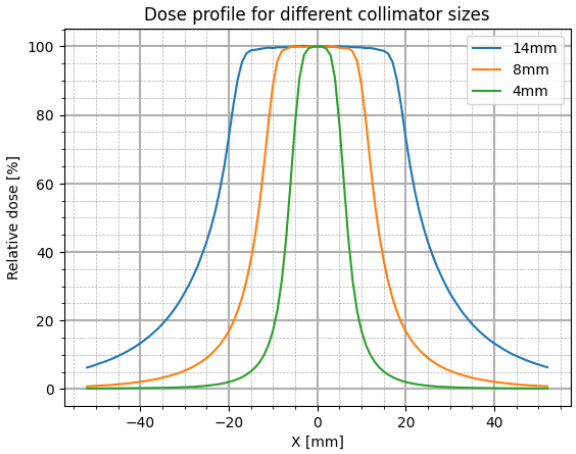

Figure 2: Dose profile along x-axis

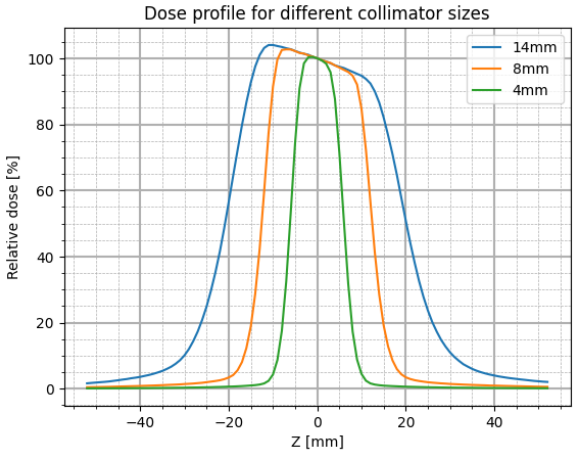

Figure 3: Dose profile along z-axis

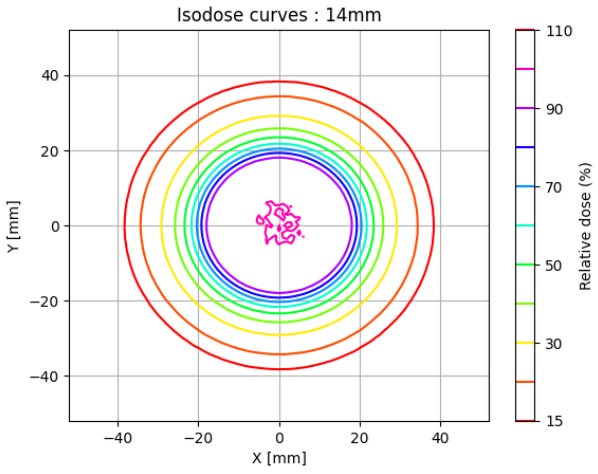

Figure 4: Isodose curves for the 14 mm collimator. Sagittal plane of cubic detector.

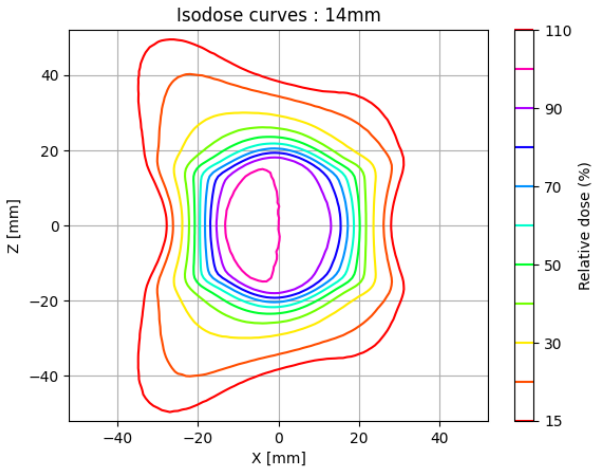

Figure 5: Isodose curves for 14 mm collimator. Axial plane of cubic detector.

3.2 Dose ratio

For dose ratio calculation, 22 detectors were positioned on the phantom surface, with an additional one at the center. Each detector is 1 x 1x 1 mm^3 in size. The ratio is obtained by dividing the total dose at the phantom center across 360 simulations by the surface dose. Table 2 shows the minimum and maximum dose ratio values for each collimator configuration.

Table 2: Dose ratios for different collimator sizes

Collimator	Ratio [min, max]
14 mm	[553,1011]
8 mm	[903,1478]
4 mm	[1742,2314]

3.3 Leakage radiation

3.3.1 Beam-off isocenter dose rate assessment

This test exclusively requires the use of the smallest secondary collimator (4 mm), as it represents the lowest dose rate when the system is in beam-off mode. In total, 360 simulations were conducted, corresponding to a one-degree rotation per simulation. Preliminary results indicate that no particles reach the isocenter, suggesting a zero- dose rate at the isocenter when the system is in beam-off mode.

3.3.2 Beam-on Stray Radiation (Clause 201.10.2.5.2.2)

The scope of this test is to evaluate the leakage radiation emitted when the iArc radiosurgery system is in the beam-on conditions measured at 1 m from the center of the ^{60}Co

source distribution. For each of the three collimator sizes, the dose resulting from leakage radiation, as measured by the 14 detectors, is compared with the dose measured by the detector positioned at the center of the phantom.

The initial results indicate that the 4 mm collimator has a single detector having a dose ratio exceeding 0.5 %. For the 8 mm collimator, four detectors exceeded this threshold, and for the 14 mm collimator, thirteen detectors surpassed it.

4 Discussion

4.1 Dose profile and isodose curves

The dose profiles and isodose curves indicate that the dose distribution along the X and Y axes is symmetrical with respect to the axis. However, along the Z axis, symmetry is not observed. This asymmetry is attributed to the 30-degree rotation of the iArc, causing the beam arriving on the Z axis to be oblique. The profiles and isodoses will be compared later to physical measurements.

4.2 Dose ratio

The results indicate that the ratio of dose at the center compared to the dose at the surface increases with the reduction of the collimator diameter. This is logical as a smaller diameter result in less scattering contributing to the surface dose. Initial simulations show that the dose ratio significantly exceeds 30, consistent with the protocol expectations.

4.3 Leakage radiation

4.3.1 Beam-off isocenter dose rate assessment

The preliminary data showing that no particles reach the isocenter when the system is in beam-off mode. These initial results highlight the potential for zero dose at the isocenter. However, it is imperative to emphasize that these conclusions are provisional, and a thorough analysis will only be possible after the completion of the entire planned set of simulations.

4.3.1 Beam-on Stray Radiation (Clause 201.10.2.5.2.2)

The leakage radiation test results offer insights into the iArc system's performance under beam-on conditions, with a criterion of maintaining a dose ratio below 0.5% for all detectors. Notably, the 4 mm collimator demonstrates promising outcomes, surpassing the threshold with a single detector. However, deviations in the 8 mm and 14 mm collimators, where four and thirteen detectors exceeded the limit, respectively, indicate challenges in achieving the desired dose ratio with larger collimator sizes. This highlights the need for further optimization and investigation to enhance system performance.

5 Conclusion

The preliminary results of the study on the iArc radiosurgery system are promising despite their preliminary nature. The dose profiles and isodose curves demonstrate a symmetrical distribution along the X and Y axes, while an asymmetry is observed along the Z axis due to the 30-degree rotation of the iArc. Dose ratios increase with the reduction of the collimator diameter, suggesting less scatter. Leakage radiation tests, particularly with the 4 mm collimator, reveal promising results, but potential challenges are highlighted with larger collimators. These findings underscore the need for optimization and in-depth investigations to enhance the overall performance of the iArc system. The data provides a solid foundation for future studies.

Oxygen Effect on Tumor Response to Irradiation: Insights from GATE Simulation Studies

Zakaria Ait Elcadi[1] and Othmane Bouhali[1]

[1]Electrical and Computer Engineering, Texas A&M University at Qatar, Doha, 23874, Qatar.

Abstract The Oxygen effect significantly influences tumor cell response to irradiation, particularly in cases of tumor hypoxia. This study, using the GATE simulation code, evaluates dose distribution in a spherical tumor within the right lung under varying oxygen concentrations. The Oxygen Enhancement Ratio (OER) is employed to quantify the impact of oxygen pressure on radiation response. Two phases of investigation involve simulations of an XCAT phantom with a 1 cm diameter spherical tumor, applying oxygen levels from 5 to 80 mmHg. Results demonstrate a correlation between deposited energy, OER values, and oxygen pressure. The study reveals that low oxygen pressure regions require higher doses for comparable effects, emphasizing the need for tailored treatments based on tumor oxygenation. This research sets the groundwork for future studies on physiological factors influencing hypoxic tumors and their spatial relationship to varying tissue densities.

1 Introduction

The Oxygen effect plays a pivotal role in how tumor cells respond to irradiation. Tumor hypoxia has been acknowledged as a limiting factor in treatment response for many years. Diverse approaches to enhance the rate of tumor control have been experimented with, aiming to amplify the radical cascade [1].

Cells with an oxygen partial pressure (pO_2) below 8-10 mmHg are generally categorized as hypoxic [2] and exhibit greater radio-resistance compared to cells with normal oxygen levels (pO_2 up to approximately 100 mmHg [2]). This phenomenon can be quantified through the Oxygen Enhancement Ratio (OER), representing the ratio between the dose at a specific oxygen pressure and the dose at normal oxygen pressure that produces an equivalent biological effect ICRU Report 30: Quantitative Concepts and Dosimetry in Radiobiology. [3]

In this study, the dose distribution was assessed in a spherical tumor positioned at the center of the right lung. This tumor was generated using an XCAT phantom of an elderly woman, and various oxygen concentrations were considered. The evaluation was conducted using the GATE simulation code (V9.3) [4], employing the Monte Carlo method.

2 Materials and Methods

The investigation into the impact of oxygen on dose distribution was conducted using a female XCAT phantom, featuring a spherical tumor with a 1 cm diameter positioned at the center of the right lung (figure 1). This selection was influenced by the effect of low-density material on a spherical tumor with a density comparable to that of soft tissue. Various levels of oxygenation were applied to the spherical tumor to assess its response under different oxygen concentrations. The study utilized previously validated phase specifications of the Varian Clinac IX for a photon energy of 6MV [5] . The field size was fixed at 1.2x1.2 cm², employing removable jaws for a spherical tumor with a 1 cm radius, ensuring the tumor's central placement within the irradiation field. Oxygenation levels applied to the tumor ranged from 5 to 80 mmHg. The XCAT phantom was positioned at a source-surface distance of 100 cm. Results were analyzed based on deposited energy and OER values relative to O_2 pressure in mmHg, following a specific equation [6].

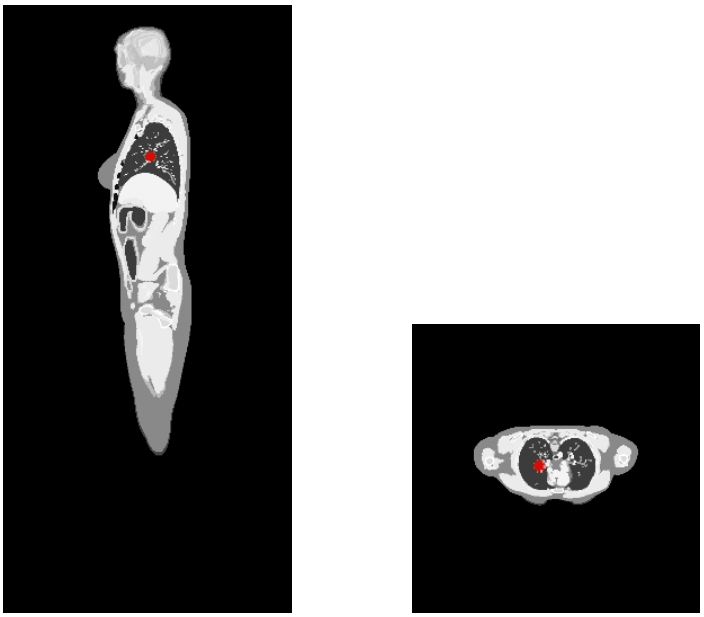

Figure 1: Coronal and transversal views of the female XCAT phantom show a spherical tumor centered in the right lung with a diameter of 1 cm.

3 Results

Nine simulations were conducted for the selected pressures in the initial phase of our study (figure 2). Figure (3) illustrates the deposited energy based on the O_2 pressure in the spherical tumor, while figure (4) displays OER values across O_2 pressures from 5 to 80 mmHg. The statistical error was a minimum of 2% for each simulation.

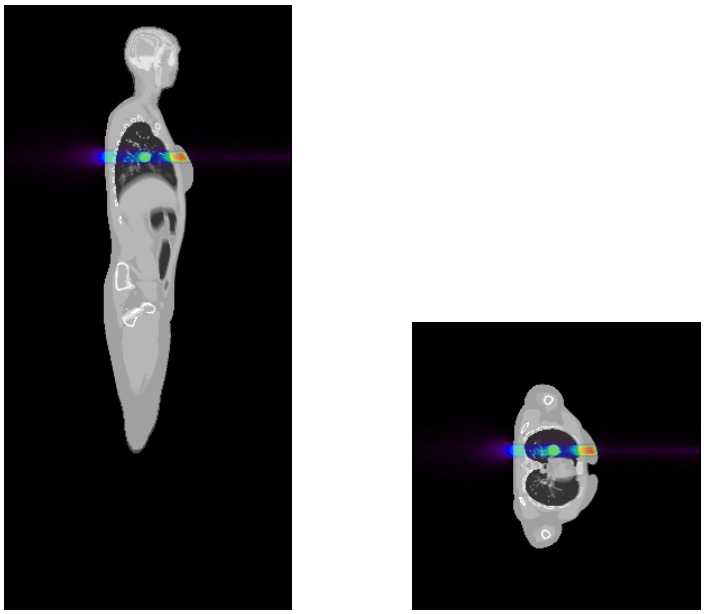

Figure 2: Coronal and transversal views of the female XCAT phantom, simulated in GATE and targeting the spherical tumor in the right lung, exhibit a 1 cm diameter with a 1x1 cm² field size.

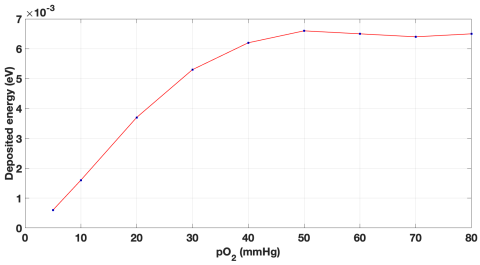

Figure 3: Energy deposition for various O_2 pressures applied to the spherical tumor.

4 Discussion

The figure 3 indicate that the deposited energy increases as the O_2 pressure grows, reaching a plateau at 60 mmHg. Beyond this point, the ratio remains constant (>60 mmHg), as illustrated in the figure. The OER values relative to O_2 pressure exhibit a linear growth up to 60 mmHg, followed by stabilization (figure 4).

In summary, the figures lead to the conclusion that regions with low oxygen pressure necessitate characterization by low deposited energy, requiring a higher dose to achieve effects comparable to regions with normal oxygenation. This consideration extends to the same biological effects to be achieved and the specific environment of the tumor, influencing the choice of a region with low density for this study.

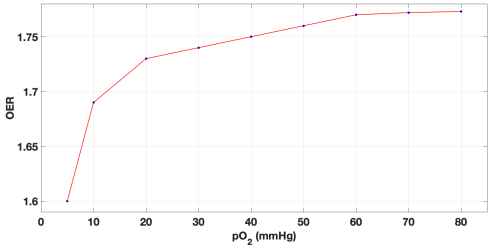

Figure 4: OER values are associated with each O_2 pressure applied to the spherical tumor.

5 Conclusion

The aim of this study was to explore the importance and necessity of oxygen (O_2) pressure in radiotherapeutic treatments. It was noted that the selected dosage for these treatments may differ, not dependent on the tumor and its location, but rather on the oxygen pressure within the tumor itself. This leads to the subsequent step of initiating a new study on physiological factors and biological effects that must be considered for tumors exhibiting hypoxia. Additionally, the study will examine the location of these tumors in relation to regions with varying densities, along with evaluating the dose received by neighboring organs.

Abstract In the context of predicting biological effects in Targeted Alpha Therapy, nano- and micro-dosimetry are essential because of the very heterogeneous dose deposition at cell level.
The NanOx [1] biophysical model has been developed and adapted to predict cell survivals to low energy ion irradiations. Combining CPOP to create complex spheroidal multicellular geometries and Geant4 to perform Monte-Carlo simulations, cell survivals can be calculated through NanOx algorithm for a given irradiation condition. This study's objectives are to investigate the impact of intratumoral radionuclide heterogeneities on mean cell survivals with our biophysical modeling chain, and to compare the results with the *in vitro* experiment of Neti et al. [2] and results obtained via the MIRDCell [3] tool.
The impact of a lognormal law on the initial activity per labeled cell, with varying shape factor, was evaluated, as well as the percentage of radiolabeled cells.
At 1% cell labeling, both MIRDCell and our model overestimate with several orders of magnitude cell survivals from the experiment. For 10% and 100% labeling, our simulation pipeline gave predictions with up to 0.89 R^2 for lognormal distributions.
This study highlights the consistency of our model's predictions with those of MIRDcell and the importance of considering realistic radionuclide distributions in calculations. However it also highlights the difficulty in reproducing as faithfully as possible experiments with limited controlled parameters.

1 Introduction

Targeted Alpha Therapy (TAT) is an emerging therapy, to treat localized cancers. It benefits from the short range of alpha particles emitted by specific alpha-emitter radionuclides, that are fixed to cancer sites with a biochemical vectors. Its recent rise is due to the improvements made in tumor targeting [4]. Being able to provide accurate dosimetry and predict part of the treatment efficacy would help clinicians in assessing the required injected activity for a patient. However, the short range of alpha particles (<100 µm, equivalent to a few cells) induces heterogeneity of dose deposition at the micrometric scale. A macroscopic dose would not be enough to predict cell survivals at the tumor scale.
Biophysical models, in the litterature, developed to calculate cell survivals to ion irradiation from nano and/or microdosimetry are validated for energies of hadrontherapy ($\sim$ 50-200 MeV/n). Experimental data are scarce to parameterize and validate the biophysical model's predictions at the few MeV of TAT. To that aim, we are currently adapting the NanOx biophysical model [1] to such low energies. Formalism and its hypotheses were previously described, and prediction results were compared to those of the previous formalism used for hadrontherapy applications to ensure autoconsistency and extension of the model's capabilities (article in submission process). In another study, we have explored the impact of intracellular distribution of radionuclides in TAT on several indexes like the nucleus physical dose or the Tumor Control Probability (article also in submission process). These studies were performed with a uniform intratumoral radionuclide distribution. This does not represent the variety of experimental cases. Moreover, there is a need for the biophysical model to be strengthened by experimental validations. The present study is dedicated to the comparison with the Neti et al. [2] experiment, that was chosen because their experimental parameters are given and controlled enough to be reproducible by simulation. The main objective of this study is to explore the impact of intratumoral distribution in TAT outcome predictions, and to compare the results with measures from the literature. Results will also be compared with the MIRDcell analytical-MC tool [3].

2 Materials and Methods

2.1 Multicellular irradiations

The multicellular irradiations were performed with CPOP [5]. CPOP is a layer on top of the Monte Carlo (MC) code Geant4, that allows the generation of complex multicellular geometries in which the particle tracking occurs. Due to its ability to allow flexible cell size and membrane deformation, compacted geometries can be used to reproduce as much as possible the different compaction level observed in *in vitro* or *in vivo* experiments.
Different degrees of intratumoral heterogeneity were considered in this study. Firstly, the percentage of radiolabeled cells was varied as 100%, 10% or 1%, meaning that only those cells contain alpha-emitter radionuclides. Secondly, the distribution of the initial activity per labeled cell (i.e. the number of alpha emitters) was investigated from a uniform to a lognormal law. Studies like Pasternack *et al.* [6] showed the importance of taking into account this type of distribution, to evaluate cell survivals. A lognormal law can be described with the mean activity per cell, and the shape parameter σ.

2.2 Cell survival calculations

Cell survival was chosen as the biological index in this study, due to the current knowledge on it and the model's abilities. The NanOx biophysical model was used to compute the cell survivals. This model has been developed for hadrontherapy applications, validated by comparison against experimental data and benchmarked to other biophysical models [1]. NanOx (like the other biophysical models) considers that only damage in a cell nucleus can induce cell death. A modified version of the NanOx formalism was used in this paper, to take into account the energy loss of ions in cell nuclei. This formalism relies on two main approximations, namely the "narrow track" and "charge equilibrium" approximations. The first one means that the secondary electrons emitted by ions are concentrated along the ion's trajectory at distances lower than 100 nm. Their tracking is therefore not required in the MC simulations. With the "charge equilibrium" approximation, all the energy transferred by the ion in the cell nucleus is deposited in it.
In MC simulations, any time an ion crosses a cell nucleus with an entrance energy E_i and an exit energy E_f, this can be converted into damage to the cell. These damage can be either lethal n_L, at the nanometer scale, or sublethal n_{SL} at the micrometric scale. Cell survival S is calculated as follows:

$$S = \exp(-n_L - n_{SL}) \quad (1)$$

2.3 Comparison to experimental data

In the experiment performed by Neti *et al.* [2], multicellular clusters of chinese hamster V79 lung fibroblast cells were created, by centrifugation. A defined percentage of cells were labeled with Po-210, a radionuclide that mainly emits a 5.3 MeV alpha particle. Clusters were made of millions of cells. For computing time and memory purposes, the cluster size has been reduced to 100 µm spheroid radius. According to the data given in the paper, the compaction level was $\sim 47\%$, and $\sim 22\%$ of radionuclides were internalized in nucleus, the rest remaining in the cytoplasm.
During the experiment, cells were irradiated in the centrifugation tube. The choice was made in this study to use a spheroidal geometry, to model a part of the cluster in the tube.
Three timelines could be defined: the activity uptake (0.5 h), the cluster maintenance (72 h) and the colony formation (96 h). Cells were maintained at a temperature that allowed them to stay in a cluster arrangement up to 72 h, without declining their ability to clone themselves [2]. After 72 h, cells were washed. As a result, radionuclides decays were supposed to be mainly happening during the cluster maintenance.
The parameters described in this paragraph were used for the following simulations. For 100, 10 and 1% cell labeling, the maximum activity per labeled cell were 0.1, 1 and 24 mBq. The default shape parameter of 2.0 for the lognormal distribution was used to follow the recommendations of [3], and different values will be tested to investigate different distributions. The cell survivals were also compared with results obtained via the MIRDcell tool [3], with the same parameters. To compare our work to the results published in Neti *et al.*, a R^2 test for goodness of fit was performed, on logarithmic cell survivals.

2.4 Studied data and parameters

The different data in this study are the measures from Neti et al., the calculations performed with MIRDCell and the ones from the CPOP - Geant4 - NanOx model (CGN). Simulation results will be compared between themselves, and against the experimental data. The studied parameters will be: the percentage of cell labeling, the type of activity distribution in cells (between uniform and lognormal), and the shape factor of a lognormal distribution. Results will be presented as a function of the mean injected activity per cell, calculated for a time of 94h. When the cluster activity is calculated, simulated activities are normalized to scale from the 2480 cells modeled to the 4.10^6 cells in the experiment.

3 Results

3.1 Impact of the distributions of initial activity per cell

Figure 1 shows the mean cell survival as a function of the mean initial activity per cell, with 10% cells radiolabeled. Are presented the experimental data from Neti *et al.*, and the prediction of our CGN model with an uniform and lognormal distribution of activity per cell. The measured mean cell survival is a fit given by the authors for their data. The shape factor (σ) of the lognormal law varied between 0.5 and 2.0. For a 2.0 lognormal shape factor, the CGN model overestimates cell survivals by up to 4 times higher than the experimental data. The lognormal distribution with σ equal to 1 stay within 2.5 times the cell survivals from the uniform distribution, $\sim$ 10 times lower than the lognormal with σ = 2.0.
For the 0.5, 1 and 2.0 shape factor, the R^2, compared to the experimental data, are respectively equal to 0.55, 0.89 and 0.23. It is equal to 0.44 for the uniform distribution.

Figure 2 represents the mean cell survival as a function of the mean activity per cell, with 100% of cells labeled with radionuclides. With MIRDcell and our CGN model, results with both uniform and lognormal radionuclide distribution are presented. Results are presented with a 2σ error, for the rest of the study.
In this logarithmic representation, the experimental mean cell survival in the Neti experiment follows a linear law with a slope of ~ -0.993, and starts to "saturate" with increasing cell activity.

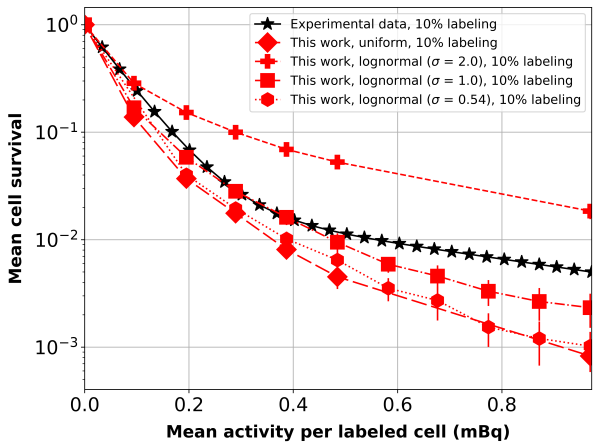

Figure 1: Mean cell survival calculated as a function of the mean activity in each cell, with 10% cells radiolabeled. Experimental data from Neti et al. [2] are in stars (solid line). Data calculated with the CGN model distributed via a lognormal law with a shape factor of 2.0, 1.0 and 0.54 are, respectively in plus signs (dashed), squares (dashdotted), hexagons (dotted). The simulations with a uniform distribution are in diamonds, with long dashes.

For lognormal distributions, MIRDcell mean survivals are 2 to 6 times higher than survivals from the CGN model.
For both models (MIRDcell and CGN), applying a lognormal distribution to the number of radionuclides in cells, increases the cell survival. For example, for the CGN results, differences can go from 10-fold differences at 0.015 mBq per cell to more than 100-fold above 0.030 mBq per cell.
For the CGN results, the R^2, compared to measured data, are 0.28 (lognormal distribution), and -47.6 (uniform distribution). For MIRDcell, R^2 are 0.78 (lognormal distribution), and -17.8 (uniform distribution)

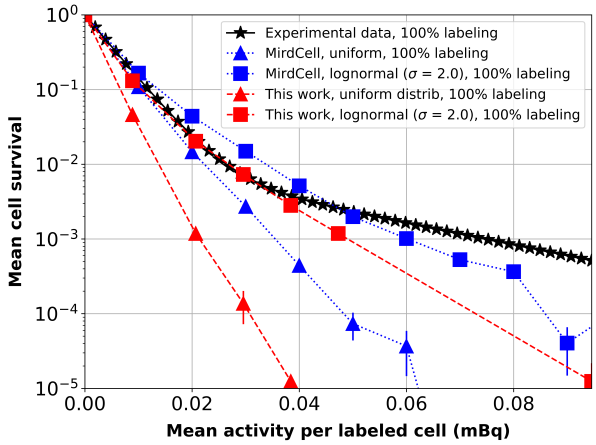

Figure 2: Mean cell survival calculated as a function of the mean activity in each cell, with all cells labeled with radionuclides. Experimental data from Neti *et al.* [2] are in stars (solid line). Simulation data with a uniform distribution are in triangle, those with a lognormal one are in squares. MIRDcell data are plotted in dotted lines, and CGN in dashed lines.

3.2 Impact of the percentage of cell labeling

Figure 3 shows the mean cell survival as a function as the total cluster activity in kBq.

For the same total cluster activity, cell survival differences range from $\sim$ 2 at 0.04 kBq to 10-folds at 0.39 kBq. The lower the % of radiolabeling, the higher the mean cell survival. In the experimental data, survivals at 1 and 10% cell labeling are similar. For MIRDcell and CGN, differences can go up 20-fold.
Looking at the 1% cell radiolabeling, the R^2, compared to experimental data, with MIRDcell are -4.61 (lognormal distribution) and -3.63 (uniform distibution). With NanOx, they are -4.47 (lognormal distribution) and -3.51 (uniform distribution).
The minimum of mean cell survival obtained with our model is 0.183 ± 0.007. For the Neti experiment, the minimum is equal to $1.7 * 10^{-4}$, for the same activity per labeled cell.

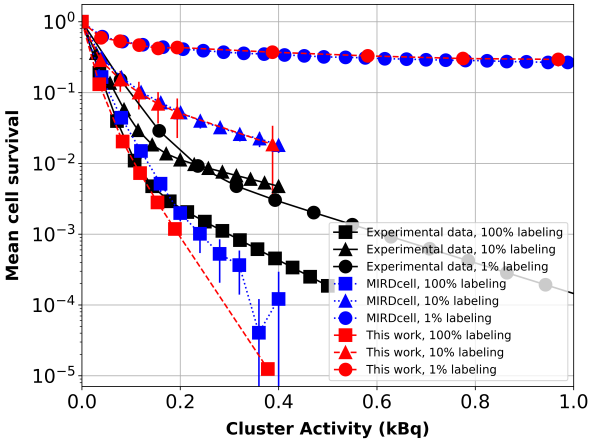

Figure 3: Mean cell survivals as a function of the total cluster activity (kBq). The measures from Neti et al. (solid lines), and calculations performed with the MIRDcell (dotted lines) and CGN (dashed lines) are presented. All calculations were done with a lognormal distribution on the number of radionuclides per labeled cell, with a shape factor of 2.0. Neti et al. data are a fit given by the authors on their experimental data. Data at 100, 10 and 1% cell labeling are, respectively, in squares, triangles and circles.

4 Discussion

This study confirms that applying a lognormal distribution seems to have a major impact in cell survivals assessment, as previously shown in the literature. A lognormal distribution could be creating some areas with lower radionuclide concentration. Even though, alpha particles can cross $\sim$ 40 µm, it is not enough to irradiate entirely a cluster of 100 µm radius. Under the activities observed, there is never a complete saturation because the emptier areas will eventually get irradiated by fixed radionuclides in this area or nearby, if a majority of cells are radiolabeled.

The shape parameter of a lognormal law can be defined as potential variations allowed for the distribution. When it tends towards zero, the distribution becomes closer to an uniform one and cell survivals get lower, as observed in Figure 1 and confirmed by experiments in the literature [6]. To model *in vitro* experiments, it appears mandatory to have measured the shape factor beforehand to set up the simulations with a lognormal distribution on the number of radionuclide per labeled cell. Considering only an uniform distribution of radionuclides could explain an overkilling in cell predictions.
The lower cell survivals when a lognormal law is applied can be associated to an overkill effect. Adding more radionuclides to a cell zone that is already mostly dead will not have an important effect on cell killing. The untouched cells will keep increasing the mean cell survival.

Results between MIRDcell and our model have similar orders of magnitude. The differences can be explained with the NanOx being closer to the physical reality. In particular, the (α, β) coefficients for cell survival calculations are constant in MIRDcell, while varying as a function of the energy in NanOx. Furthermore, the NanOx model was built to be flexible and easily enhanced.

At 100% cell labeling, according to the R^2 goodness of fit test, the simulations with a lognormal distribution at $\sigma = 2.0$ are fitting better the experimental data. The negative R^2 from the uniform distribution means that the prediction is worse than using the average horizontal value. Except for MIRDcell under 0.05 mBq per cell, models tend to overestimate cell death. Especially, the saturation of cell survivals in the Neti et al. experiment is not well reproduced, and the explanation is not straightforward. Several hypotheses are under investigation like cellular protection could be happening, as well as reparation effects.

To explain why cell survivals at 1% radiobeling are off the charts compared to Neti et al. experiments, regardless of the model used, multiple paths are guessed. Firstly, as pointed in the reference article [2], bystander could be a non-considered effect that increases cell death. Adding bystander damage to the model is an option to understand if this path is enough to explain the differences. Secondly, experimental uncertainties not taken into account in this paper could induce some deviations. For example, radionuclides could diffuse in the cluster and alpha particles emitted could hit more cells than in our simulations.
The saturation in our simulations could be explained by a geometric effect, where all cells that could be hit by helium ions are already dead, and increasing the dose would only kill those already dead cells. Moreover, the washes made to remove radionuclides from cells could not be optimal and cells could be still irradiated during the clonogenic assays, which this study doesn't take into account.
The Geant4 simulations were performed only in spheroid configurations. But, in the Neti et al. experiment, the geometry changes after 72 h, with cells still being irradiated. The impact of this geometry change has yet to be evaluated.
The effect of the percentage of radiolabeling heterogeneity, major in our simulations, is slim between the 10 and 1% Neti et al. experiments, although significantly different at 100% labeling. A comprehensive study of the impact of this type of heterogeneity on cell survivals or other physical and biological indexes will be done in the future.
This study underlines the difficulty of working with experimental data of low energy ion irradiation. Even with the multitude of controlled parameters in the Neti et al. experiment, many uncertainties restrain the perfect reproduction of it. However, the flexibility of our simulation pipeline allows the user to adapt to many complex irradiation configurations.

5 Conclusion

This ongoing study is a first validation step of the CGN pipeline for TAT. To model and predict properly *in vitro* experiments, one has to consider the intratumoral distribution of radionuclides in cells and, at best, to have it first measured depending on the vector. On top of that, knowing the ability for the targeting vector to fix to cells, i.e. the percentage of radiolabeling is mandatory to avoid errors up to several orders of magnitude.
The results given by our pipeline, using an intratumoral distribution of radionuclides is promising, although gaps have to be overcome, like the lack of saturation in our cell survivals for high radiolabeling and the severe underkilling at low radiolabeling.

DINo: Deep learning Intelligence for Nuclear reactions

Lévana Gesson[12], Greg Henning[1], Uli Weber[2], Marie Vanstalle[1]

[1]Université de Strasbourg, CNRS, IPHC UMR 7178, F-67000 Strasbourg, France
[2]Biophysiks, GSI-Fair, Darmstadt, Germany

Abstract In radiation therapy, precise dose calculations are crucial for treatment plan improvement, relying on advanced algorithms based on Monte Carlo simulations. Persistent discrepancies between experimental data and hadronic models in particle therapy highlight the need for improved accuracy. This study introduces DINo (Deep learning Intelligence for Nuclear reactions), a deep learning algorithm designed to explore solutions for these challenges. DINo uses partial proton nuclear reactions cross-sections to extrapolate total cross-sections, mitigating limitations in existing models. Focused on protons, with an extensive representation in the TENDL nuclear data library, DINo, as a dense neural network, learns from TENDL's 2019 model values, effectively predicting total cross-sections for unexplored initial energies. Preliminary results tend to indicate DINo's superior predictive capabilities compared to the TENDL model, promising enhanced precision in nuclear reaction data and refined dose calculations for particle therapy.

1 Introduction

Dose calculations in radiation therapy heavily rely on advanced algorithms incorporating both physical and biological processes, based on data provided by Monte Carlo simulations. However, discrepancies persist between experimental data and hadronic models, particularly in nuclear reactions in particle therapy, leading to potential inaccuracies in dose calculations. Therefore, the implementation of measured data into existing codes is challenging but essential [6]. This abstract proposes the development of a deep learning algorithm called DINo (Deep learning Intelligence for Nuclear reactions) that proposes to leverage partial proton nuclear reactions cross-sections to extrapolate total cross-sections data, mitigating the data limitations within current models.

2 Materials and Methods

The TENDL nuclear data library [1], based on TALYS theoretical code, includes the state of the art in nuclear reaction models, taking into account all major reaction mechanisms encountered in light particle-induced nuclear reactions. The library encompasses a great amount of proton data, leading to the choice of protons as the focal point for this study. Figure 1 illustrates the cross-sections for incident protons on a ^{12}C target, given by the TENDL library, focusing on the comparison between the TENDL model results with experimental data from EXFOR [7] for the p(^{12}C,X)^{11}C reaction alongside with the total cross-section.

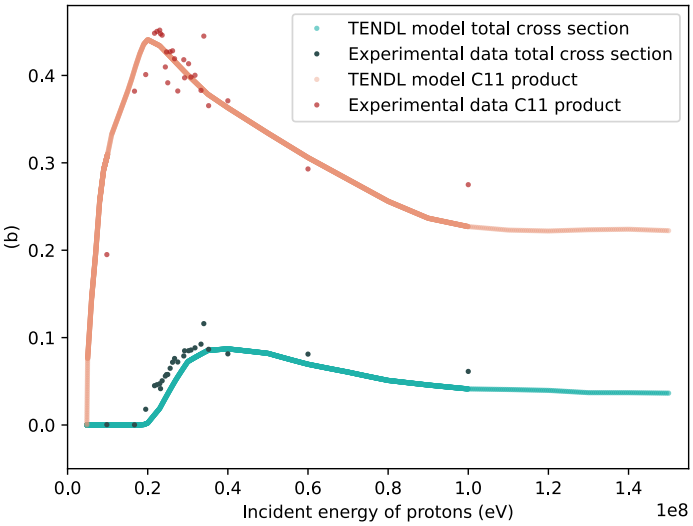

Figure 1: ^{11}C product cross-sections and total cross-section for incident protons on a ^{12}C target – TENDL model results compared to experimental data (data error in the order of 2% not visible on the plot).

The $\chi^2 = \sum \frac{(predicted-expected)^2}{expected}$ value for the comparison between TENDL model and experimental data for total cross-section is 4.5±1.0.

Introduced as a dense neural network (DNN), the DINo algorithm learn from the TENDL 2019 model values, focusing on charge changing cross-section of ^{11}C as a function of proton projectile initial energy, alongside with their corresponding total cross-section. DINo aims at predicting total cross-sections for initial energies not covered by current experimental data. On figure 3 is shown a simplified scheme of the algorithm global structure.

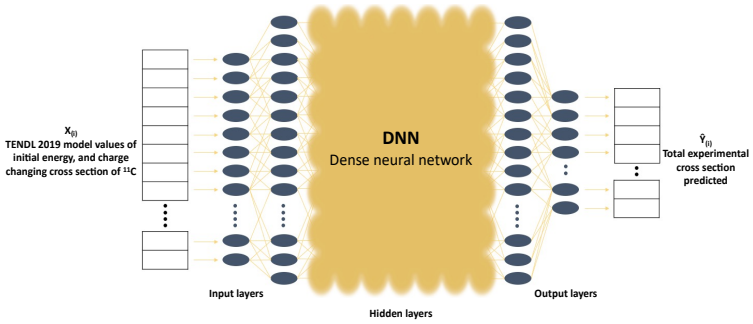

Figure 3: DINo simplified structure

During the algorithm learning phase, 70% of the TENDL model values of ^{11}C charge-changing cross-sections, alongside with their corresponding initial energy, serve as input data. Simultaneously, the total cross-section values, linked to the respective initial energies, are designated as output. To evaluate the algorithm's proficiency, 30% of the TENDL model values are reserved for testing at each epoch. Following 60 epochs, the algorithm is ready for application to experimental data.
During the algorithm testing phase on data, it receives experimental values for ^{11}C charge-changing cross-sections with associated initial energy, enabling it to predict the corresponding experimental values for total cross-sections at those specific initial energies.

3 Results

Figure 4 presents predicted experimental total cross-sections values by DINo alongside TENDL model values and actual experimental data.

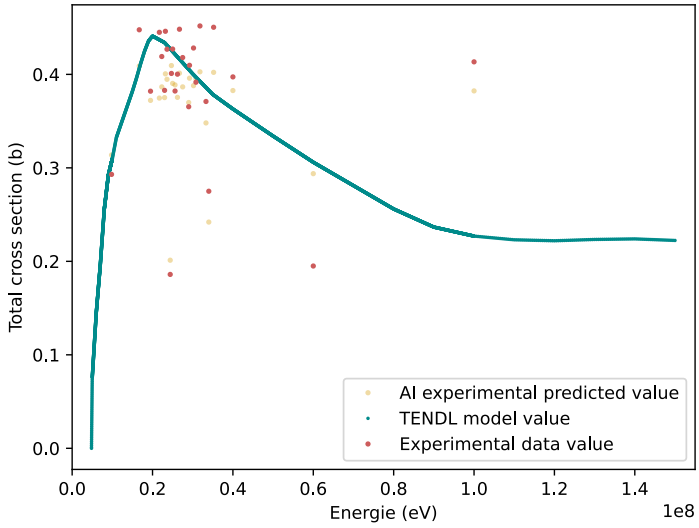

Figure 4: Total cross-section for incident protons on a ^{12}C target as a function of incident energy: TENDL model results and DINo prediction compared to experimental data (data error in the order of 2% not visible on the plot).

The comparison in Figure 5 highlights the efficacy of DINo predictions in relation to both TENDL model results and experimental data. The χ^2 values demonstrate a superior compatibility between the experimental data and the DINo algorithm predictions compared to the TENDL model.

Indeed, the χ^2 between the experimental data and the TENDL model is, like said in previous section, 4.5 ± 1.0 when the χ^2 between the experimental data and the DINo algorithm prediction is 2.9 ± 0.6.

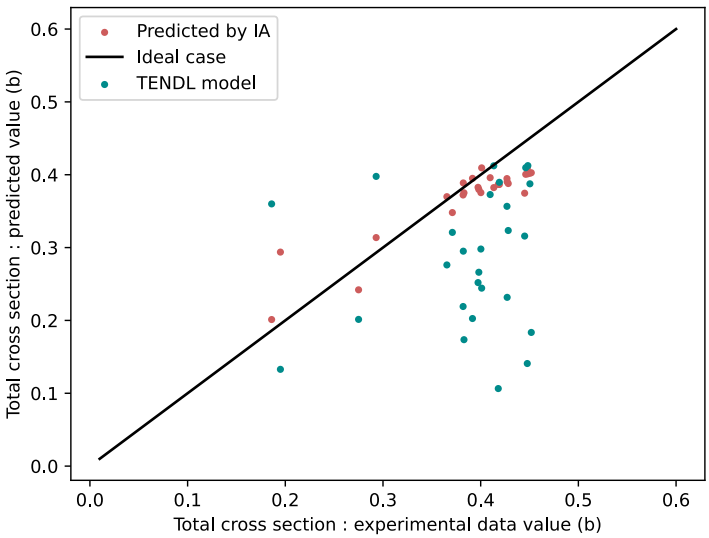

Figure 5: ^{11}C product cross-sections and total cross-section for incident protons on a ^{12}C target: TENDL model results and DINo prediction compared to experimental data (data error in the order of 2% not visible on the plot).

4 Discussion

In this study, the deep learning algorithm DINo exhibits enhanced predictive capabilities for total cross-sections compared to the TENDL model. Even in the worst case scenario, DINo's prediction align with TENDL's performance. Indeed, the χ^2 of 3.5 is reached as the best TENDL's performance and the worst DINo's performance. In optimal situations, DINo outperforms the TENDL model by a factor 2.4.

5 Conclusion

These findings underscore the potential of the deep learning approach in improving the accuracy of predicting nuclear reaction data, in order to to enhance the precision of dose calculations in particle therapy.

To establish the efficacy and reliability of the proposed algorithm in predicting missing experimental data, further investigations on additional charge-changing cross-sections and different target materials are needed. This study lays the foundation for future research aimed at expanding the scope and applicability of the deep learning algorithm in the realm of nuclear reactions.

Abstract This study aims to optimize the design of the low dose radiotherapy machine for the osteoarthritis to develop the dedicated machine. Monte Carlo (MC) simulation was employed in the optimization by using the GEometry ANd Tracking 4 (Geant4). Firstly, the appropriate source for the osteoarthritis treatment was defined by comparing physical characteristics of different radionuclides currently used in radiotherapy. Next, geometry of the collimator, housing and source were optimized. Geometry of the collimator and housing was optimized in terms of its thickness by evaluating transmission rate of photons from the source according to different tungsten thickness. The source geometry was optimized in terms of its length and diameter as it had cylindrical shape. Finally, the dose distribution produced by the dedicated machine was evaluated according to its rotation steps. The results is expected to contribute development of compact and simple treatment machine for the osteoarthritis.

1 Introduction

Osteoarthritis is one of the most common disease in those over 65 in Korea with incidence rate of approximately 37.8% [1]. Typically, both surgical and conservative treatment have been employed for the osteoarthritis. However, these treatment methods have been reported to have limitations and side effects, for example, cardiovascular damage and increment of gastro-intestinal hemorrhage due to usage of nonsteroidal anti-inflammatory drugs [2, 3].

Low dose radiotherapy (LDRT) was reported as one of the effective methods to cure the osteoarthritis with 63-90% reduction of its symptom [4]. The LDRT have been employed for the osteoarthritis in Europe since early 1900s and over 85% of the therapeutic facilities carry out the LDRT in countries such as German [5]. Meanwhile, the LDRT has never been employed to cure the osteoarthritis in Korea even considered as a treatment option for the osteoarthritis.

Currently, the dedicated RT machine is not available in hospital. The LDRT for the osteoarthritis is carried out by using medical linear accelerators (LINACs), which is inefficient because the LINAC mainly targets cancer patients and its cost is very expensive to buy new machine just for treating the osteoarthritis. Therefore, the LDRT machine for the osteoarthritis with appropriate structure and reasonable price is required.

The aim of this study was to define the optimal design of the dedicated RT machine to develop the clinically available machine. Monte Carlo (MC) simulation was carried out to decide the optimal design of the RT machine. Subsequently, dose distributions in cylindrical water phantom, which mimicked knee joint, were assessed according to different beam delivery technique.

2 Materials and Methods

The design optimization was carried out by using the GEometry ANd Tracking 4 (Geant4) tool-kit, which was written in C++ language with high flexibility and powerful calculation of particle transportation. The optimization was carried out for the radiation source, collimator, and housing of the treatment machine. Figure 1 shows illustration of the dedicated RT machine. The machine delivers therapeutic beams from different beam directions by rotating the radiation source around patient's leg located at rotation axis of the RT machine.

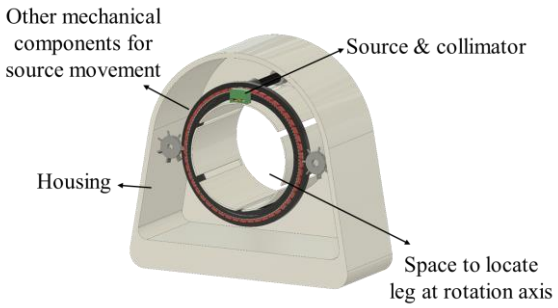

Figure 1. Illustration of the LDRT machine for the osteoarthritis

The RT machine was designed to use radionuclide as the radiation source. The optimization started from decision of which type of radionuclide would be appropriate for treatment of the osteoarthritis. Evaluation was carried out on physical characteristics of radionuclides being commonly used in current radiotherapy, such as gamma knife, brachytherapy, and etc. The energy of the gamma ray decides the available depth of the treatment. The half-life refers replacement period of the source. The specific activity is related to available dose rate of the treatment machine. The source was defined with consideration of the requirements for the LDRT of the osteoarthritis.

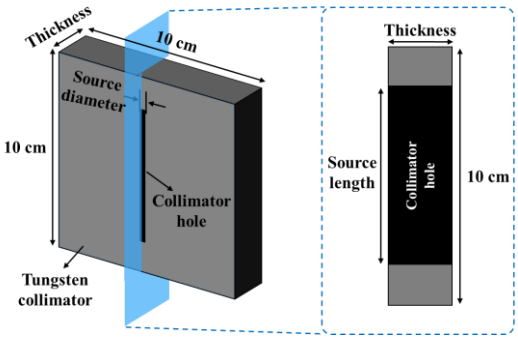

Figure 2. Design of the tungsten collimator

The collimator and housing consisted of tungsten (ρ = 19.3 g/cm^3). The collimator was designed to have parallel hole, which minimize the beam divergence due to isotropic emission of the gamma ray from the radionuclide (Figure 2). It was important because sequential beam delivery is required to cover the treatment site. The fall-off region of each field should be steep as possible to avoid dose overlap at field junction, especially at surface of patient. Size of the collimator hole was defined as that of the source.

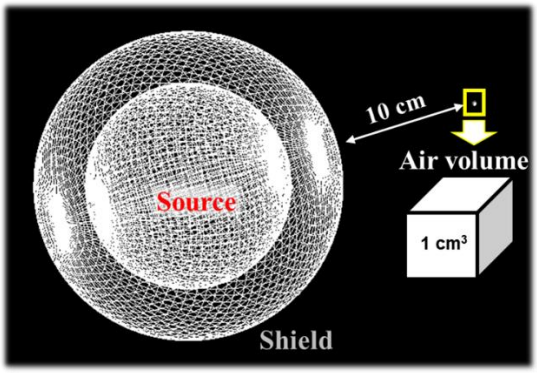

Figure 3. Monte Carlo simulation to calculate gamma transmission according to tungsten thickness

Thickness of the collimator and housing was optimized to stop at least 95% of the gamma ray from the source. The MC simulation was employed to define the optimal thickness of the collimator (Figure 3). Transmission of the gamma ray was calculated according to different thickness of tungsten, which varied from 1 to 4 cm with 0.5 cm steps. Total of 8×10^7 photons were generated at each simulation. Fluence of the gamma ray was assessed in the air volume that located at 10 cm from the tungsten surface. The results were compared to that calculated mathematically based on the equation below:

$$I = I_0 e^{-\mu t}$$

Shape of the source was determined as cylinder. To decide the optimal source geometry, dose distributions in the knee phantom were simulated according to source diameters and lengths. Diameter of the source was varied as 1, 5, 10, and 20 mm. Nominates for source length were 10, 27, and 50 mm where 27 mm was the length of the radiation source embedded in the MR/^{60}Co machine manufactured by ViewRay®.

Figure 4 shows the simulation setup for calculating dose distribution in the knee phantom. The source was attached to the collimator while the beam angle was fixed at 0. The distance between the source and center of the phantom was 27.5 cm, which refers the source-to-surface of the phantom of 15 cm. The number of generated photon in each simulation was 8×10^7. The knee phantom was modelled to simulate dose distribution in patients given the LDRT for the osteoarthritis (Figure 4). The phantom was filled with water. It had cylindrical shape with diameter and height of 25 and 20 cm, respectively. The diameter of the phantom was decided by considering Korean standard of knee width (16 cm) with its variation, and compensation to produce uniform dose distribution in the entire treatment site. The length was decided as it describes stretched leg.

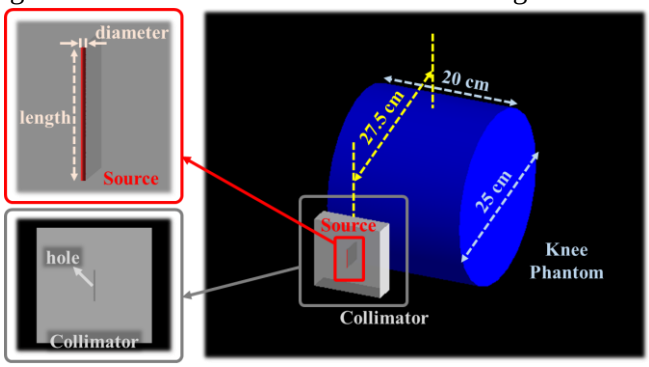

Figure 4. Monte Carlo simulation for calculating dose distribution in the knee phantom

Finally, the dose distributions were calculated according to different intervals of beam angles consisting a single arc. The interval was 60, 45, 40, 30, 20 and 10 degrees. Simulation condition was identical to that represented in Figure 4 except that the optimized source rotated around the phantom.

3 Results

Table 1 shows physical characteristics of radionuclides used in the radiation treatment. Among the radionuclides, ^{125}I and ^{103}Pd are not appropriate for the osteoarthritis treatment since the photons cannot reach the treatment site at center of leg joint. In addition, ^{103}Pd has too short half-life that requires frequent source replacement, which can make the performance maintenance of the RT machine be challenging. Meanwhile, ^{137}Cs has much lower specific activity than other radionuclides, which can lead to lower treatment efficiency due to low beam output. Therefore, ^{60}Co was defined as the radiation source of the RT machine with better stability of activity for long period and availability to dose delivery to deeper region than ^{192}Ir. Despite that ^{192}Ir has higher specific activity than ^{60}Co, ^{60}Co has sufficient specific activity to be used in LDRT and even larger specific activity requires thicker radiation shielding due to unnecessarily high dose rate.

Table 1. Physical characteristics of radionuclides used in the radiation treatment

Source	Energy (keV)	Half life	Specific activity (Ci/g)
^{137}Cs	661.6	30.05 yr	86.49
^{60}Co	1173, 1331	5.2 yr	1,130
^{192}Ir	310 - 380	74 d	9,220

	(average)		
^{125}I	28 (average)	60 d	17,000
^{103}Pd	21 (average)	16.99 d	> 67,600

Figure 5 shows the transmission of the ^{60}Co gamma ray according to different tungsten thickness with comparison between the MC simulation and mathematical calculation. Both results decreased exponentially as tungsten thickness increased. The difference between the simulation and mathematical calculation increased with larger tungsten thickness due to the contribution of the scatter, which was excluded in the mathematical calculation. In the results, tungsten with thickness larger than 3 cm could stop 95% of the gamma ray. This implies that thickness of the collimator and housing needs to be larger than 3 cm.

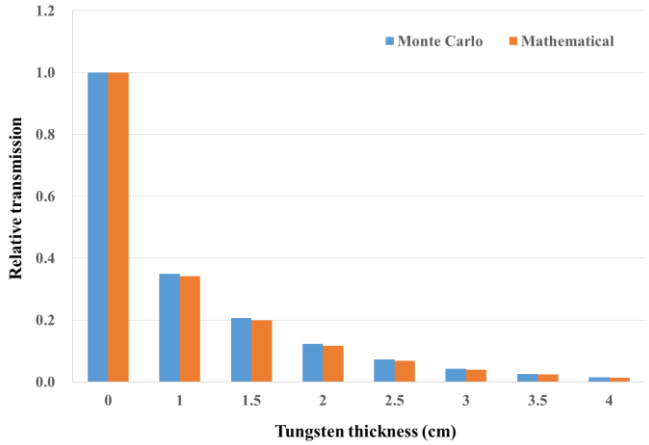

Figure 5. Transmission rate of ^{60}Co gamma ray according to tungsten thicknesses with comparison between the Monte Carlo simulation and mathematical calculation

The dose distributions according to different source diameter and length were shown in Figure 6. The diameter was fixed at 1 mm in the investigation of effect of the source length on dose distribution. The dose distribution was obtained on the transverse plane at center of the phantom. The source produced broader dose distribution with length of 27 and 50 mm than 10 mm. Since larger source has higher activity that requires more bulky shielding, the source length was decided as 27 mm.

In the investigation of dose changes because of different source diameter, the source length was fixed at 27 mm. The dose distribution was obtained on the coronal plane at center of the phantom. Larger source diameter produced broader dose distribution with increased penumbra. This can lead to enhancement of hot or cold spots at the field junction when the beam scans patient's leg along the rotation axis. The beam divergence along superior-to-inferior direction of the phantom should be minimized. Therefore, the diameter of the source was defined as 1 mm.

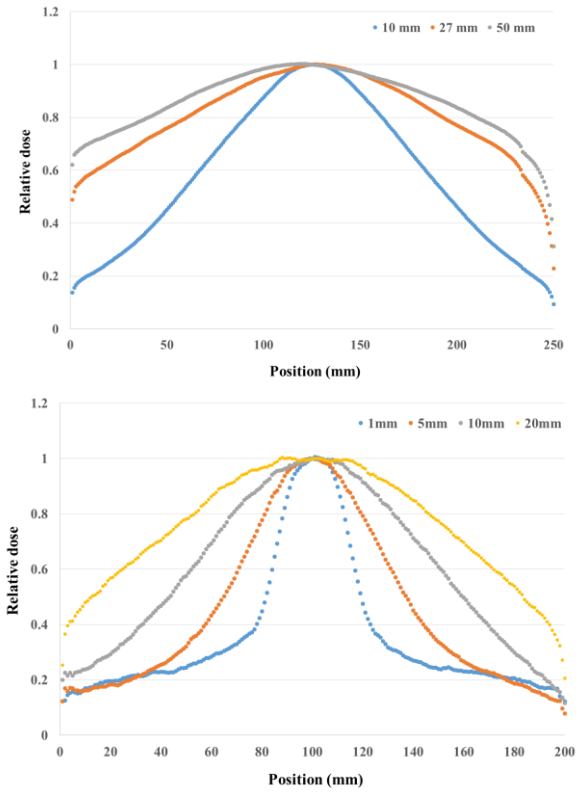

Figure 6. Dose distributions according to different source length (upper) and diameter (lower). Note that, the dose distributions with different source length and diameter were obtained on the transverse and coronal plane of the phantom, respectively.

As shown in Figure 7 and 8, the dose distributions were compared among the beam delivery techniques with different beam angle interval consisting a single arc. The lateral dose of 60-degree interval was higher than the other when the profile was obtained along vertical direction. Meanwhile, it was the lowest in the horizontal profile. This was due to sparse beam delivery compared to the other beam delivery conditions. However, all of the results showed that the region with diameter of 20 cm at the center was given the dose with the variation less than 10%. In addition, the dose distribution was almost identical when the beam angle interval was larger than 45 degrees.

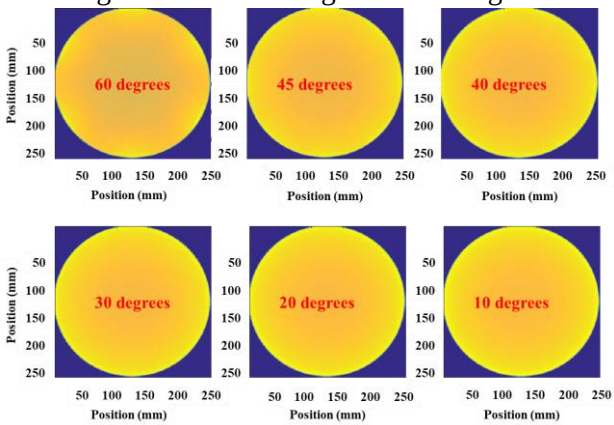

Figure 7. Dose distributions according to different beam angle intervals

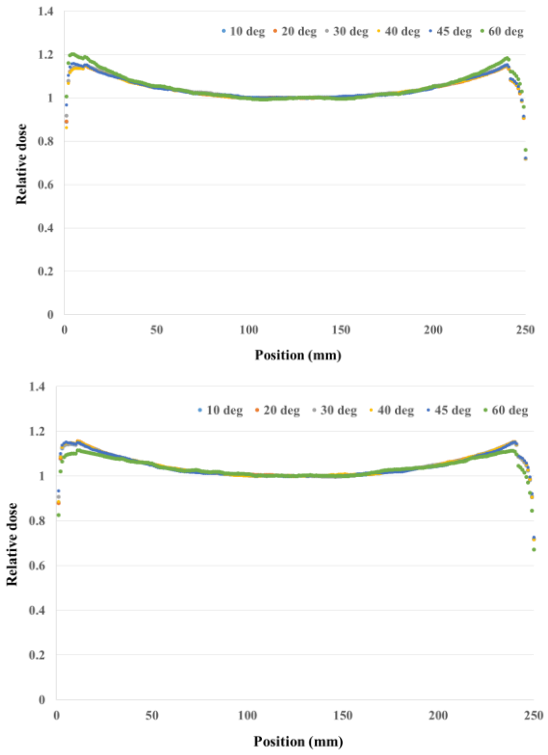

Figure 8. Vertical (upper) and horizontal (lower) profiles of the dose distribution in Figure 7

4 Discussion

In this study, investigation for the optimal design of the LDRT machine for the osteoarthritis was carried out. The machine consisted of the radiation source, the collimator, and the housing. The machine showed uniform dose distribution in broad region, which can sufficiently cover patient's leg.

As the radiation source, radionuclide was selected rather than the x-ray generator. The machine was designed to be compact and simple. The x-ray generator requires additional space for producing accelerated electrons, which can make the machine more bulky than using radionuclides even required x-ray energy is hundreds keV. In addition, radionuclide as the radiation source does not require mechanical maintenance. In the case of radionuclide with long half-life, such as ^{60}Co in this study, the dose output can be stable for more than year.

The dose distributions according to the source lengths showed acceptable tendencies. The difference was smaller between 27 and 50 mm than 10 and 27 mm. It was due to the cylindrical shape of the phantom. Depth of water was insufficient for build-up of the gamma rays reaches border of the phantom. The dose distribution was broader with larger source diameter. However, the width of the dose distribution was much larger than that of the source. Even parallel-hole collimator produced diverged beam due to the clearance between the collimator and patient. Since the dose output can be decreased as the collimator is located closer to patient, further investigation on the optimal distance between the collimator and patient is required.

The dose distribution produced by the arc beam delivery showed possibility of the dedicated RT machine to be used in the clinic. Even the beam was discretely delivered at different directions but produced uniform dose distribution with the variation less than 10%. Since the radiation treatment of the osteoarthritis requires uniform dose in large treatment site, the results proved availability of the RT machine. In addition, the results also showed that uniform dose can be delivered by continuous rotation of the radiation source with fixed speed. Further, relation between the rotation speed and dose per a single arc should be investigated to apply the dedicated machine in the clinic.

Current study focused on design of the dedicated machine based on the MC simulation. Study on application of the machine to actual treatment plan is required based on both the simulation and measurement. Algorithm for establishing treatment plan of the patients undergoing the osteoarthritis is also necessary. For clinical application of the dedicated RT machine, investigations on safety-related managements, such as evaluation of leakage dose, are also required. Therefore, further studies will be carried out to develop the LDRT machine for the osteoarthritis and to apply the machine in the actual treatment.

5 Conclusion

In this study, the design of the dedicated RT machine for the osteoarthritis was defined and its availability on clinic was evaluated. It is expected that the machine can be applied to the actual treatment by manufacturing its hardware and developing its treatment planning algorithm. Further, the machine can contribute improved treatment quality of the osteoarthritis.

Abstract We present a variance reduction technique (VRT) for Geant4/GATE Monte Carlo (MC) simulations, tailored to the simulation of prompt-gamma (PG) radiation caused by proton inelastic processes in the patient. This technique is based on a track-length estimator to generate 3D sources of PG energy and emission-time yields. Results show minor discrepancies with respect to analog MC. A gain in efficiency of about 50 is reported for the detection of PG.

1 Introduction

Compared with standard radiotherapy, monitoring the dose delivered in proton therapy is much more problematic because no primary particles leave the patient. On-line monitoring of secondary radiation such as prompt-gammas (PG) emitted after nuclear inelastic processes is one of the techniques being developed to ensure that the dose delivered complies with the treatment plan. The design and optimization of the detector setup require multiple Monte Carlo (MC) simulations, and the use of variance reduction techniques is highly desirable. An estimator based on track length was originally proposed to build 3D sources of PG energy yields [1, 2]. It has recently been adapted to compute 3D sources of PG emission-time yields, in addition to PG energy yields. We present a benchmark of this module named vpgTLE-tt against analog MC in the Geant4/GATE simulation framework.

2 Materials and Methods

2.1 Description of the vpgTLE-tt module

The vpgTLE-tt module consists of three stages as depicted in Figure 1. Stage 0 is run off-line to build the database of PG energy yields (indexed by proton energy E_p) for a set of elements characterized by their atomic number Z. Stage 1 is then set according to the scene to be studied. The outputs of Stage 1 are two 3D voxelized sources (assumed to be uncorrelated) of PG energy $\boldsymbol{E}_{pg}$ and emission-time $\boldsymbol{t}_{pg}$ yields: for each step of the proton track in a given voxel, the PG energy yield is read (from Stage 0 corresponding to the voxel material and the proton energy) and scored in an histogram with a weight corresponding to the track length. Likewise, the PG emission time is randomly drawn between the pre- and post-step points and scored in an histogram with a weight corresponding to the track length. In Stage 2, the voxelized yield sources $\boldsymbol{E}_{pg}$ and $\boldsymbol{t}_{pg}$ are then read and a number of PG events is run according to the total PG yield (integral of $\boldsymbol{E}_{pg}$) and the requested number of proton N_p.

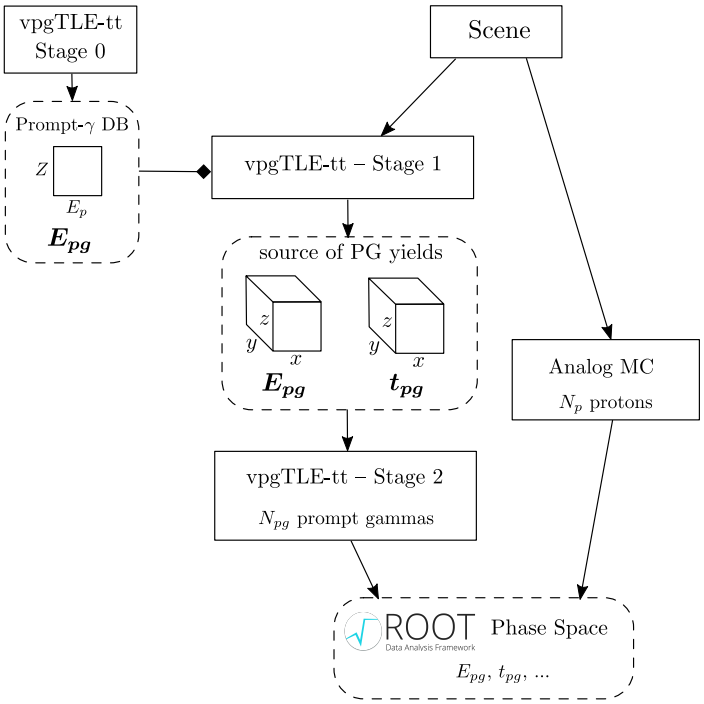

Figure 1: Diagram of the vpgTLE-tt module (see description in section 2.1).

2.2 Test case

A 3D Geant4/GATE view from the clinical Radiation-Therapy plan (RT-plan) is illustrated Figure 2. Only the 7 spots of the distal layer are considered, the proton energy is 133.08 MeV. The Geant4 physics list QGSP_BIC_HP_EMY has been used with 1 mm cuts for all particles. A statistics of 10^8 proton events has been used, which gives a statistics of 1.2×10^7 emitted prompt-gamma events. The ROOT scoring volume is a sphere shell (55 cm radius) around the patient head. The creator processes of the detected gammas in the analog MC simulation are first investigated to estimate the relative importance of the gammas coming from proton inelastic processes. The 2D gamma-yield distributions of the emission-time vs energy are therefore saved for the major creator processes from the ROOT output file. A benchmark study is finally conducted to assess the accuracy of the vpgTLE-tt module against analog MC. The relative error distributions correspond to the difference of the 2D gamma yield distributions divided by the respective analog maximum PG yields.

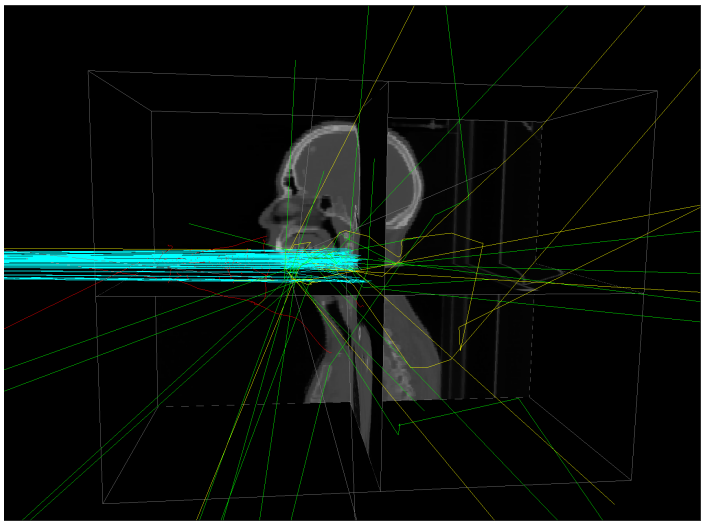

Figure 2: 3D scene view (with 100 incident protons) of the clinical RT-plan test case with 100 protons with Geant4/GATE. Protons are in cyan, gammas in green, neutron in yellow, electrons in red and positrons in blue.

3 Results

3.1 Creator processes of the detected gammas

The 2D distributions (emission-time vs energy) for several creator processes of the detected gammas in the scoring volume (sphere shell) are shown in Figure 3. Among all processes, the major six (in descending order) are: proton inelastic, annihilation, neutron inelastic, neutron capture, radioactive decay, and e-/e+ bremsstrahlung. Note that annihilation photons other than 511 keV have been either scattered in the patient (below 511 keV) or comes from positrons which are not at rest (above and below 511 keV). Table 1 lists the relative importance of all these processes.

process	counts	%
proton inelastic	1.17×10^7	53%
annihilation	7.14×10^6	32%
neutron inelastic	1.57×10^6	7.1%
neutron capture	7.94×10^5	3.6%
radioactive decay	6.96×10^5	3.2%
e-/e+ bremsstrahlung	8.96×10^4	0.4%

Table 1: Creator processes of detected gamma rays (any time). See the corresponding 2D histograms in Figure 3.

3.2 Benchmark: vpgTLE against analog MC

The 2D distribution of the detected gamma yields given by the vpgTLE-tt module is depicted at the top of Figure 4. The corresponding distribution given by the analog MC simulation is shown in the second row of Figure 4 for all creator processes (left column) and only proton inelastic (right column). The relative error of the vpgTLE-tt module with respect to each of these analog outputs are shown in the bottom row of Figure 4.

4 Discussion

The prompt-gammas (PG) resulting from proton inelastic processes represent the majority of all gammas detected (any time) by the scoring sphere shell. In the $[4,6]$ ns time window and above 1 MeV, the only non-negligible contribution comes from neutron inelastic processes, which is nevertheless an order of magnitude below proton inelastic. This confirms our decision to restrict to proton inelastic processes.
In the present study, the efficiency gain of Stage 2 compared to analog MC is about 50: the variance is the same since a comparable PG statistics is simulated, the gain just comes from the computation time gain. Huisman et al. [2] reported efficiency gain for Stage 1 of the order of 10^3 to reach the same variance at the voxel level to compute the PG source yields. The efficiency of the vpgTHE-tt method (Stages 1 and 2) should therefore only be marginally affected by the on-line simulation of protons by Stage 1.
The relative error remains within $\pm 20\%$, and even then this is for very localized places (in energy and emission time), most of the other regions have a relative error of only a few percent. The main sources of these small discrepancies come from (i) the de-excitation times of some nuclear products which are much greater than the nanosecond (and they are not modeled by vpgTLE-tt) and (ii) for some PG, energy and emission time are correlated (in the Bragg peak area).

5 Conclusion

We have presented and validated a new acceleration module based of on a track-length estimator to compute voxelized prompt-gamma yields in energy and emission-time. Further work is needed to handled gamma lines with long de-excitation time.

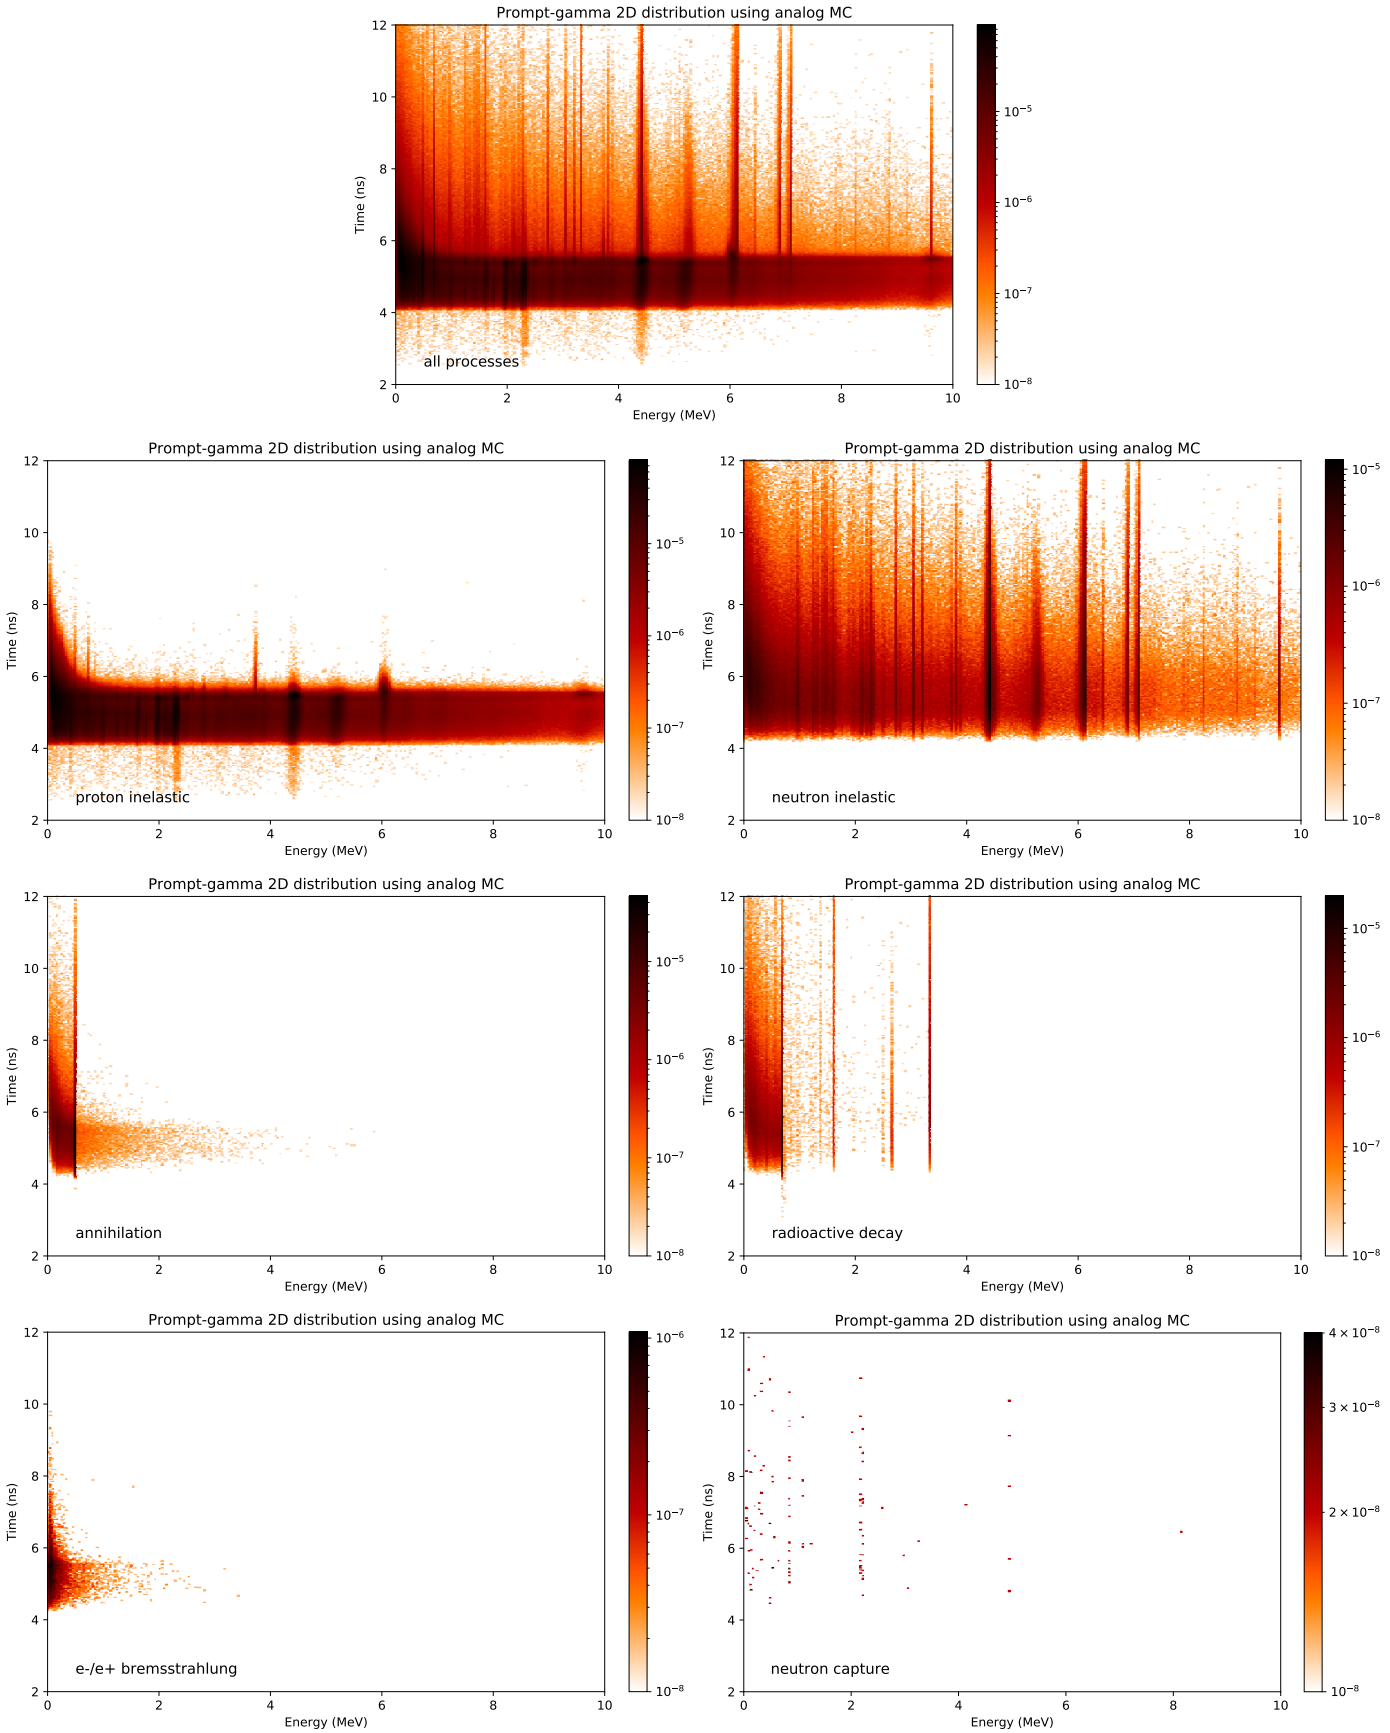

Figure 3: 2D histograms of prompt-gamma rays per creator process. Total counts of gamma rays per process are given in Table 1. Top row: all creator processes. Then in the reading direction: proton inelastic, neutron inelastic, annihilation, radioactive decay, electron/positron bemsstrahlung, and neutron capture. Caution: the colorbars (log scale) are normalized to their maximum value.

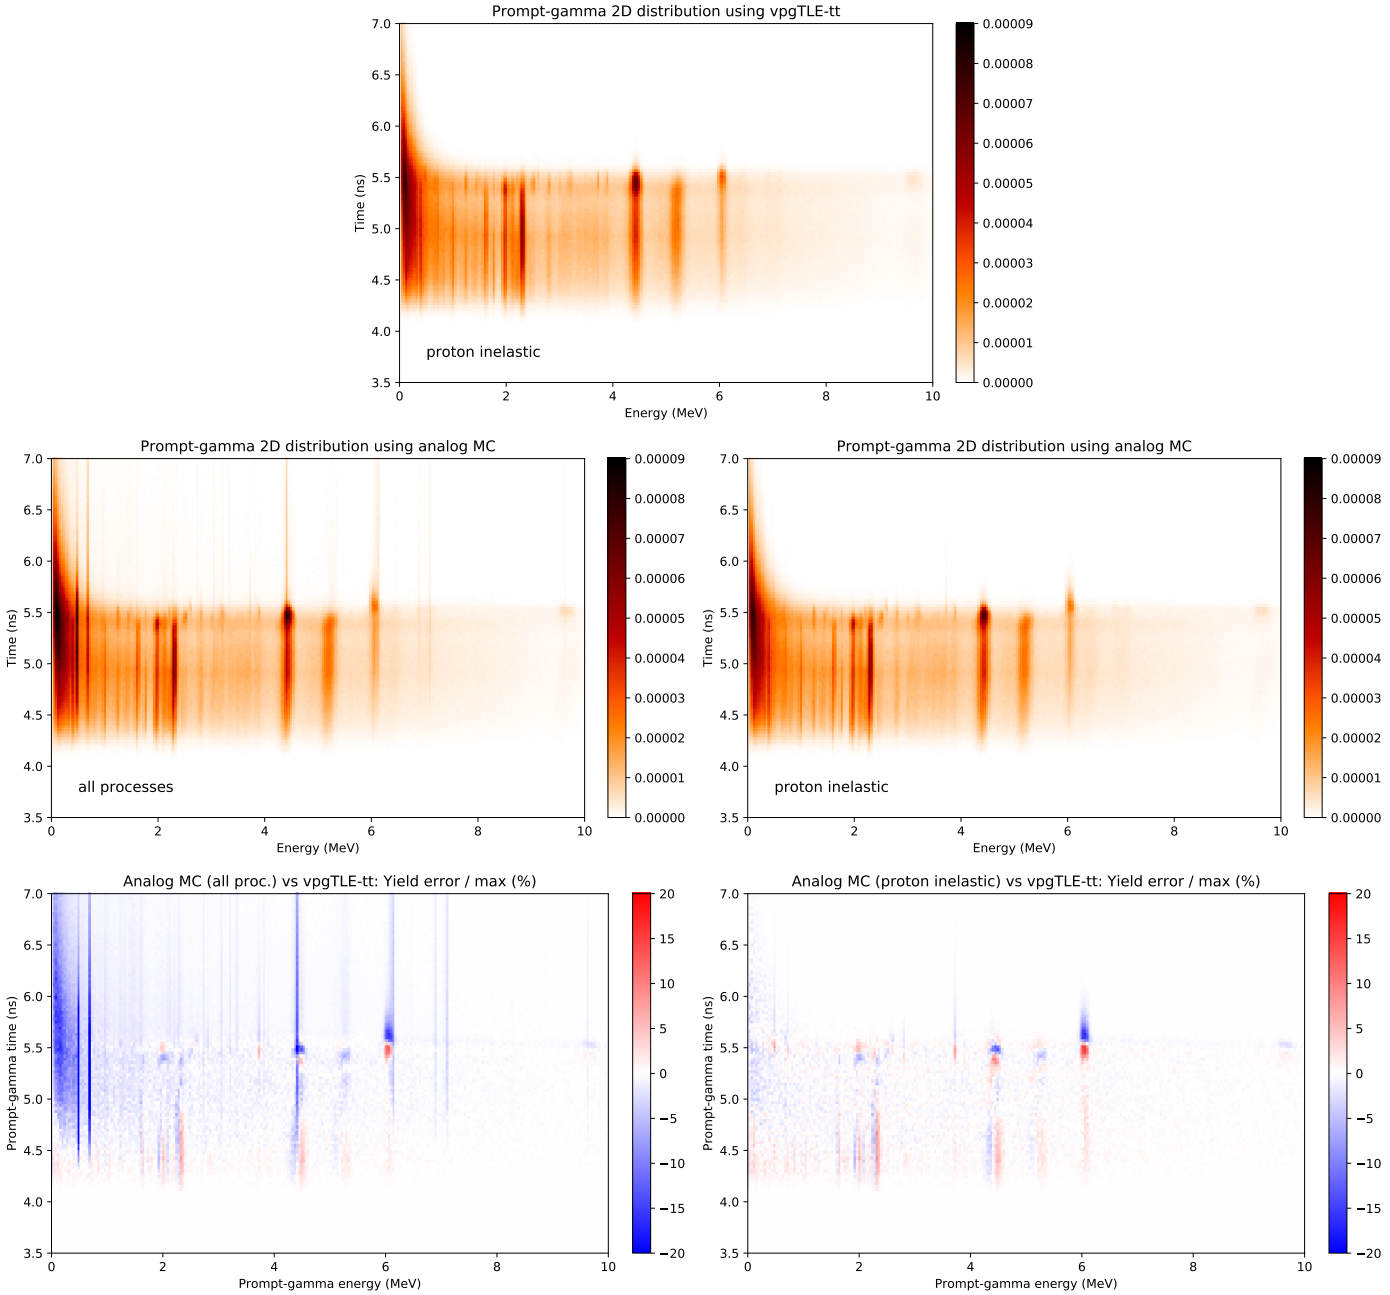

Figure 4: 2D histograms of prompt-gamma yields. Top row: vpgTLE-tt module. Middle row: analog MC with gammas from all processes (left) or from just proton inelastic (right). Bottom row: corresponding relative yield error (normalized by the bin maximum). Caution: the colorbars of the PG 2D distributions are similar (same linear scale) and the error plot with respect to all processes (bottom left) has been clipped to $\pm 20\%$ for better visual comparison.

Identification of suitable probing locations for a proton radiography-based quality control of CBCT-based synthetic-CTs

Abstract

Background

Cone-Beam CT (CBCT)-based adaptive proton therapy is nowadays technically feasible and has the potential to enhance patient outcomes. To use CBCTs for proton dose calculations, synthetic CTs (sCT) need to be generated with sufficient precision in their density information that proton dose calculations can be performed. Proton Radiography (PR) can be employed as a quality control (QC) tool for such sCTs in order to validate their accuracy with respect to prediction of proton ranges. The objective of this study is to identify PR probing locations that are robust towards any confounding factors like patient positioning errors, and therefore can be suitable as sCT QC positions.

Method

A cohort of five patients with cranial CTs was used to predict and evaluate PR probing locations. As a measure for the robustness of the probing locations, the energy bandwidth in a surrounding region was investigated. To assess this, positioning errors were applied to the probing locations, and resulting range shifts were evaluated.

Result

The total number of investigated locations per patient was ranging from 76 to 92. A correlation between the energy bandwidth and range shifts was found. This trend was observed in all five patients and was already apparent for small positioning errors of 1mm. A minimum of 19 suitable probing locations was found in each of the patients with a maximum range error of 0.6% of transverse water equivalent thickness.

Conclusion

This study showed that PR locations suitable for sCT QC can be found by determining and assessing the energy bandwidth in a surrounding area.

1 Introduction

Proton therapy (PT) has the potential to deliver highly conformal dose distributions with a low integral dose, thus sparing healthy tissue. Protons offer a low entrance dose followed by a sharp dose rise and a subsequent dose decline called a Bragg peak. The location of the steep dose gradient is sensitive to changes in the patient anatomy, such as tumor shrinkage, filling of nasal cavities, or weight loss/gain [1].

A typical treatment course of 30 fractions lasts 6 weeks, during which anatomical changes are likely to occur. As the treatment plan is usually based on a single planning CT, safety margins and robust optimization are applied to avoid loss of target coverage in the case of such changes. Resulting in a compromise of target dose conformity. Adaptive Proton Therapy (APT) monitors the dosimetric impact of anatomical change and aims to modify the treatment plan accordingly [2]. With knowledge of anatomical changes, the dose to healthy tissue can be minimized whilst maintaining conformal target dose coverage.

To monitor anatomical changes, frequent medical images of the patient are needed. Frequent medical imaging places a significant imaging dose burden on the patient.

Cone-Beam CT (CBCT) offers low-dose 3D images and is generally available in the treatment room for daily patient positioning.

Whilst suitable for positioning, CBCT's suffer from various artifacts, such as beam hardening and scattering. They therefore have a significantly lower image quality than diagnostic planning-CTs.

To enable accurate proton dose calculations based on CBCT, corrections are therefore needed [3].

For this, information from the initial planning CT and the daily CBCT can be combined to generate synthetic CTs (sCT's), with the aim of providing updated patient anatomy with the image quality of the diagnostic planning CT. Several studies have reported the ability to generate sCT's that are suitable for proton dose calculations [4–6]. Their use in a clinical workflow for adaptive proton therapy however requires an appropriate Quality Control (QC) procedure. Proton Radiography (PR) is a promising approach for this [7, 8]. PR uses proton beams of high enough energy to penetrate the patient such that the residual Bragg peak can be measured at the opposite side of the patient. From the residual range of this measured Bragg peak, the Water-Equivalent Thickness (WET) of the patient at the traversed location can be determined. By comparing PR simulations performed on the sCT with PRs measured after the patients, the HU accuracy and imaging quality of the sCT can therefore be assessed [9].

When using PR to check the accuracy of HU in the sCTs, it is vital however to minimize the influence of any confounding factors. Proton beams are very susceptible to density variations and even patient positioning errors can alter the Bragg peak location. This study aims to locate and predict PR locations that are robust to such changes and would therefore be suitable for sCT QC in a clinical environment. The assessment of suitable locations is based on a calculation of Energy Bandwidths (EB). For five patients with cranial CTs, we calculated optimal PR locations and assessed their robustness by simulating positioning errors and analyzing resulting range shifts.

2 Materials and Methods

2.1 Dataset

This study is based on diagnostic planning CT images in the cranium of five patients.

2.2 Robust PR Probing Locations

A sagittal WET image is generated from the planning CT data with a resolution of 1mm×1mm. The WET values are then translated to proton energy by PSTAR Continuous Slowing Down Approximation (CSDA) in liquid water (https://physics.nist.gov/PhysRefData/Star/Text/PSTAR.html) resulting in an energy map.

For each patient, the outline of the skull was manually drawn as the Region of Interest (ROI) on the energy map, as shown on the left side of fig. 2. Each pixel within the ROI is considered as a potential PR probing location.

As a measure for the robustness of a PR probing location, the EB within an area surrounding the probe location is calculated.

In fig. 1, a sketch of the 17mm×17mm considered area for the EB calculation is shown. The size of the area is well covering the two-sigma extent of a typical clinical proton pencil beam. For the next steps, the EB distribution is truncated between the 1st and 99th percentiles to mitigate the impact of outlier values.

The robustness of a probing location is ranked according to the EB. To avoid clusters of suitable probing locations, each location had to fulfill eq. (1)

$$(AP \geq 5\,\text{mm} \cap IS \geq 5\,\text{mm}) \cup (d \geq 12\,\text{mm}) \qquad (1)$$

where AP corresponds to the distance between two probing locations in Anterior-Posterior direction, IS in Inferior-Superior, and d is the diagonal distance. The locations of the spots in the order of robustness are written into a DICOM file that can be used as input in the simulation environment described below.

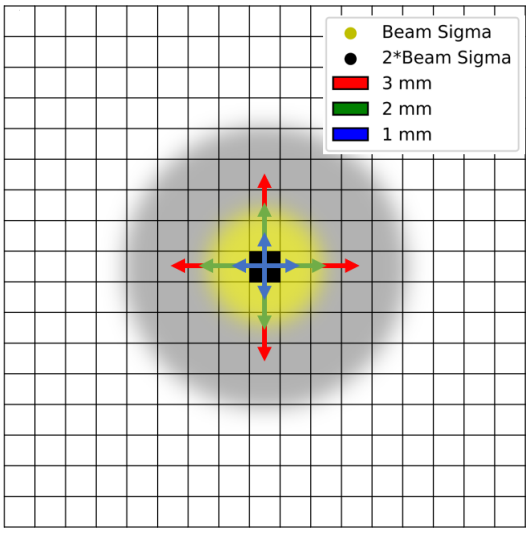

Figure 1: Illustration of the 17mm×17mm box considered for the EB calculation in relation to a typical proton beam sigma. In black, the investigated probing location is shown. The red, green, and blue arrows indicate the positioning errors which are simulated to evaluate the robustness of the probing location with respect to confounding factors.

2.3 Evaluation of PR Probing Locations

To assess the robustness of each probing location with an EB threshold below 10 MeV, the resulting range shifts when applying positioning errors were assessed. Positioning errors of ± 1, 2 and 3mm in the AP and IS directions were applied as illustrated by the blue, green, and red arrows in fig. 1. For each positioning error, an Integrated Depth Dose (IDD) curve for the residual Bragg peak was created by integrating the dose along the beam axis. The IDDs of the nominal and the positioning error simulations were fitted using a least-squares method to determine the resulting range shifts.

2.4 Simulation Environment

PR simulations were performed within the open-source program OpenREGGUI (https://openreggui.org/) with proton beams being simulated to enter from the left of the patient. The residual Bragg peaks were scored on the patient's right side, in a water structure that was included in the patient's planning CT to mimic a PR detector.

3 Results

The number of investigated PR probing locations per patient is listed in table 1, showing a cumulative count of locations with increasing EB. A maximum of 92 PR locations with an EB below 10 MeV was found in patient 1, as shown on the right of fig. 2. The distribution of PR locations appears symmetrical, with low EB locations in the center of the brain and higher EB locations towards the outer regions. Similar distributions were found for all five patients.

Table 1: Cumulative count of PR Locations Found per EB per Patient

EB[MeV]	1	2	3	4	5	6	7	8	9
Pat. 1	0	1	10	26	41	58	66	78	92
Pat. 2	1	2	5	16	21	35	50	57	77
Pat. 3	0	0	0	9	19	36	47	56	76
Pat. 4	3	14	22	32	44	54	64	74	82
Pat. 5	0	0	4	17	25	37	53	60	82

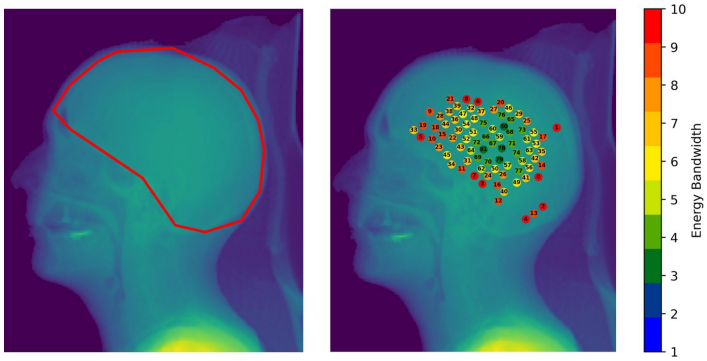

Figure 2: Left: Illustration of the ROI in which PR probing locations were investigated. Right: Set of PR probing locations with an EB below 10 MeV. Both images show Patient 1

When simulating positioning errors, an increase in resulting range shifts can be observed in relation to an increase in EBs, as shown in fig. 3.

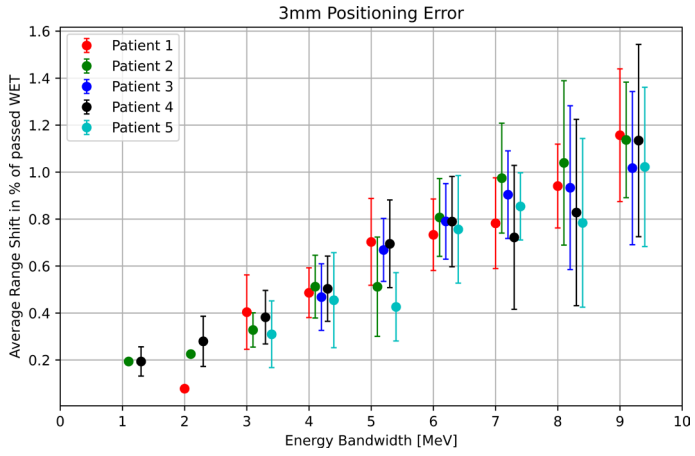

Figure 3: Average range shifts for simulated 3 mm positioning shifts in the AP and IS directions.

This correlation is clearly observable even for smaller positioning errors of 1mm, as shown in table 2, and was apparent in all five investigated patients.
For a positioning error of 3mm, the maximum range shifts in % of the average WET in an area based on two-sigma around the PR location, in relation to the EB is shown in table 3.

Table 2: Average range shift in % of passed WET for 1, 2 and 3 mm positioning errors (PE) for each EB averaged over all five patients

EB MeV	1mm PE	2mm PE	3mm PE
1	0.06	0.12	0.19
2	0.06	0.12	0.19
3	0.12	0.24	0.36
4	0.16	0.32	0.48
5	0.2	0.4	0.6
6	0.26	0.52	0.78
7	0.28	0.56	0.85
8	0.30	0.60	0.90
9	0.36	0.73	1.09

Table 3: Maximum range shifts in % of passed through WET in relation to the EB for positioning error simulations of 3mm.

EB	Patient1	Patient2	Patient3	Patient4	Patient5
1		0.36		0.48	
2	0.10	0.40		0.73	
3	1.03	0.59		0.91	0.72
4	1.21	1.08	0.96	1.15	1.11
5	1.86	0.98	1.26	1.61	1.01
6	1.58	1.60	1.58	1.64	1.68
7	1.50	2.19	1.78	1.82	1.61
8	2.09	2.16	2.04	1.95	1.69
9	2.19	2.67	2.62	2.51	2.34

4 Discussion

PR is a promising tool for the QC of CBCT based sCTs generated for adaptive proton therapy. Due to the sensitivity of protons to density variations however, it is essential to locate PR probing locations that are robust to confounding factors. In this study, we conducted an analysis of potential PR probing locations for five patients. The PR probing locations were selected based on the EB in the areas surrounding proton pencil beams.
The EB was determined by considering an area of 17mm×17mm on the energy map around a potential probing location. The size was chosen considering a typical sigma of proton pencil beams and potential positioning errors.
To evaluate the robustness of the predicted PR probing locations, and to verify that the EB can be used as a metric for robustness, positioning errors of ± 1, 2, and 3mm in the AP and IS directions were applied, and the resulting range shifts analyzed. During treatment planning for head and neck patients, positioning uncertainties up to 3mm are considered [10]. The positioning errors considered for this study therefore reflect the magnitude of uncertainty that can occur clinically.
For an EB threshold of 10MeV, at least 76 PR probing locations were identified in each of the five investigated patients.

Realistically, not more than twenty PR QC acquisitions can be done per patient due to dose and time constraints. Consequently, we did not explore PR locations with a higher EB.

Our findings showed that the EB of a probing location correlates to the size of observed range shifts when simulating positioning errors of the probing location. This trend was observed for all five patients and for all investigated magnitudes of positioning errors.

To understand the maximum size of possibly occurring range uncertainties for a specific EB, we also calculated the maximum range shifts per EB. Range uncertainties for proton dose calculation are estimated to be around 3% [11]. They depend on several factors, such as the type and model of the CT scanner, the CT calibration, and the conversion of HU to stopping powers [12]. All maximum range shifts reported in table 3 are smaller than 3% and could therefore be considered as suitable PR probing locations for sCT quality control.

The investigation for this study was limited to patients with cranial CTs. When expanding to other body regions, more inhomogeneous anatomical regions will be encountered. For instance, sCT generation might work well for soft tissue, but less so for muscle and bone.

5 Conclusion

This study showed that PR locations suitable for sCT QC can be found by determining their EB. By simulating positioning errors, we demonstrated that the EB of an area surrounding a probing location correlates with the magnitude of the resulting range shift when simulating positioning errors.

We were able to locate a minimum of 19 suitable PR probing locations for sCT QC in each of the five investigated patients with a maximum of 0.6% of average range shift.

Abstract: Bayesian Networks (BNs) represent a graphical modelling approach derived from the field of artificial intelligence (AI). They have demonstrated promise in assisting with the identification of errors in radiotherapy treatment plans. This study externally validated the BN developed with data from the University of Washington (UW), University of Vermont (UVM), and MAASTRO clinic in the Netherlands, using an independent dataset from the radiotherapy department of the Greater Poland Cancer Centre (GPCC) in Poznan. We used a dataset of 378 Volumetric Modulated Arc Therapy VMAT treatment plans, consisting of 802 treatment arcs. The results showed that the BN trained on the three centres (MAASTRO, UVM and UW) outperformed (AUC:78%) of the BNs trained in single centres (UW 66% and MAASTRO 75%). Future steps include the construction of a BN applied to specific treatment modalities and tumour locations for the creation of a more robust model.

1 Introduction

Radiotherapy (RT) represents an intricate multidisciplinary process wherein diverse professionals collaborate to formulate and execute a treatment plan [1]. Every stage of the RT workflow [2] is vulnerable to errors that can adversely affect the treatment outcome, carrying severe implications. For instance, errors such as radiation overdose during treatment delivery may result in radiation toxicity, leading to inflammatory or autoimmune diseases [3]. Presently, clinical RT care heavily relies on manual quality assurance (QA) tests to identify abnormalities and potential errors in radiotherapy processes [4]. Given the rapid technological advancements and increasing complexity in RT, ensuring quality through QA is paramount for delivering high-quality healthcare in radiation oncology.

In recent years, artificial intelligence (AI) techniques have been integrated into various facets of the RT workflow [5]. Specifically, AI has played a pivotal role in automating and expediting the RT treatment planning procedure [6], delineating organs at risk (OARs)[7], and developing decision support systems for patient treatment [8]. However, AI developments in quality assurance have been somewhat constrained[9]. Some efforts have been directed towards evaluating patient-specific QA and machine QA using datasets based on (inter)national treatment protocols and safety guidelines [10]. AI holds the potential to enhance the efficiency and effectiveness of QA without necessitating an increase in human resources [11].
Bayesian networks are probabilistic graphical models that depict interactions among a network of variables, offering the ability to estimate the probability of an event based on partial information. Their capacity to handle missing datavalues, a common occurrence in RT datasets, coupled with the intuitive nature of probabilistic reasoning, positions BNs as an ideal method for decision support in radiation oncology [12]. In comparison to rules-based algorithms and checklists designed to aid treatment plan review, both in-house and commercially [13], [14], [15], [16], BNs possess the advantage of emulating human reasoning and adapting to changes in clinical practice by updating the network model with new data [9].

Luk et al. [12] introduced a Bayesian network (BN) model for early detection of potential errors in RT treatment plans. Drawing on various diagnostic, treatment planning, radiation dose prescription, and patient setup variables, Luk et al.[17] devised an intelligent alert system that can notify medical physicists of potentially erroneous or suboptimal parameters in the RT treatment plan. The BN structure was constructed using a dependency-layered ontology [12], [18], [19] and insights from RT experts at the University of Washington [UW] (Seattle, WA, USA). Later, Kalendralis et al. built upon the BN proposed by Luk et al. and trained it on data from UW, University of Vermont (UVM), and MAASTRO clinic in the Netherlands.

The external validation of models in radiotherapy (and also in every scientific field) is essential for their potential clinical implementation [20]. The main goal of this study is to externally validate the BN model developed by Kalendralis et al. [21] by using an independent/external patient dataset collected at the radiotherapy department of the Greater Poland Cancer Centre (GPCC) in Poznan, Poland.

2 Materials and Methods

We used a patient dataset of 378 Volumetric Modulated Arc Therapy (VMAT) treatment plans who were treated at GPCC between January to May 2022 with TrueBeam accelerators (Varian Medical Systems, Palo Alto, USA).Furthermore, we have included head and neck, thorax, abdomen and pelvic cancer patients who were treated according to the treatment protocols prescribed based on the diagnosis and the localisation of the tumour. The treatment plans we used were created with 6 MeV photons based on the GPCC protocols and guidelines, based on conventional and stereotactic fractionation schemes. For the external validation of the BN we used simulated errors in 3% of the total number of treatment plans. The simulated errors were categorised into three types: Linear Accelerator (LINAC), dose prescription and general radiotherapy errors (Table 1). For the statistical analysis and the calculation of the error probabilities we have used the Java based application programming interface (API) Hugin Researcher 7.4 [22]. Additionally, for each error category we instantiated the variables Anatomic tumour location, T stage, N stage and M stage and calculated the error probabilities for the remaining variables of the dataset. The overall variables we had available in our dataset can be found in table 2.

To assess the model's performance in comparison to the results reported by its authors, we generated a receiver-operating characteristic curve (ROC) and computed the area under the curve (AUC) on our dataset. The AUC serves as an indicator of the model's discriminatory capability. We conducted this analysis for the entire dataset, combining all variables, and separately for variables with simulated errors: collimator angle, table angle, gantry angle, PTV dose, and bolus. Using the R language (version 2022.02.0 +443)[23] and the "classifierplots" package, we plotted the ROC but also calculated the AUC.

Table 1: Error categories

LINAC	Collimator angle
LINAC	Gantry angle
Dose prescription	Planning tumour volume (PTV)
General radiotherapy errors	Monitor Units (MU) per CentiGray (cGy)
General radiotherapy errors	Monitor Units (MU) per degree (Gantry angle)

Table 2: Variables used

Variable categories	Variable names
Clinical variables	Clinical T stage, Clinical N stage, Clinical M stage,Anatomic tumour location, Treatment intent
LINAC	Table angle, Gantry angle, Collimator angle
Radiotherapy generic	Number of plan adaptations,Radiation type, Plan technique, Number of beams, Control points, Source to surface distance (SSD), Beam energy, Table orientation, Monitor Units/cGy, Monitor Units/degree,
Dose prescription	Dose per fraction,Total dose, Number of fractions

3 Results

As presented in figure 1, in terms of the area under the receiver operating characteristic curve (AUC), the BN trained on the three centres (MAASTRO, UVM and UW) outperformed (AUC=78%) of the BNs trained in single centres (UW-66.1% and MAASTRO 75.%).

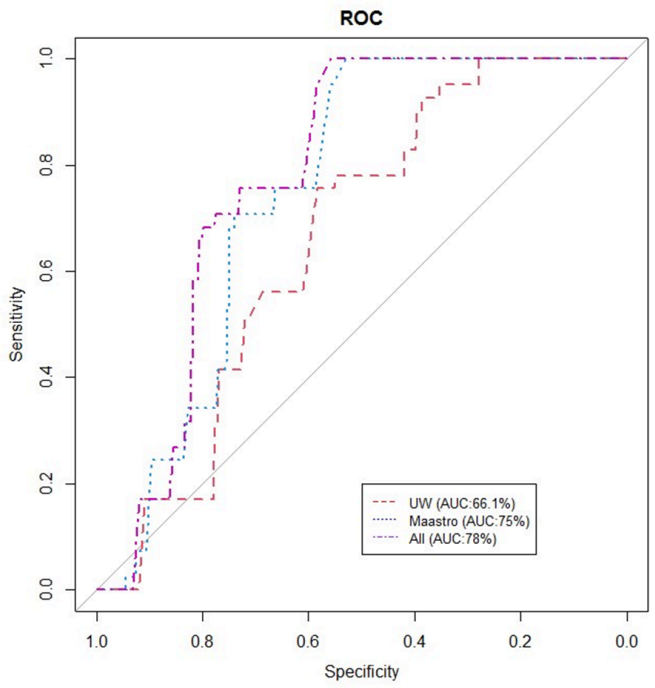

Figure 1: The receiver operating characteristic curves (ROCs) for the three Bayesian Networks (BNs) externally validated on GPCC data: the one trained on Maastro, UW and UW+UVM+Maastro.

4 Discussion

In this study we performed an external validation experiment having as a goal to test the performance of the BN developed by Kalendralis et al.[21] using an independent dataset of patients treated with different protocols and machines than the patients of the original BN dataset. The results showed that the BN is reproducible from other external institutes. Furthermore, according to the AUC results, the external validation showed that a BN trained on the data from multiple centres outperformed BNs trained on data from single centres.

This study includes several limitations. Initially, the categories of simulated errors were less than the original BN studies[17], [21]due to the absence of the "Bolus", "Wedge" and "Tolerance table" variables, which were included in the initial training of the BN[17], [21]. Secondly, the simulated error categories were selected based on the consultation of medical physicists and radiation oncologists of the centre in order to investigate the variables of interest based on their clinical practice.

Future steps will include the development of a novel error simulation method that will be applicable and reproducible by a wide range of international centres. Additionally, the development of more sophisticated algorithms that can predict the probabilities of radiotherapy treatment planning errors to happen is more than essential. For instance, deep learning (DL) algorithms have already shown their potential [24] as decision support systems in radiotherapy. Finally, the inclusion of additional treatment planning quality parameters such as imaging, Dose Volume Histogram (DVH) and dosimetric variables will have the potential to enrich the results of an AI assistance for the detection of treatment planning outliers for medical physicists.

5 Conclusion

In conclusion, we have presented an improvement of the BN performance, including an independent dataset from a European institute in order to potentially aid medical physicists and radiotherapy professionals in the treatment planning procedure.

Development of an Automated Radiotherapy Daily QA System

Marcus Tyyger[1], Matthew Carlisle[1], Jack P.C. Baldwin[1], Richard Homer[1], Phillip Rixham[1], and Steve Weston[1]

[1]Medical Physics and Clinical Engineering, Leeds Teaching Hospitals NHS Trust, UK

Abstract

Purpose: Develop an EPID-based daily constancy check system, which does not require a phantom, and can reduce overall quality assurance (QA) burden.

Materials and Methods: Daily images were acquired across 12 linear accelerators for 6 and 10MV FFF and flattened beams. Local computing infrastructure was setup to automatically transfer data and analyse images. Results were made visible through a webserver for online and offline analysis. Image analysis was validated against standard QA measurements.

Results: Output median error 0.1% (range: -0.9, 1.7). The median symmetry and flatness errors were less than 0.1 % (range: -2.3, 2.0), and -0.6% (range: -3.1, 3.3) respectively.

Conclusion: In-house development can provide solutions for RT departments where commercial solutions are unsuitable or unavailable. The developed system can be employed as an output daily constancy check, and trend analysis of beam characteristics enables potential reduction of monthly QA tasks.

1 Introduction

Radiotherapy (RT) departments continue to see increasing patient workloads[1] and increasingly time-consuming treatment pathways. Given this, departments are incentivised to increase linear accelerator (linac) capacity where possible. One potential solution is to reduce the quality assurance (QA) burden, on a monthly and daily timescale.

Daily output constancy checks ensure linac performance for that day, and are regularly performed using external devices which require setup, training, and management. Ideally, daily QA would capture a wide range of linac performance metrics, and enable assessment of long-term performance. This may allow a reduction in monthly quality control (QC) tasks when linac performance is stable. For departments to substantially benefit from this approach, daily workloads cannot simply be increased. Therefore, daily QA checks must require minimal human and linac resources for setup, analysis, and recording of results.

Amorphous-silicon electronic portal imaging devices (EPID) have previously been shown to be suitable for linac QA[2], which led to various commercial products[3,4]. However, these can be manufacturer or linac specific, require a phantom, or only provide online analysis whilst the operator is performing the test. RT departments may be unable to purchase a tool that suits their clinical pathways. This can lead to departments spending significant resources on investigation, evaluation, and commissioning of products that do not make QA as efficient as possible.

Herein, the development of a system for daily QA which uses EPID images without additional build-up or phantoms is described. The aim is to show the potential for RT departments to develop bespoke tools to suit their clinical need, and highlight the potential of EPID-based QA to reduce the overall QA burden.

2 Materials and Methods

Daily images were acquired on twelve VersaHD linacs (Elekta AB, Stockholm, Sweden) between 18th December 2023 and 26th January 2024. Flattening filter free (FFF) and flattened beams were delivered at 6 MV and 10 MV at maximum dose rate, with 100 monitor units (~1Gy), and a 20 x 20 cm open field at isocentre. All images were acquired on an IViewGT EPID panel without any additional build-up, at gantry and collimator angle 0°.

Data Pipeline and Infrastructure

Acquired images were automatically exported as DICOM images from the IView acquisition station to a PACS server and then on to a dedicated virtual machine (VM) running a DICOM service class provider (SCP). Each field's associated xml file was automatically copied from the local database to the VM, as this was required for dosimetric analysis.

Image processing was performed on the VM using software developed in Python, with results stored in an SQL database. Users accessed results through a locally hosted webserver which directly queried the database. As processing was automatic and results were stored, this allowed online review and offline trend-analysis.

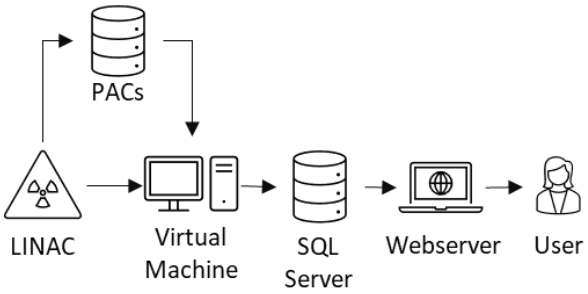

Figure 1: Developed data transfer and processing pipeline

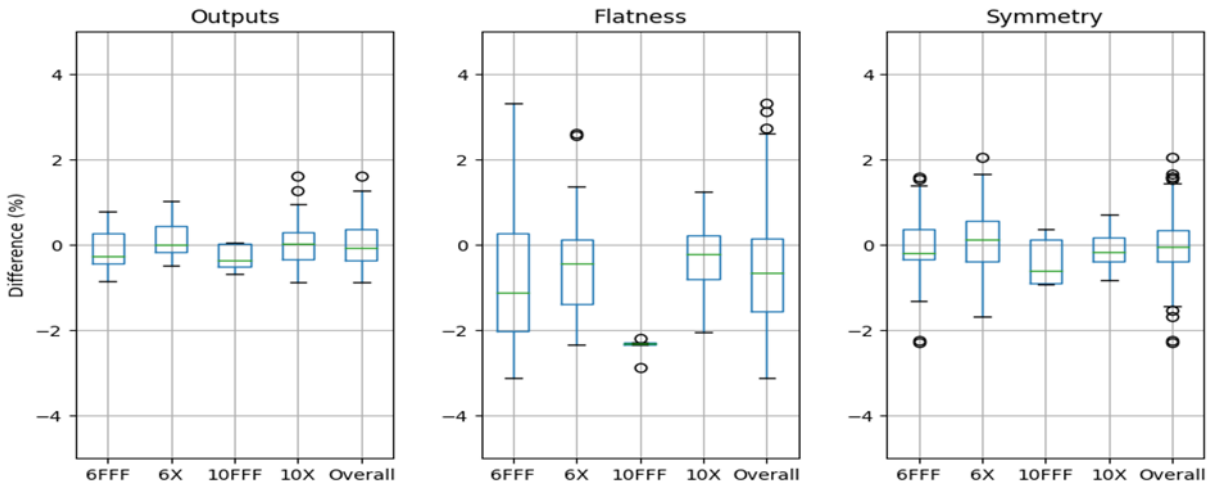

Figure 2: Validation results, "overall" is all beams combined. Outputs compared to ionisation chamber measurements. Flatness and symmetry results compared to 2D array measurements.

Image Processing and Analysis

Outputs were determined through the equation below, where P_{avg} is the average pixel value within the central 50 x 50 pixel (~ 12.5 x 12.5 mm measured at isocentre) region. F_{cal} is the beam and linac specific calibration factor. F_{pix} is the image specific dosimetric pixel factor.

$$Output = \frac{P_{avg} \cdot F_{cal}}{F_{pix}}$$

Output validation was performed by comparing ionisation chamber readings with software results of images taken within 1 day of the measurement.

Flatness and symmetry were determined through profiles through the x- and y-axes within the "field region". Initially 10 pixel wide profiles through the central beam axis were averaged and subsequently normalised. FFF normalisation was performed using the technique proposed by Fogliata et al[5] using Elekta VersaHD factors from Fogliata et al[6]. Flattened beams were normalised to 100% on the beam central axis. Field sizes were calculated by determining 50% dose points, and subsequently the field region was defined as 80% of the field size centred on the beam central axis.

Beam flatness was calculated through the ratio of the maximum (D_{max}) and minimum (D_{min}) doses. FFF unflatness was determined through the ratio of central axis dose (D_{cax}) and the dose off-axis at the edge of the field region (D_{edge}). For simplicity, "flatness" refers to both flattened beam flatness and FFF beam unflatness.

$$Flatness = \frac{D_{max}}{D_{min}} \qquad Unflatness = \frac{D_{cax}}{D_{edge}}$$

Beam symmetry was calculated by the maximum ratio of dose values at opposing points either side of the central axis, where x is the distance from the central axis.

$$Symmetry = \left(\frac{D_x}{D_{-x}}\right)_{max}$$

Flatness and symmetry results were validated by monthly QA results, measured using a 2-dimensional ionisation chamber array STARCHECK, with an additional 20 mm RW3 build up (PTW, Frieburg, Germany). Images taken within 1 day of the measurements were used for the comparison.

3 Results

Development was undertaken by a small team of clinical scientists and technologists alongside their routine workloads, and the first prototype was finished within six months. Additional work was required over the following months to correct minor infrastructure issues, such as VM access, DICOM SCP stability issues, and setting up automatic processing. Changes were also required to improve FFF beam analysis. Tolerance development and long-term validation is on-going and predicted to take approximately 6-months. This would give an overall time period from conception to clinical release of approximately 15-18 months, including contingency for potential delays.

Outputs were found to be in close agreement with ionisation chamber results. The median error was under -0.1 % across all energies and linacs, with a minimum and maximum error of -0.88 % and 1.61 % respectively. Due to issues with beam setup, five 10FFF results were analysable compared to ~30 for the other beams.

Across all energies, linacs, and profile orientations compared to array measurements symmetry errors were found to have a median value of -0.1 % (range: -2.3, 2.0).

For flatness this median value was -0.7 %, with a broader range of -4.3 to 3.3 %. Due to issues with availability, only six 10FFF images were processed.

4 Discussion

The development life-cycle of this tool has been roughly equivalent to the estimated time required to procure and commission a commercial product. Given only a small team was used, and no member was pulled from routine clinical duties this shows the potential for in-house development when no suitable commercial products are available. However, it cannot be ignored that in-house development requires staff expertise which may not be readily available in all RT departments.

Output results were within the recommend constancy action limit[7], giving confidence the developed system could be used as a constancy device. Locally this can reduce the time taken for daily QA as data can be acquired from morning run-ups rather than from a dedicated QC session. The results presented are only over approximately 30 days, meaning long-term stability needs to be validated prior to clinical deployment, although previous studies have shown EPID panels to be stable for this purpose[8,9].

Symmetry results found a minor median error compared to 2-dimensional array measurements, although, the range of errors did exceed +/- 2 %. Given the recommended monthly QA limit is also 2 %[7], this approach should not be used for individual accurate measurements. This is also true for flatness measurements which had an even broader range of errors compared to the Starcheck at approximately +/- 4 %. These results are likely in part due to the lack of charge particle equilibrium for EPID measurements of 10 MV beams. This work has demonstrated that the system can be used as a constancy device to monitor performance over time. Given stable results within local tolerances, the frequency of conventional output, flatness and symmetry measurements could be reduced. Tolerance analysis is necessary to commission this approach, and this work is currently locally on-going.

Flatness measurements showed a distinct difference between FFF and flattened beams, with FFF beams showing a larger range of errors and a bias towards underestimating flatness. It is hypothesised that this might be due to underlying issues with panel response rate; as if the panel is under recording the maximum delivered dose then it will calculate a lower FFF beam flatness. EPID panels have been shown to have differing responses due to dose rate[8]. Additionally, the results here show 10FFF having larger errors than 6FFF and it has a significantly higher delivered dose rate. If this is the underlying cause then simply reducing the delivered dose rate would remove this source of error.

5 Conclusion

The potential for in-house development where commercial solutions are not suitable has been demonstrated in the context of EPID-based daily QA. Validation against commissioned QA devices show the system performs adequately for use as an output constancy check, without the need to setup a phantom. Trend analysis of beam characteristics: beam flatness and symmetry, enables potential reduction of certain monthly QC tasks, or as a predictive tool of linac failures.

Isocenter deviation assessment and model for Halcyon Radiotherapy Systems

Linda Lankinen[1,2], Antti Kulmala[3], Jouko Lehtomäki[1], and Ari Harju[1]

[1]Varian Medical Systems, a Siemens Healthineers Company
[2]Department of Physics, University of Helsinki, Finland
[3]Clinical Research Institute HUCH Ltd., Helsinki, Finland

Abstract The radiation isocenter position on a Halcyon radiotherapy system was measured and the deviation from the intersection of the rotation axes, the ideal isocenter, implemented in Monte Carlo (MC) model. With a test VMAT plan, the isocenter deviation was assessed by analyzing the difference between the film measurement and MC simulated dose distribution. The implementation of the deviation improved the agreement between the MC model and the measured dose distribution especially in the steep dose gradient regions. While the treatment system delivery met all isocenter related specifications, the improvements demonstrated by the modeling of the isocenter displacements could lead to more accurate dose predictions for treatments where steep dose gradients are needed around small targets.

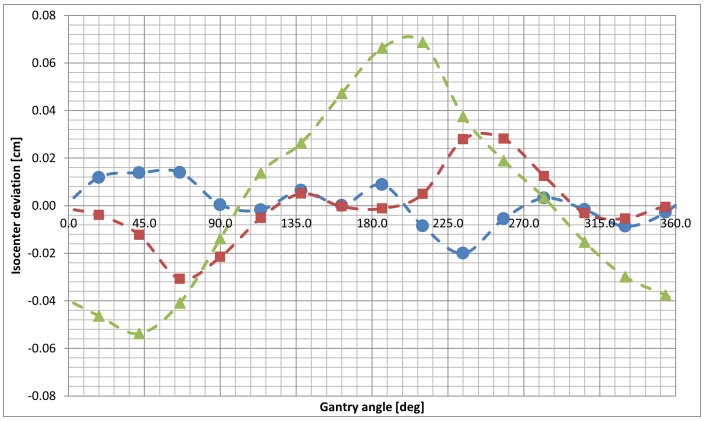

Figure 1: The radiation isocenter deviation of a Halcyon treatment unit (S4, Cancer Center, Helsinki, Finland) as a function of a gantry angle in IEC61217 coordinate system. The variations along the X-axis (blue dots), Y-axis (green triangle) and Z-axis (red square) are shown.

1 Introduction

The isocenter is the primary reference location of external radiotherapy beam. In ideal conditions, the mechanical isocenter of linear accelerator is defined as the point of intersection of gantry, collimator, and treatment table rotation axes. However, the gravity pull on the beam centerline and the mechanical uncertainties of the gantry cause systematic deviations of the isocenter position as a function of the gantry angle [1,2]. The geometric position of the radiation isocenter during rotation is usually assumed to be inside a virtual spherical volume. The AAPM Task Group Report 142 (2009) recommends that up to $\pm$ 1 mm deviation is acceptable for stereotactic treatments [3]. Discrepancies in the isocenter position may lead to loss of target coverage or increased dose delivery to the healthy tissues as the exact position of the target is relative to the mechanical isocenter, and by considering the isocenter movement, the accuracy of stereotactic treatments could be improved [1].

The goal of this study was to measure the radiation isocenter position on a Halcyon radiotherapy system (Varian Medical Systems, a Siemens Healthineers Company). The results also represent Ethos Radiotherapy Systems as the platform shares the same beam generation and collimation components [4]. The deviation of the isocenter position was replicated with Monte Carlo (MC) model. On one hand, the MC model can act as a computational copy of an actual machine and provide a reference without uncertainties due to the mechanical variations, and on the other hand, it can inherit the known mechanical variations and mimic the behavior of the actual machine.

2 Materials and Methods

The deviation of the isocenter position on the Halcyon radiotherapy system ("S4") installed in the Helsinki Cancer Center was measured. Lateral (= XIEC61217) and vertical (= ZIEC61217) variation was determined using a star-shot procedure with fifteen equally spaced gantry angles [1]. For the longitudinal (= YIEC61217) variation, a special film measurements procedure was designed. The projections of the star-shot beams were measured on XY- and YZ-planes with beam projections from the reference angles. Then, the alignment of the beams was compared to the alignment of the reference geometry and the offset was determined. The measurements were repeated to reduce the random uncertainty.
The measured isocenter deviation data was implemented to the MC model by adjusting the source position and treatment head rotation accordingly. Each direction was interpolated and processed separately. The MC model has been validated to match to the vendor provided pre-configured beam model [5]. The machine-specific mechanical leaf gap (MLG) of -0.65 mm in nominal positions was used for both proximal and distal MLC stacks.
To analyze the impact and quantify the agreement between the machine delivery and predicted dose distributions, a test Volumetric Modulated Arc Therapy (VMAT) plan was produced. The test VMAT plan, from a manuscript under review [6], had two optimized VMAT arcs (Photon Optimizer

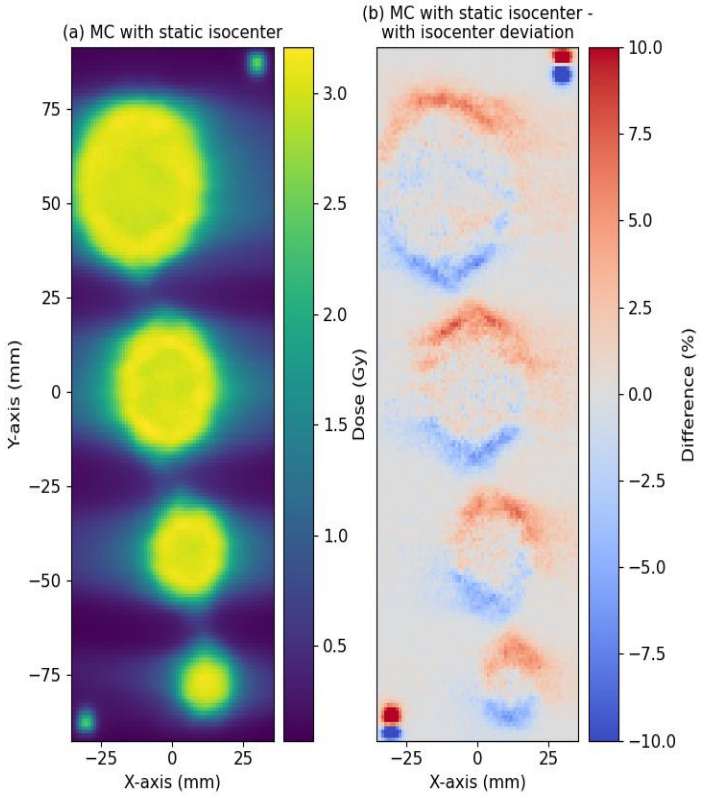

Figure 2: The MC simulated dose plane with static isocenter on the left and the relative dose plane difference between MC simulated dose planes with static isocenter and with isocenter deviation. Both graphs share the same Y-axis.

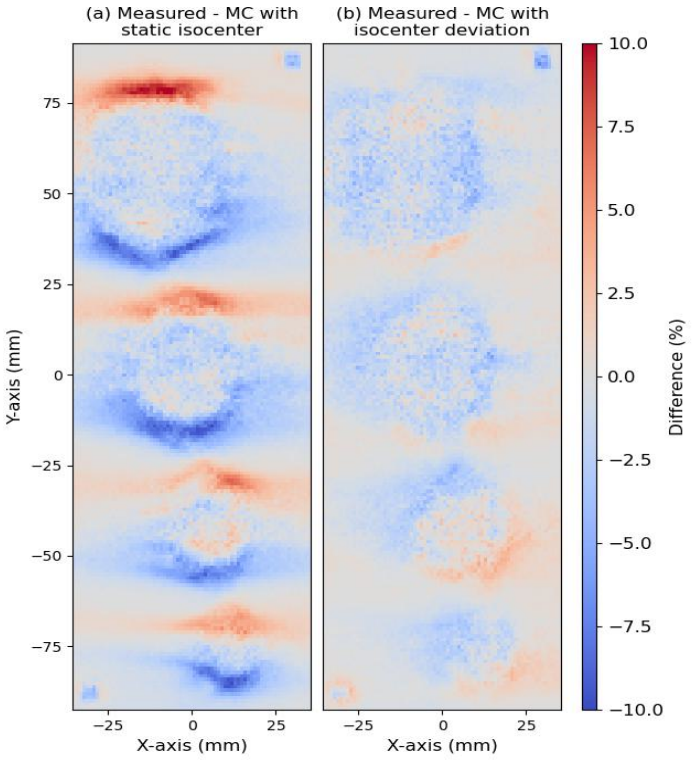

Figure 3: The relative dose plane difference between the measured and MC with static isocenter on the left and with isocenter deviation on the right. Both graphs share the same Y-axis.

18.0.0[7]) with the collimator angles 30° and 330°, and one static alignment field with zero-degree gantry, which was used for confirm the film position. The plan had four spherical targets with the diameters of (4.0, 3.0, 2.0, 1.0) cm and the static alignment field had square 5 mm x 5 mm openings. The measured dose distributions were obtained by using GafChromic™ EBT3 radiochromic film (Ashland Speciality Ingredients G.P., Bridgewater, NJ), the Vidar DosimetryPro Advantage (red) densitometer (Vidar Systems Corporation, Herndon, VA), and the RW3 water-equivalent plastic phantom (PTW, Freiburg, Germany). The phantom size was 30 cm × 30 cm × 10 cm and source to surface distance (SSD) was 95 cm. The machine type had fixed 800 MU/min dose rate.

3 Results

The minimum distance between the center of the beam and the ideal treatment isocenter on a Halcyon radiotherapy system was measured with different gantry rotations. Figure 1 shows the isocenter deviation for each direction in IEC61217 coordinate system (X, Y, Z) as a function of a gantry angle. The range of the variation along X-direction was ± 0.02 cm (blue dots), ± 0.07 cm in Y-direction (green triangles), and ± 0.04 cm in Z-direction (red squares). The largest value of 0.069 cm was measured along Y-direction at 210°. The uncertainty in determining the isocenter deviation in each direction separately was found to be <= 0.01 cm and the gantry angle uncertainty was ± 0.15°.

The measured isocenter deviation was implemented in the MC model and the results in comparison to static isocenter analyzed. For a test VMAT plan with the two fields and the collimator angles of 30° and 330°, the MC simulated dose plane is presented in Figure 2 (a). The dose plane has the four sphere targets, and on the two corners, 5 mm x 5 mm openings from the alignment field with zero-degree gantry. The relative dose difference between MC simulated dose with static isocenter and with isocenter deviation is shown in Figure 2 (b). The most profound differences are shown with the alignment field openings. With the VMAT fields, the effect is smaller, but shift-like differences up to 8 % are observed on the Y-edges of the targets.

The differences between the measured and MC dose planes are shown in Figure 3. The dose plane difference between the measured and MC with static isocenter is presented in Figure 3 (a). A systematic difference is observed on the Y-edges of the sphere targets similar to Figure 2. The largest dose differences reach up to 10 %. The positioning is correct as the alignment fields openings show no systematic differences.

An improved agreement can be observed between the measured and MC with the implementation of the isocenter deviation in Figure 3 (b). Systematic differences are no longer present and the maximum difference is below 4.1%. By taking profiles passing through the spherical targets, the same

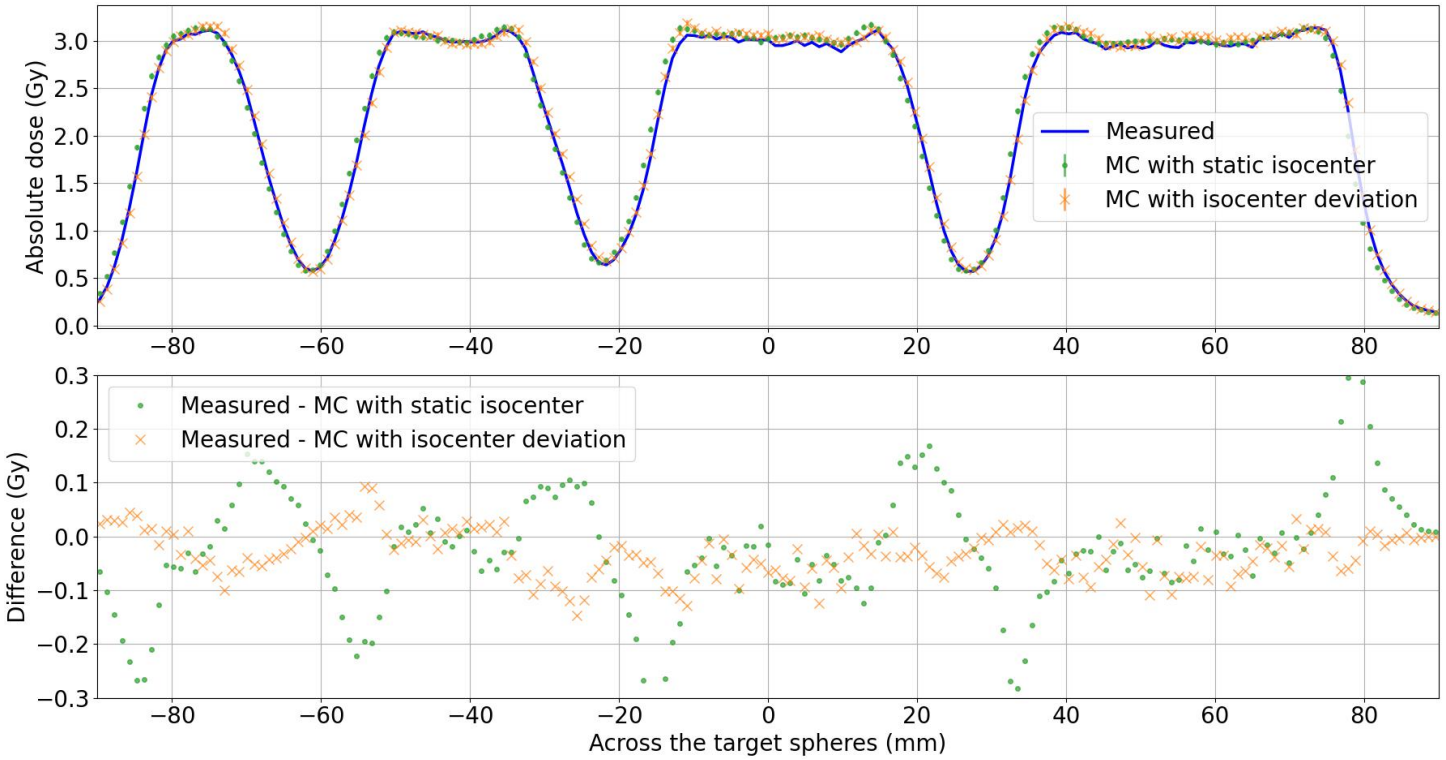

Figure 4: The dose profiles across the target spheres and the dose difference between the measured and MC.

observations can be confirmed in Figure 4. The dose profiles of the measured (blue line), MC with static isocenter (green dots), and MC with isocenter deviation (orange crosses) are presented on the top of the graph and beneath the local dose difference between the measured and MC dose profiles. The systematic shift between the measured and MC with static isocenter creates local deviations up to $\pm$ 0.3 Gy in the dose gradient regions. Between the measured and MC with isocenter deviation, the difference is smaller and the local deviations are only up to $\pm$ 0.15 Gy.

4 Discussion

The radiation isocenter deviation as a function of a gantry rotation was measured in all three dimensions on a Halcyon radiotherapy system. The deviation was less than 0.1 cm. The largest range of offset was observed with the longitudinal Y-axis up to $\pm$ 0.07 cm. The vertical Z-axis range was less than 0.04 cm and the lateral X-axis range was less than 0.02 cm. However, all directions are coupled by the collimator and the gantry angle. The effect of the isocenter deviation on the VMAT test plan was analyzed by taking into account the difference between the center of the beam and the ideal treatment isocenter in the MC model as a function of the gantry rotation. This study quantified the radiation isocenter deviation and its impact on the delivered dose for a test VMAT plan with spherical targets and high dose gradients. Although, the coincidence of the radiation beam to the mechanical axis was well below 1 mm, the effect can be modeled, leading to improved accuracy in the predicted dose delivery. As the focus of this study was on the isocenter, the uncertainties from the MLC position and the gravity effect on the position during the gantry rotation was ignored. It should be kept in mind that with a clinical case, target delineation, patient setup error, and target movement would be larger sources of uncertainties.

5 Conclusion

Based on the measured data, a gantry angle-specific isocenter deviation was applied to a Monte Carlo model validated for the Halcyon and Ethos radiotherapy systems. The consideration of the isocenter variation with the gantry angle improved the argeement between the measured and simulated dose in the gradient regions of the test VMAT plan. Further considerations such as the impact on clinical plan quality of more sophisticated radiation isocenter modeling will be addressed in future studies.

Abstract: Arc therapy in radiotherapy (RT) allows for better conformation of the dose deposition but requires patient-specific quality assurance (QA). The aim of this study was to develop a predictive model of Delta4-QA outcomes based on RT-plan complexity indices to reduce QA workload.

Methods: From 1632 RT-VMAT-plans, six complexity indices were extracted. Machine learning (ML) and deep hybrid learning (DHL, for complex tumor locations, ie breast, pelvis and head and neck) models were developed to predict QA-plan compliance.

Results: ML model achieved 100% specificity and 98.8% sensitivity for non-complex RT-plans (with brain and thorax tumor locations). For more complex RT-plans, sensitivity drops to 87%, innovative method using DHL achieved 100% sensitivity and 97.78% specificity.

Conclusion: QA results were predicted with high accuracy. A similar approach was realized to predict intensity-modulated RT QA compliance for breast tumor treatment with Halcyon machine. These results will also be presented during the conference.

1 Introduction

Over the past decade, numerous technological strides have advanced radiotherapy techniques, resulting in enhanced methodologies. One notable technique among them is volumetric intensity modulated arc therapy (VMAT) [1]. VMAT operates by dynamically adjusting the beam fluence as the accelerator arm rotates (or arcs), facilitating the delivery of a tumoricidal dose while preserving the integrity of healthy tissue. During the rotation of the accelerator arm, the multi-leaf collimator (MLC) modulates photon fluence. This complexity adds an additional layer of complexity to arc therapy treatment plans compared to conventional treatments [2]. As the complexity of treatment plans increase, a significant challenge to accommodate the patient anatomy, dosimetric constraints, optimization algorithms and the capabilities of the linear accelerator (linac) to guarantee that the administered treatment aligns with the initially planned parameters on the treatment planning system (TPS). In this context, it is imperative to conduct patient-specific quality assurance (QA) for each treatment plan before the actual patient treatment takes place. Using dedicated phantoms, the QA process assesses whether the planned dose in the TPS aligns with the dose administered to the patient on the accelerator. This evaluation uses two metrics, mean gamma and gamma index [3], to determine the compliance of the treatment plan. It is important to emphasize that QA is a time-consuming process, leading to a substantial period of unavailability for the machines dedicated to patient treatment. Furthermore, only five percent of the treatment plans at out center are non-compliant, with a gamma index < 0.95 and a tolerance of 3%/3mm.

Various alternatives to QA have been explored and discussed in diverse literature reviews [4]–[8]. Among the approaches investigated for predicting QA using complexity indexes derived from treatment plans, one method involves employing a threshold approach for these complexity indexes [9]. The second approach involves a more complex method relying on prediction models like machine learning regression and classification. As outlined in the recent review [10], various studies have explored the application of artificial intelligence (AI) in patient QA for radiotherapy. Nevertheless, apart from two studies [11], [12], most AI models were developed using a limited number of radiotherapy (RT) plans (between 250 and 600). This limited dataset size hinders the assessment of model robustness across a larger set of plans. A study [13], an auto encoder deep learning-based model was trained ton 426 RT plans and validated on 150 RT plans. The results indicated improved performance, achieving 100% sensitivity and 83% specificity for technical validation and 100% sensitivity and 72% specificity for clinical validation.

These results were obtained with a high degree of accuracy, but still with a high degree of error, especially for RT plans with a high arc count, high flow variability, high accelerator arm speed, leaves speed, and the opening of multi-leaf collimators (MLC). Furthermore, the absence of publicly available solutions derived from these models hampers their applicability in clinical practice. Consequently, the demand persists for more complex AI models tailored to complex RT plans, along with user-friendly solutions accessible for widespread clinical use.

Subsequently, more complex and innovative AI models have been developed. These include the combination of machine learning and deep learning approaches known as deep hybrid learning (DHL). Automating the analysis of radiographic images to diagnose various pathologies is one example of its application [14]. No study has used the DHL model to predict QA outcomes for multiple RT plans to our knowledge.

The aim of this study was to develop clinically applicable AI models. These models are more complex than those proposed in the literature. The models predict QA outcomes based on complexity indices of treatment plans. Machine learning classification models for simple to moderately complex RT VMAT plans were developed in the first step. More complex and innovative DHL models for more complex RT VMAT plans were developed in the second step. Finally, a freely accessible online platform was developed for the use of these models in clinical practice.

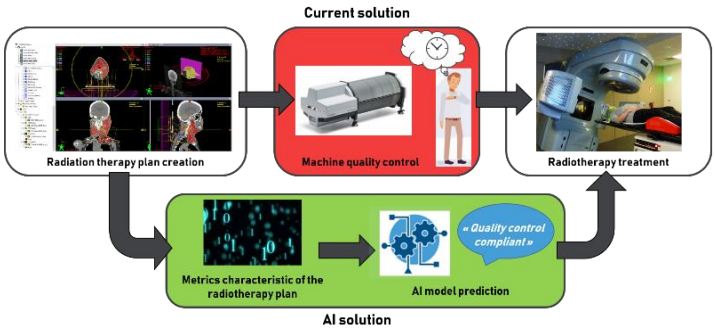

Figure 1: Can AI predict radiotherapy plan compliance?

2 Materials and Methods

2.1 Patient Cohorts

For this prospective study one thousand, six hundred and thirty-two patients with cancer referred to our oncology center between June 2019 and March 2022 were included. MR-004 a French national institution (INDS) that sets guidelines for the conduct of health research was used for this study. A few locations (digestive, rachis, other, member and skin tumor location) have a small number of cases, which is too small to build efficient models for these sites. Therefore, we only combine these cases in the "all" model and we did not develop specific models for these locations.

2.2 Radiotherapy Plan

Radiation therapy was delivered using volumetric modulated arc therapy (VMAT). A RapidArc (Varian®, Le Plessis-Robinson, France) machine was used. Eclipse® TPS was used to calculate radiotherapy plans (RT-plans). The complexity indexes were obtained from RT-plan using Raystation® TPS and an in-house python code available at https://github.com/AurelienCD/DeepHybridLearning_RadiotherapyQA_Depository_ManuscriptID_Diagnostics.
Only six complexity indexes were used to achieve a simple solution applicable to routine clinical settings: Leaf Sequence Variability (LSV), Aperture Area Variability (AAV), Modulation Complexity Score (MCS), Leaf Travel (LT), combination of LT and MCS (LTMCS) and Small Aperture Score (SAS10) [5]. Complexity indexes were derived from the treatment plan and not individually from each arc.

2.3 Patient Specific Quality Assurance

The Delta4® phantom manufactured by Scandidos® was employed for patient-specific QA. To verify the QA conformance, the local gamma index must surpass 95% with a 3%/3mm criterion, and the gamma mean should be below a predefined threshold. By identifying gamma mean values that are significantly ($p<0.05$), a specific gamma mean threshold was determined for each tumor location.
For AI construction models, conformance and non-conformance QA was assigned to 1 and 0, respectively.

2.4 Statistical Analysis

The ML and DHL performance models was assessed by examining the accuracy scores from Sklearn and TensorFlow on the test dataset, along with the Area Under the Curve (AUC) values derived from the ROC curves, specificity, sensitivity and the number of false positives. All statistical analyses were conducted in Python, utilizing the statistical data visualization and Seaborn library [15], [16].

3 Results

3.1. Model predictions for all tumor location

The initial strategy involved creating machine learning models capable of predicting QC conformity regardless of the tumor specific location. Various ML models were employed for this purpose. The large dataset of RT plans contributed to robust training and validation scores across the diverse ML models used. Random Forest. Classifier exhibited the highest training and validation scores at 100% and 89.9 respectively.

The performance of the Random Forests ML algorithm is depicted through a confusion matrix with a sensitivity of 98.6% and a specificity of 86.47%. Notably, only 1.10% of false positive (FP) values were recorded. Additionally, the ROC analysis conducted on only 18 RT-plans using the Random Forests ML algorithm resulted in an AUC value of 0.97.

While achieving positive outcomes, the application of general ML models to specific tumor locations did not provide acceptable results for clinical implementation. For instance, utilizing the Random Forests Classifier model for brain tumor radiation therapy plans results in a 4.49% false positive rate and a specificity of 30%. Consequently, it became necessary to develop ML models to each tumor location to enhance overall model performance.

3.2 Machine Learning Models: Prediction for Brain and Thorax Tumor Location

ML models to specific tumor locations outperformed the model developed for all tumor locations. In the case of brain tumor RT plans, a perfect prediction was achieved with zero false positives, leading to an AUC of one. The accuracy and specificity were both 100%. Similar outcomes were observed when employing the specific ML model for thorax tumor RT plans. Nevertheless, for RT plans with greater complexity, such as those for the pelvis, breast and head and neck (H&N) tumors, standard ML models did not exhibit sufficient accuracy. For example, ML models for breast tumor RT plans demonstrated a specificity of only 87%. Consequently, more AI models, using deep hybrid learning (DHL), were specifically developed for pelvis, breast and H&N.

3.3 Deep Hybrid Learning: Prediction for Pelvis, Breast and H&N Tumor Location

The DHL models presented highly accurate results. For instance, the DHL model designed for breast cancer significantly decreased the number of FP from 9 with ML to 0. The enhancement elevated the specificity to 97.7% compared to the 87% achieved with the ML only model.

Semblable outcomes were observed with DHL models designed for H&N tumor locations (FN from 5.88% with the standard ML model to 1.47% with the DHL model).

3.4 Clinical Practice Solution

The requirement of this study was to create a simple approach that could be implemented in clinical practice. Consequently, an application programming interface (API) was developed which can easily be used in a clinical environment. The API is accessible at: https://aureliencd-radiotherapy-quality-api-cq-patient-predictor-2clxve.streamlitapp.com/. The performance of the API has been exclusively optimized on out dataset and need to be validation before external application. The average time (in minutes) required for computing the complexity indexes and predicting conformance using the platform was five minutes per plan. When focusing just on plans with a non-conformance predicting, the time saved per week amounts to approximately 135 minutes compared to the typical 150 minutes required for patient-specific QA. This time efficiency potentially allows for the treatment of seven additional patients.

4 Discussion

Patient-specific QC is mandatory in radiotherapy, but it can be time-consuming and affect the availability of RT machines to treat patients [17]. To address this issue, we propose to use prediction models that use RT plan complexity indices as input to predict QC outcomes while ensuring treatment safety [2].

VMAT is a more complex technique compared to intensity-modulated radiation therapy (IMRT). Therefore, the development of a predictive solution for QA is of high importance. To the best of our knowledge, our study is the first to use the innovative deep hybrid learning approach for the prediction of QA on a patient-by-patient basis. Referring to the literature, Kimura and colleagues developed a deep learning solution for QC of prostate plans and obtained a specificity value of 0.986 [18], which is consistent with our study (specificity value for pelvic tumor location=1). However, no studies have been published for complex VMAT dosimetry plans (breast or H&N).

To speed up the process of patient quality assurance in RT, a significant number of studies have developed AI models. However, the number of studies with clinical implementation of the models has been very small. In one study, a clinical implementation was performed, but the results obtained for the AUC were at best 0.869 [19]. Our first goal in this study was to develop an AI solution for QC in VMAT. This solution should be easy to use for everyone and should be implemented in clinical routine. For this reason, we used only six complexity indices in the modeling, which can be easily obtained during the dosimetry step. At the same time, we packaged the solution in an API for easy use by everyone.

Prediction of QA for IMRT breast tumor treatment using Halcyon machine

We also develop a model for new RT machines such as Halcyon can deliver a maximum dose rate of 600 monitor units per minute, allowing an increase in the number of patients treated per day. However, patient-specific QA is still required to ensure treatment safety, which dramatically decreases machine availability for patients. Innovative AI algorithms could predict the QA results immediately after dosimetry planning, based on complexity metrics to be used have not been definitively determined. The aim of this study was to develop an AI solution capable of firstly determining the complexity indexes to be obtained and secondly predicting patient-specific QA in routine clinical setting. Three hundred and eighteen beams from 56 patients with breast cancer were used in this study. Seven complexity indexes including Modulation Complexity Score (MCS), Small Aperture Score (SAS10), Beam Area (BA), Beam Irregularity (BI), Beam Modulation (BM), Gantry and Collimator angles were used as input to the AI model. ML and DL models using artificial neural network with TensorFlow and Keras were set up to predict the classification problem with conforming and non-conforming QC.

Statistical analysis showed that MCS, BI, gantry and collimator angle are not significantly correlated with QC compliance. Therefore, ML and DL models were trained using SAS10, BA and BM complexity indices. ML models did not show satisfactory performance with an AUC of 0.87 and specificity and sensitivity of 0.89 and 0.84. However, the optimized DL model showed better performance with an AUC of 0.96 and specificity and sensitivity of 0.98 and 0.92. Furthermore, DL model have been able to predict QA conformity in five cases of dose difference/distance to agreement: 2.5%/2.5mm, 3%/3mm, 3%/2mm, 2%/3mm, 2%/2.5mm. As for the first study with VMAT, API have been developed for whom which are interested to use the DL model for IMRT Halcyon QA prediction: https://aureliencd-halcyonqualitycontrolapi-ba47xul4ukaxjrwn4vxp5s.streamlit.app

5 Conclusion

Patient-specific QA requires time on the treatment machine, during which time it is impossible to treat patients. Therefore, the objective of this study was to propose an alternative solution for patient-specific QA that would make treatment machines more available to patients. To predict patient-specific QA compliance for treatments, we developed AI models based on complexity indices. In a busy RT department, the AI solution was used to automate patient-specific assurance. The results were conclusive for the VMAT in Rapid Arc machine as well as for IMRT in Halcyon machine. To implement this study in clinical routine, APIs were developed.

Analysis of a decade's worth of oncology information system data from a large US healthcare system

Christian Velten[1,2], Ping Yan[1,2], Madhur K. Garg[1], and Wolfgang A. Tomé[1,2]

[1]Department of Radiation Oncology, Montefiore Medical Center, Bronx, USA
[2]Institute for Onco-Physics, Albert Einstein College of Medicine, Bronx, USA

Abstract Over a decade of oncology information system data were analyzed to investigate practice patterns and changes with respect to the treatment planning process across several sites. Evaluated metrics were physician conformity to submit target contours and prescriptions, available time for treatment planning, including quality assurance and physics checks, overall development of the number of plans treated, and treatment planning and physics check workload. Changes in practice patterns, e.g. the impact of the COVID-19 pandemic and its variation in the type of treatments performed at different sites, as well as the increasing number of patient plans treated with decreasing time available was identified. Interventions e.g., increasing time allotments and the implementation of a treatment planning progress monitoring system were identified in the data. Leveraging big data can generate insights and drive pro-active over reactive workflow changes.

1 Introduction

Radiation oncology practices rely on the collaboration of an interdisciplinary team to treat patients effectively and safely in a timely fashion. Between treatment simulation up to the delivery of radiotherapy physicians and physicists – in some countries supported by dosimetrists – work mostly in sequence to generate treatment plans using computerized treatment planning systems.

Treatment planning processes and workflows have been evolving over time to adjust to new technologies, organizational changes, and incrementally to improve efficiency and alleviate insufficiencies, actual or perceived. These changes are usually slow, making it difficult to measure their efficacy independent of short-term environmental changes. Moreover, changes may be initiated by temporary or short-term issues or subjective anecdotal evidence, ultimately failing to achieve their intended goal or even be detrimental to the overall evolution of the department's processes.

Before the advent of computerized oncology information systems (OIS), analyses of workflows and processes had been cumbersome and slow. Widespread implementations of OIS have enabled efficient aggregating of data relating to physician and physics tasking, patient scheduling, and many more over time frames of individual days or many years.

Our Medical Center provides radiation oncology services across six different sites, both hospital-based and freestanding, with four sites being integrated into the same OIS database. Of these, one hospital-based and freestanding site treat the majority of patients, each using two linear accelerators (one C arm, one ring gantry based). The other two sites treat an average of ten to fifteen patients per day using one C arm linac each.

Treatment planning is initiated by physicians by providing target and critical organs-at-risk (OAR) definitions, radiation dose prescriptions, and acceptable doses to OARs. External beam radiotherapy planning is centralized for the integrated sites and was performed by an on-site staff of six dosimetrists spread over the two main sites until the COVID-19 pandemic. Since then, dosimetry staff are primarily remote with staffing levels augmented through third party contracts. Towards the end of the planning process, treatment plans are submitted to be reviewed by

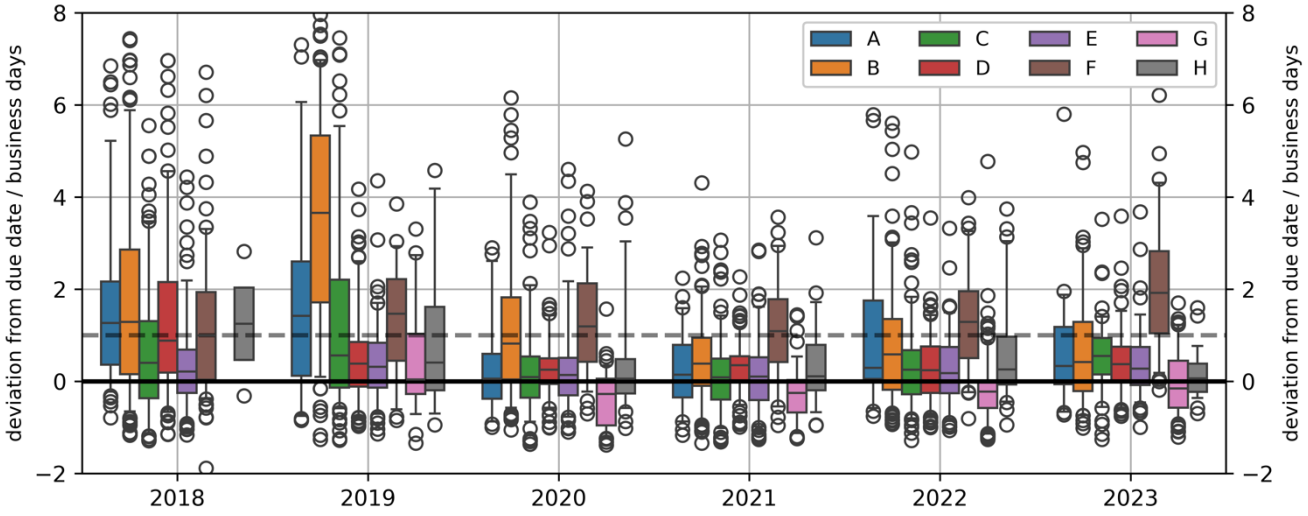

Figure 1. Deviations from physician input due date in business days for eight attending radiation oncologists over six years. Whiskers correspond to the 90% confidence interval.

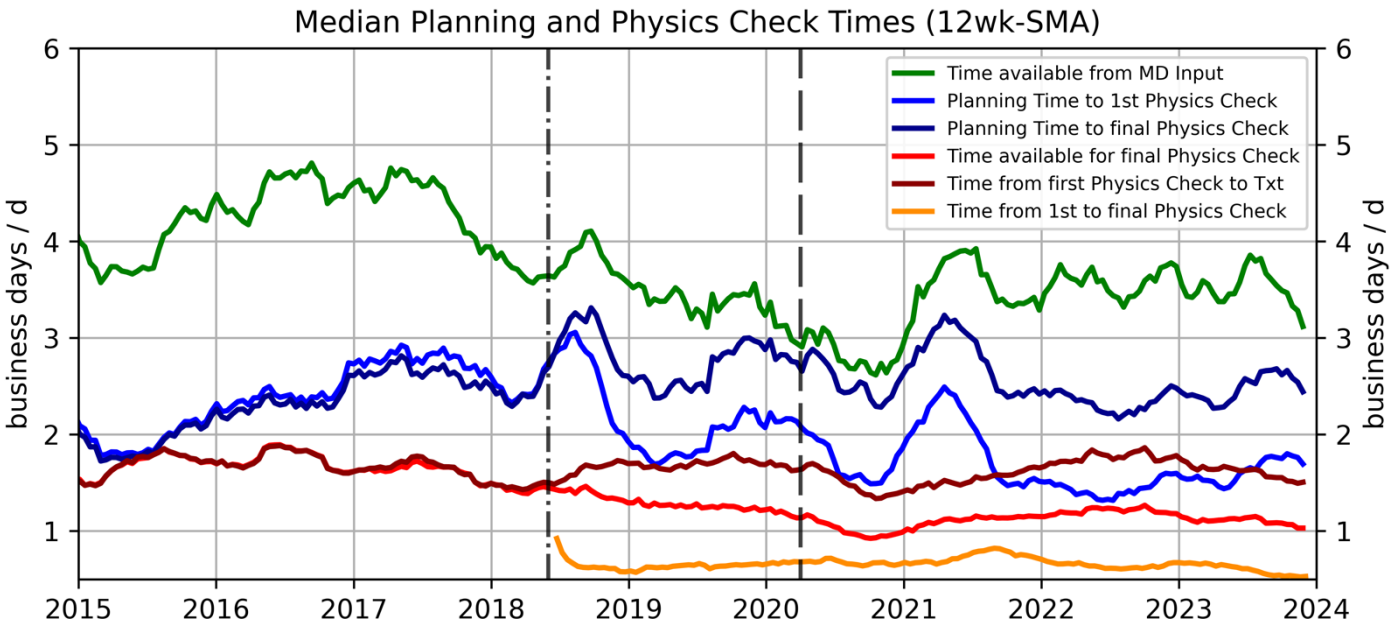

Figure 2. Evolution of planning and physics check times over nine years. In June 2018 physics checks before physician review (pre check) were implemented. Beginning with April 2020 (these time points are indicated by vertical lines), New York City was in a COVID-19 shutdown.

physicists to assess overall plan quality, safety, and consistency with the physician prescription.

We investigated treatment planning practice patterns across integrated facilities to evaluate treatment planning workloads, bottlenecks, differences among departments and staff groups, and the impact of planning interventions.

2 Materials and Methods

Physician and physics tasks, as well as patient appointments were queried from the Varian ARIA OIS database using SQL queries. Processing and analyses were performed using Python (pandas, seaborn, scipy). Dates and times were adjusted for US business days and hours (08:00 to 18:00) excluding federal holidays and weekends.
Physician conformance was evaluated as the deviation from physician input due date (including early completion) in business days. Boxplot whiskers extend from the 5% to 95% quantiles. Workload for the physics group, composed of dosimetrists and physicists is evaluated as the ratio of number of tasks and the average time available for completion in the same time span. Time available to complete a task is assumed to be inversely proportional with stress associated with its completion and hence task intensity. With this our definition follows the US Centers of Medicare and Medicaid Services and American Association of Physicists in Medicine Abt IV report definition for workload.

3 Results

Physician conformance is shown in figure 1 with the deviation from due date distributions from 2018 through 2023. From 2018 to 2019 several physicians consistently exceeded their allotted time by at least one day with one physician (B) reaching a median of almost four days in 2019 with 90% of all submissions being late and at least 25% overdue by more than 5 days. Coincident with the NCOV-19 pandemic in 2020, physician inputs became less overdue with the majority now submitted up to one day late. Since then, delays have increased slightly across all staff members. Notably, physician F's inputs did not decrease substantially during 2020 and have become increasingly late from a median of 1 day in 2021 to 1.5 days in 2022, and approximately 2 days in 2023.

Time series of available planning and physics check times are shown in figure 2. The available time for planning (green line) decreased from 4-5 days during 2016-17 to 3 days during 2019, extending into most of 2020, and has since increased to on average 3.5 days. With total planning time (dark blue line) remaining somewhat constant during that time, the time available to perform QA and perform physics checks decreased from a median of 1.5-1.9 days to 1 day in mid-year 2020. With the increase in available planning time in early 2021 both utilized planning time and the time available for QA and physics checks increased slightly.

The total number of plan check tasks performed across the OIS-integrated sites is shown in figure 3. Few tasks were

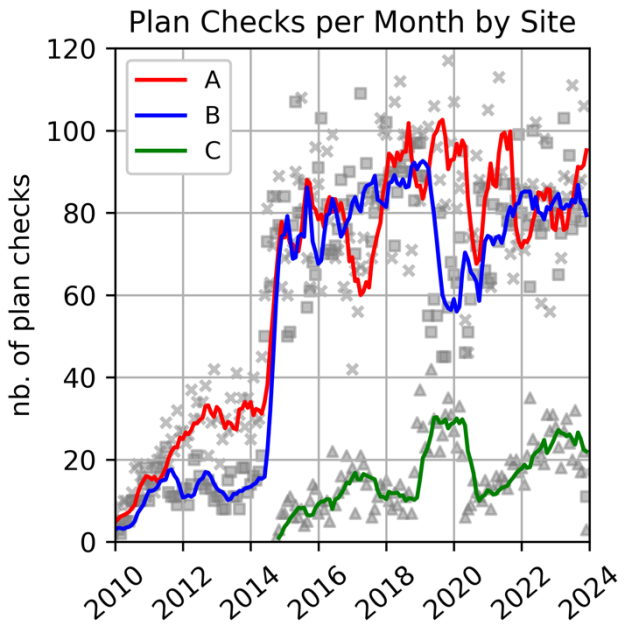

Figure 3. Number of physics plan check tasks submitted per month by department. C includes all secondary sites treating few patients cumulatively.

completed before 2015 with a total of approximately 50 per month after which the number of monthly plan checks jumped to approximately 75 for sites A and B. From 2015 through 2019 numbers increased to approximately 90 per month. Site-specific decreases in 2017 (A) and 2019 (B) of about 20-30 per month were compensated by increases in numbers for the other sites. All sites experienced a sharp decrease in monthly plan checks during the first half of 2020, from which A recovered rapidly within a few months with the recovery at sites B and C somewhat slower. The number of monthly plan checks at the end of 2023 has reached levels previously seen in 2018.

Planning and physics workloads are shown in figure 4. Planning workloads reached a minimum of 2.5 in 2017 before increasing in 2018 and varying between 3.5 to 5.5 since then. During 2022 planning workloads remained somewhat constant just above 5 and have been increasing since the beginning of 2023. Physics workloads reached a minimum of 5 in 2017 and have generally been varying substantially by up to a factor of two between 7.5 and 15. Since the beginning of 2023, physics workload again doubled from 10 to 20.

4 Discussion

Decreases in available planning times from 4-5 days during 2016-17 to 3 days during 2019 and extending into 2020 are consistent with physician input delays of one day or more (Fig. 1 & 2). Substantial improvements in physician conformance were observed for 2020 (Fig. 1), driven in part by the substantially decreased number of patients seen during the first three quarters that year due to the COVID-19 pandemic. Another factor was actuarial in that the scheduled time available to complete the physician input was increased from 3 to 5 days for most cases. During that year available planning time continuously deteriorated despite increased physician conformance (Fig. 2, green line). And while this did not translate to a substantial change in the total time utilized for planning (Fig. 2, dark blue line) compared to pre-pandemic levels it did decrease the time available for physics checks and QA times by almost 30%. This inconsistency between increased on-time submission and available time for planning is likely due to two factors: first, time-to-treatment was kept the same or did not increase as much as the time allotment for physician inputs increased, and second, physician tasks were completed despite no workable target structures or prescription available, circumventing the tasking system.

Available time for physics checks and QA was also reduced, perhaps unintendedly, by the implementation of a pre-physician review physics check (Physics Pre Plan Check) in 2018. Its intention is to catch planning errors and mistakes early in the process and to improve efficiency. However, most of these pre-checks are now being submitted at times that final checks used to be submitted. In cases where substantial changes had to be made due to planning errors or physician requests, this substantially increases the peak workload for physics staff.

With increasing patient numbers towards the end of 2020 and continuously deteriorating available planning time a planning progress monitoring system was implemented in November of that year. This system automatically sent out reminders about physician input due and overdue times. Almost immediately, the median available planning time increased and has since remained at around 3.5 days. The

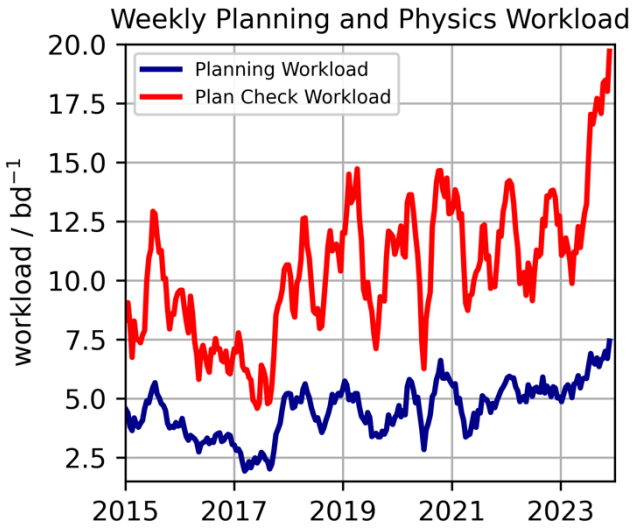

Figure 4. Weekly planning and physics workload measured as ratio of number of tasks to average time allotted for task completion.

time available for final physics checks had similarly recovered to 2019 levels by mid-year 2022.

Since mid-2022 actual planning times have consistently increased, while physics times for both pre and final checks have decreased by the same amount. During that time an automated whiteboard was implemented in 2022 to aid in reducing late plan submissions, however, it appears like it may have had the opposite effect. One potential reason is that dosimetrists may not be assigned to plans more than two days prior to scheduled start or dosimetrists may be delaying plan generation given the increased workload levels since 2022 (Fig. 4). This suggests that an intervention is warranted to identify cases where planning has not been initiated within a certain time of physician input. The need for such an intervention is even more evident given the sharp increase in physics workload during 2023 from 10-12 at the beginning of the year to almost 20 by December. This increase can only in part be explained by an approximately 20% increase in plans at site A (Fig. 3) where turnaround times are usually less than 3 days.

5 Conclusion

A centralized OIS database was leveraged to query and aggregate physician, dosimetry, and physics task data from more than 10 years to give insights into practice patterns and their evolution. Internal (machine replacements) and external (COVID-19 pandemic) impacts could clearly be identified. Correlating available task times and workloads can be used to inform and substantiate changes to workflows to increase efficiency.

Fast many-scenario robust IMPT planning through constrained dose-mimicking

Franziska Knuth[1], Michelle Oud[1], Wens Kong[1], Hazem Nomer[1], Joep van Genderingen[1], Linda Rossi[1], Steven Habraken[2,3], Ben Heijmen[1], and Sebastiaan Breedveld[1]

[3]Department of Radiation Oncology, Leiden University Medical Center, Leiden, the Netherlands

Abstract
Patient setup variations and proton range uncertainties need to be taken into account in robust treatment planning for intensity modulated proton therapy (IMPT). In this study, a two-step approach is proposed that aims at fast generation of IMPT plans that are robust for many robustness scenarios. In the first step, automatic multi-criterial optimization (MCO) with Erasmus-iCycle is used for generation of a plan that is robust for 13 scenarios. In the following dose mimicking step, this plan is converted into a plan that takes into account 53 scenarios. The potential of this approach is demonstrated for 14 oropharyngeal cancer patients. Compared to the initial plans generated with the 13 scenarios, the converted plans show much improved target coverage robustness for the final 53 scenarios, similar to plans directly generated with 53 scenario based automatic MCO. The two-step approach with dose mimicking was also a factor 10.7 faster than direct automatic MCO, with dose mimicking times of on average 1.4 min. The proposed dose-mimicking is applicable to various treatment sites, providing a practical solution for enhancing IMPT plan robustness with significant time savings compared to direct robust optimization.

1 Introduction

Intensity modulated proton therapy (IMPT) is susceptible to patient setup variations and proton range uncertainties. To account for this, treatment planning is performed using a set of scenarios, i.e. patient shifts and range variations, to ensure adequate CTV coverage and adherence to maximum doses for critical organs at risk (OARs). However, optimization times increase with the number of included scenarios. In clinical practice, 21 scenarios are often used for planning, with more scenarios desirable for more accurate modeling of the impact of variations and uncertainties. For fast robust optimization with a large set of scenarios, we propose a two-step approach: 1) automated multi-criteria treatment planning using a small set of scenarios, 2) fast constrained dose-mimicking to make the plan robust for a much larger set of scenarios.

2 Materials and Methods

For 14 patients with oropharyngeal cancer, Erasmus-iCycle with large scale sparsity-induced spot selection (SISS) [1–3] was used to automatically generate two robust IMPT plans. The first, with only 13 robustness scenarios (iCycle13), was used as input for the proposed dose mimicking (details below), aiming at fast generation of the Mimic53 plan that should be robust for 53 uncertainty scenarios. The second Erasmus-iCycle plan (iCycle53) was compared to the Mimic53 plan for validation of the dose mimicking. Setup- and range robustness settings of 3 mm/3% were used. The scenarios were distributed on a unit sphere following Korevaar et. al. [4], where the 13 scenarios were a subset of the 53. Figure 1 illustrates the distribution of setup errors. Doses of 70 GyE and 54.25 GyE were prescribed to the primary and elective CTV, respectively. All three plan generations were constrained for adherence to minimum and maximum MU constraints and maximum number of energy layers, following the requirements in our clinic.

In the dose mimicking, a quadratic penalty function was minimized aiming at updated iCycle13 spot weights that closely reproduced all voxel doses of iCycle13 in the 13 scenarios, while enforcing obedience to the clinical CTV voxel-wise minimum dose constraints for all 53 scenarios.

Mimic53 plans were compared to ground truth iCycle53 plans and to the input iCycle13 plans. All plans were evaluated on 53 scenarios, via nominal, voxelwise minimum (VMin) and voxelwise maximum (VMax) dose distributions. The two-sided Wilcoxon signed-rank test was used to evaluate differences in dose-volume-histogram (DVH) metrics with a significance level of 0.05.

3 Results

Figure 2 compares plan parameters of iCycle13 and Mimic53 with the highly robust gold truth plans, iCycle53. Consid-

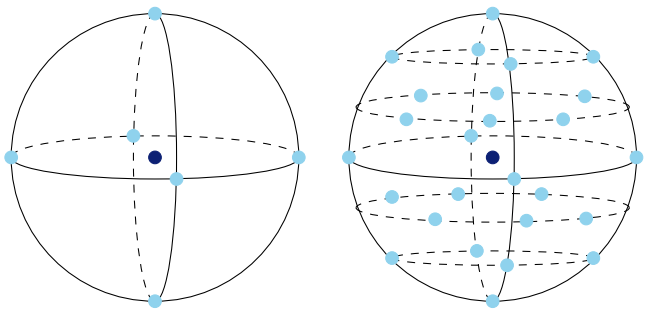

Figure 1: Illustration of setup uncertainties for 13 (left) and 53 (right) scenarios. For each setup scenario case (light blue), the positive and negative range error case is included, with exception of the nominal scenario (dark blue).

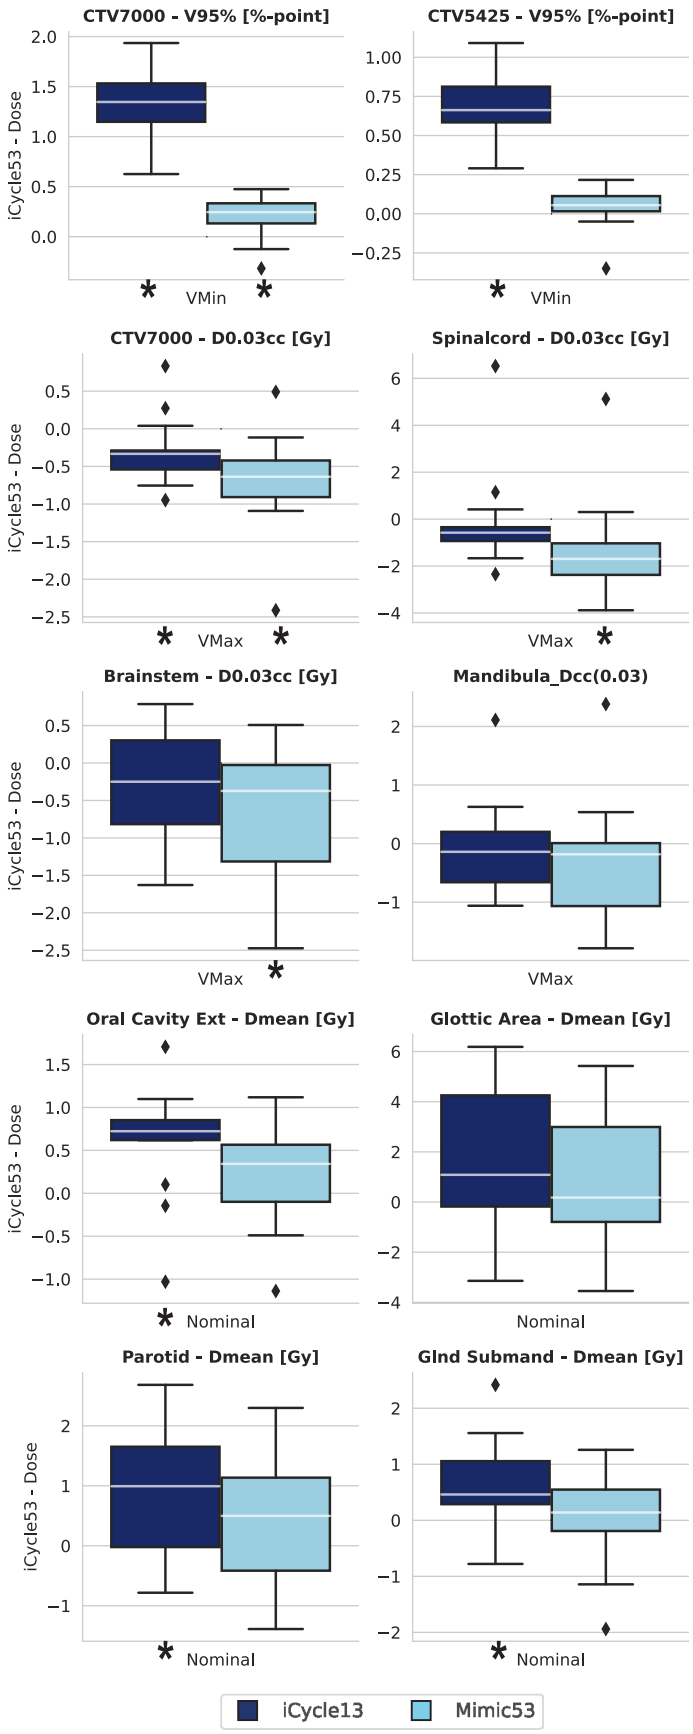

Figure 2: Boxplots showing the differences between both iCycle13 and Mimic53 to iCycle53, where all plans were evaluated on 53 scenarios. In the boxplots, the box indicates the median and interquartile range. Outliers are outside the 1.5 the interquartile range. Significant differences as denoted by the wilcoxon signed-rank test are indicated as *: p<0.05.

Table 1: Computation times (min) for the different plans

Step	iCycle13	Mimic53	iCycle53
PBC for SISS	54±8		869±118
SISS MCO	24±6		115±32
PBC for Mimicking†	-	12±3	-
Mimicking	-	1.4±0.3	-
Total	78±10	92±11	984±116

PBC: Pencil beam calculation; SISS: Sparsity-induced spot selection; MCO: Multi criteria optimization; †: Computation of pencil-beams in the 40 new scenarios.

ering all 53 robustness scenarios, iCycle13 plans show significant VMmin $V_{95\%}$ losses for both high (p=0.0001) and low (p=0.0001) dose CTV compared to iCycle53, with median differences of 1.3%-points and 0.66%-points, respectively. For the Mimic53 plans, these differences to the gold truth were reduced to 0.25%-points for CTV 7000 (p=0.009) and 0.055%-points for CTV 5425 with no statistical significance. Compared to iCycle13, mimicking also reduced differences with iCycle53 in nominal mean OAR doses (Dmean), eliminating the significant differences for iCycle13. For the parotids, the difference with iCycle53 in median Dmean reduced from 0.99 Gy (p=0.013) in iCycle13 to 0.5 Gy (p>0.05) in Mimic53. The same trend can be observed for the median Dmean of submandibular glands and the extended oral cavity. The difference in median Dmean also decreased for the glottic area, as well as the VMax near maximum doses (D0.03cc) of the mandibula, while the difference was already not significant for iCycle13. Differences in VMax D0.03cc for brainstem and spinal cord were slightly higher for Mimic53, compared to iCycle13, however well within the hard constraint of 35 GyE for all plans. Table 1 summarizes the optimization times in minutes for the different plans as well as the times for the spot dose calculations. Overall, the speed-up factor for the dose mimicking approach (Mimic53) compared to the direct highly robust optimization (iCycle53) was 10.7 including initial pencil beam dose calculations. Excluding times for pencil beam calculations, generation of a gold truth iCycle53 plan took 115 min, which reduced to 25.4 min for generating the Mimic53 plan. Dose mimicking to convert an iCycle13 plan into a Mimic53 plan only took 1.4 min.

4 Discussion

When robustly evaluated for 53 scenarios, iCycle13 plans, that were robustly generated considering only 13 scenarios, showed substantial plan parameter deviations from ground truth iCycle53, especially for target coverage. With the proposed dose mimicking, an iCycle13 plan could in 1.4 min be converted into a Mimic53 plan with no coverage differences with gold truth. This study includes only 14 patients, which

is a limitation, even though the proposed dose mimicking approach does not require fine tuning of parameters. The presented mimicking approach is not limited to the presented treatment site and prescription, and can be applied without special adjustments to other treatment sites or dose prescriptions. Oropharyngeal cancer cases were chosen as demonstration because of the challenging anatomy with many OARs in close proximity to the targets. The presented approach can also be easily extended to an even larger set of scenarios.

5 Conclusion

We have introduced a dose-mimicking approach to obtain IMPT plans which are robust for a large number of scenarios (53) with computational costs similar to full robust optimization for a low number of scenarios (13). The additional time for dose mimicking took on average 1.4 min.

DeepTuning: Tune Radiotherapy Plan Dose Distribution in Real Time by Deep Learning

Lin Ma[1], Huan Liu[2], Mingli Chen[3] and Weiguo Lu[3]

[3]Department of Radiation Oncology, University of Texas Southwestern Medical Center, Dallas, Texas, USA

Abstract Radiotherapy treatment planning is a teamwork collaborated by physicians, dosimetrists and physicists. Physicians inform dosimetrists regarding their desired dose distributions and trade-offs, while dosimetrists provide physicians with the best plans can be achieved. It often requires multiple rounds of consultation between physicians and dosimetrists to tune plans and select one with desired trade-off. The back-and-forth between different parties prolongs planning process. To reduce the back-and-forth resulting from trade-off exploration, we proposed a new framework called DeepTuning. The framework utilized a deep learning model to predict spatial dose distributions with different trade-offs given a set of contours. The predicted dose distribution can be tuned in real time by manipulating the deepest layer of the model. We validated this method with a dataset consisting of prostate VMAT plans. The model can generate plans ranging from prioritizing PTV coverage to prioritizing rectum sparing. The DeepTuning framework has the potential to empower physicians to tune dose distributions immediately after they complete contours. A desired dose distribution can be sent to dosimetrists to inform dosimetry planning. As the trade-off selection occurs before dosimetry planning, the back-and-forth can be minimized, promoting the efficiency of treatment planning workflow.

1 Introduction

Radiotherapy treatment planning is a teamwork collaborated by physicians, dosimetrists and physicists. Physicians prescribe treatment dose to target and place constraints for normal organs. Dosimetrists provide feasible solutions to satisfy physician's orders by optimizing plans in treatment planning system (TPS). It often requires multiple rounds of consultation between physicians and dosimetrists to tune plans and explore trade-offs before plan approval. The back-and-forth between different parties prolongs planning process, because their schedules are not aligned.

Multi-criteria optimization (MCO) has been developed to allow real-time trade-off exploration and reduce the off-line back-and-forth. However, it wasn't adopted widely in the clinic because of its nature of being an optimization method. The optimization time is longer than usual planning, but accuracy is limited. Deep learning (DL) has shown promise in predicting dose distribution directly from contours without optimization [ref 1]. However, its prediction is fixed rather than adjustable. Physicians cannot tune the predicted dose and explore trade-off with DL tools.

We proposed a "DeepTuning" framework to reduce the back-and-forth in treatment planning. It is a DL model that can predict a distribution of dose distributions with different trade-offs from just contours. Users can tune the predicted dose in real time. It combines the advantages of DL and MCO because it can derive a dose in real-time and the doses can be adjusted for different trade-offs.

2 Materials and Methods

Theory: VMAT dose distributions are determined by two types of information: geometry and trade-off. On the first order, geometry information (contour location, shape and size) dictates the dose distribution because VMAT doses conform to the targets and carve around OAR contours. Furthermore, contour-to-dose is not a one-to-one mapping. Each patient can have multiple plans with different trade-offs, for example, between target coverage and OAR sparing. Therefore, on the second order, the trade-off information also affect dose distributions. Geometry information dominates dose distributions, while trade-off information represents dose tuning, whose influence is lesser.

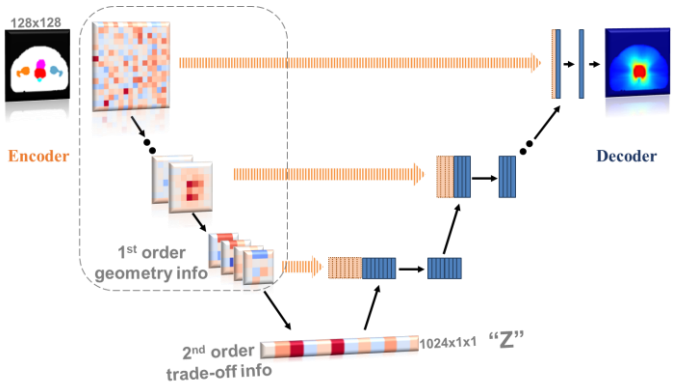

Figure 1. Network structure of a U-Net for dose prediction. It is composed of an encoder and a decoder. The feature maps at different depth encode geometry information and trade-off information.

A deep learning model (U-Net) takes contour as input and predict dose distribution. It comprised an encoder and a decoder. We hypothesized that the geometry information were store in the feature maps in shallow layers while the trade-off information were stored in the deepest feature map, which has been down-sampled to the resolution of 1 by 1 with 1024 channels. Hereafter, we refer to the deepest feature map as "trade-off encoding vector" by symbol Z. Given patient contours, the goal of DeepTuning is to generate dose distributions with different trade-offs by manipulating trade-off encoding vector Z.

Data: The models were trained by an anonymized dataset comprising 99 prostate VMAT cases. The structures of each case are PTV, bladder, rectum, left and right femur head. The PTVs were expanded from intact prostate or prostate plus seminar vesicle. For each case, we retrospectively optimized two VMAT plans with our in-house optimizer. One plan prioritized PTV coverage (referred to as "pro-ptv" plan

below), while the other plan prioritized rectum sparing (referred to as "pro-oar" plan below). The two plans were optimized with same objectives (80Gy to PTV, etc) except that the coverages in the PTV-rectum overlap were relaxed to 77Gy and rectum doses were penalized harder in the "pro-oar" plans. For each case, the two plans constitute a set plans with different trade-offs.

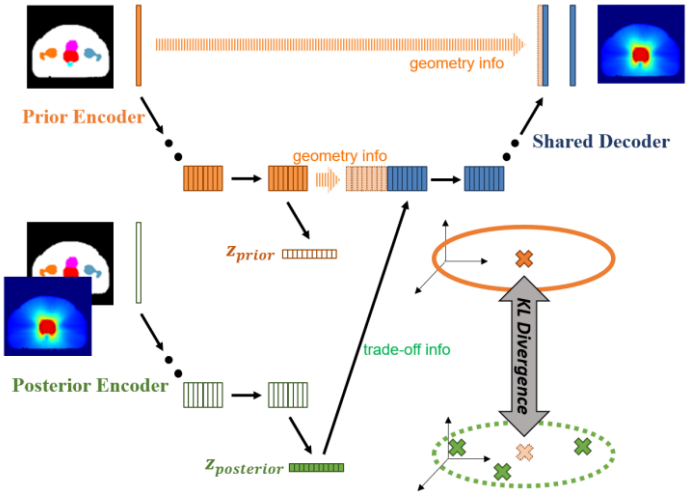

Figure 2. Training scheme for DeepTuning. Prior encoder (orange), posterior encoder (green) and shared decoder (blue) are trained together. The green crosses in the bottom right corner represent the Z_qs of different input doses. Orange cross represents the Z_p predicted by prior encoder, which is the average of Z_qs.

Model architecture: The DeepTuning framework has three components: prior encoder $\mathbb{E}_{prior}$, posterior encoder $\mathbb{E}_{post}$, and decoder $\mathbb{D}$. They serve for different purposes.

Prior encoder $\mathbb{E}_{prior}$ takes contour C as input. The shallow feature maps it generated represent geometry information G and the deepest feature map Z_p (p for prior) represents trade-off information. As contour is the only input, we expect Z_{prior} to encode a balanced trade-off, corresponding to the average of training dataset. An example of prior encoder is at the left side of figure 1.

$$G, Z_p = \mathbb{E}_{prior}(C)$$

Posterior encoder $\mathbb{E}_{post}$ takes contour C and dose D as input in two channels. It has the same structure as prior encoder except for the number of input channels at the first layer. We discard the shallow feature maps it generated and only use its deepest feature map Z_q (q for posterior). We expect Z_q to encode the trade-off of input dose.

$$\sim, Z_q = \mathbb{E}_{post}(C, D)$$

Decoder $\mathbb{D}$ can be used with a prior encoder alone to form a U-Net and predict dose distribution D. In this case, the inputs to $\mathbb{D}$ are the geometry information G and balanced trade-off Z_p extracted by encoder (from contour alone).

$$D = \mathbb{D}(G, Z_p)$$

Decoder $\mathbb{D}$ can also be used with both encoders. In this case, the inputs to $\mathbb{D}$ are the geometry information G extracted by encoder (from contour alone) and the trade-off Z_q extracted by posterior encoder from the input dose distribution.

$$D = \mathbb{D}(G, Z_q)$$

Model training: We trained the model with the prostate VMAT dataset described above. In each training epoch, we ran over all training cases. For each case, we randomly pick a plan, which could be pro-ptv or pro-oar. The contours were fed into prior encoder $\mathbb{E}_{prior}$ to extract geometry information G. The contour and the dose (pro-ptv or pro-oar) were fed into posterior encoder $\mathbb{E}_{post}$ to extract trade-off information Z_q. The shared decoder $\mathbb{D}$ combined the two information and predicted a dose. The three models were trained by minimizing two loss functions. First, we forced the output dose to be the same as input dose. Therefore, the posterior encoder can extract trade-off from input dose. Second, when posterior encoder was fed with plans with different trade-offs, it generated different Z_q(green points at the bottom right of figure 2). We forced the Z_p to be the average of the Z_qs by a KL divergence loss. Therefore, prior model can generate a Z_p corresponding to balanced trade-off, average of training plans. Please find training details in figure 2 and algorithm 1.

Algorithm 1: Model training

For i th case in training dataset

1. Get contours C^i. Randomly pick a plan (could be pro-ptv or pro-oar) and get its dose D^i
2. Feed contour C^i to prior encoder. Derive geometry information G and balanced trade-off encoding vector Z_p
$$G, Z_p = \mathbb{E}_{prior}(C^i)$$
3. Feed contour C^i and dose D^i to posterior encoder. Extract trade-off Z_q from input dose
$$\sim, Z_q = \mathbb{E}_{post}(C^i, D^i)$$
4. Feed geometry info G and the extracted trade-off info Z_q to decoder, which predicts dose $\widehat{D}^i$
$$\widehat{D}^i = \mathbb{D}(G, Z_q)$$
5. Calculate dose loss $||\widehat{D}^i - D^i||^2$
6. Calculate trade-off feature loss $KL\ Div(Z_p, Z_q)$
7. Optimize the parameters of models ($\mathbb{E}_{prior}$, $\mathbb{E}_{post}$ and $\mathbb{D}$) by minimizing the two losses

Model inference: After training, we obtained three models. The prior model can extract geometry information and derive Z_p representing balanced tradeoff from just contour. The posterior model can extract tradeoff from input dose distribution. The decoder can be used in conjunction with encoders to predict dose.

The application of models to new cases is consisted of two steps. First, extract desired trade-off ΔZ from template plans. Second, apply the desired trade-off ΔZ to new case and predict dose with desired trade-off.

In the first step, template plans refer to the plans of the patients treated before. The template plan has the desired trade-off (eg. trading a little PTV coverage for a lot OAR sparing). Physicians preferred this trade-off and wanted to replicate this trade-off in future cases. To extract trade-off from a template plan, we feed it into prior encoder and

posterior encoder separately, which generated a Z_p that represents balanced trade-off and a Z_q that encodes the trade-off of template plans. Their difference ΔZ can tune the trade-off of a dose distribution. Please find the details in Algorithm 2.

Algorithm 2: Extract trade-off from template plan

Input: Contours C and dose D of template plan with desired trade-off

Output: trade-off of template plan, ΔZ

Steps:

1. Calculate the balanced trade-off encoding vector Z_p by prior encoder
$$\sim, Z_p = \mathbb{E}_{prior}(C)$$
2. Calculate the trade-off Z_q of template plan dose by posterior decoder
$$\sim, Z_q = \mathbb{E}_{post}(C, D)$$
3. Extract trade-off of template plan by subtracting from balanced tradeoff
$$\Delta Z = Z_q - Z_p$$

In the second step, we use prior encoder to predict doses for new patients. When we feed just contour into prior encoder and run through decoder (step 1 and step 2 in Algorithm 3), it generates a dose with balanced trade-off, average of training dataset, functioning as a conventional dose prediction model. The novelty of DeepTuning roots in the next step. If we apply the trade-off ΔZ extracted to this new case, (step 3 in Algorithm 3), the output dose distribution changes, from balanced trade-off to the desired trade-off. Our DeepTuning framework tunes the trade-off of dose prediction by manipulating the trade-off encoding vector Z. Please find the details in Algorithm 3 and figure 3.

Algorithm 3: Predict doses for new case

Input: Contours C of the new case, the desired trade-off ΔZ extracted from template plan

Output: dose distribution for new case with desired tradeoff

Steps:

1. Feed contour C to prior encoder. Derive geometry information G and balanced trade-off encoding vector Z_p
$$G, Z_p = \mathbb{E}_{prior}(C)$$
2. Predict dose D with balanced trade-off by Z_p
$$D = \mathbb{D}(G, Z_p)$$
3. Or, predict dose D with desired trade-off by applying ΔZ
$$D = \mathbb{D}(G, Z_p + \Delta Z)$$

Training specifics: We split the dataset into training set (60 cases), validation set (10 cases) and testing set (29 cases). The models were trained by training set. The models in the iteration with lowest validation loss were selected as the final models. The DeepTuning project was implemented in Python language v3.7 and Pytorch deep learning framework v1.1.0. We trained the models by 200 epochs with Adam optimizer and a learning rate of 1e-4.

The contours and doses were resampled to an isotropic resolution of 0.25mm. The input and output are 128*128 2D patches, corresponding to 32cm*32cm, large enough to accommodate high and intermediate dose regions for dose prediction purpose.

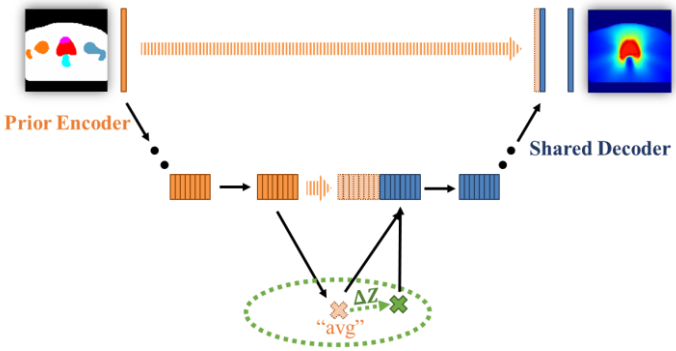

Figure 3. Prior model predicts dose for new case. It predicts average dose w/ balanced trade-off, or apply ΔZ to predict a dose with trade-off.

3 Results

In this section, we first evaluate the accuracy of posterior inference on testing set by comparing the output dose distribution to the dose input to the posterior encoder. This is a sanity check to validate that posterior encoder can extract the trade-off from input dose. Then we examine the prior inference on testing set by comparing the prior model prediction to the pre-optimized doses with trade-offs. The prior model should generate a plan with balanced trade-off, straddling between the pro-ptv plan and the pro-oar plan. Then we select a pro-oar plan from training set as "template plan", visualize the trade-off encoding vectors Z_p, Z_q and their difference ΔZ that can tune the trade-off. Finally, we apply the extracted ΔZ to testing set, to validate that our DeepTuning framework can rise above predicting average doses and succeed in predicting doses with the desired trade-off.

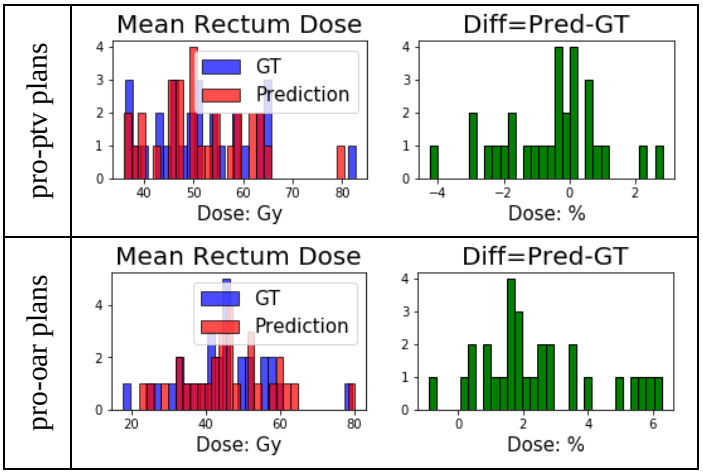

Figure 4. Histogram of predicted dose vs GT doses. It evaluates the accuracy of posterior model which replicates input dose distribution.

Posterior model inference: The results of posterior model in 29 testing cases were in Figure 4. The mean rectum doses in ground truth (GT) are 52.0±10.6Gy in pro-ptv plans and 44.2±12.2Gy in pro-oar plans. The predictions of posterior model match close to GT doses, with only differences of -0.6±1.5% and 2.4±1.8% in the two types of plans.

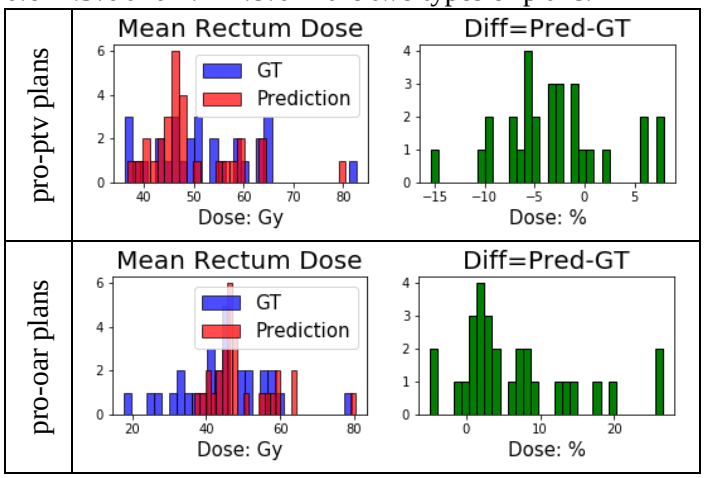

Figure 5. Histogram of predicted dose vs GT doses. It evaluates if prior model can predict an "average" dose with balanced trade-off.

Prior model inference: The results of prior model in 29 testing cases were in Figure 5. The prior model itself functions to predict an "average" dose with balanced trade-off. The mean rectum doses predicted by prior model are 49.5±9.0Gy, -3.1±5.3% colder than the pro-ptv GT plans and 6.6±7.9%colder than the pro-oar GT plans, which validated our hypothesis.

Trade-off extraction: We selected a case from training set and used its pro-ptv dose as template plan for pro-ptv trade-off and its pro-oar dose as template plan for pro-oar trade-off. The trade-off encoding vectors ΔZ were calculated for the two trade-offs. The Z_p for balanced trade-off (predicted by prior model), Z_q derived from pro-oar template plan and their difference ΔZ are shown in Figure 6.

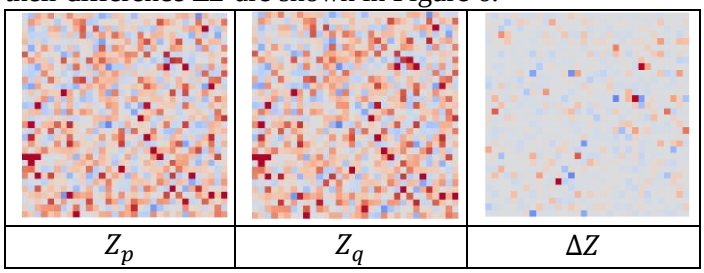

Figure 6. Example of the trade-off encoder vectors. Z_p is for balanced trade-off, Z_q here is for prioritizing rectum sparing, and ΔZ is their difference. Each Z is a vector with 1024 elements. We resize it into a 32x32 matrix for better visualization.

Apply trade-off to prior model inference: We applied the extracted trade-off ΔZ prioritizing PTV coverage and another ΔZ prioritizing OAR sparing to the 29 testing cases. Results were shown in Figure 7. With trade-off ΔZ for pro-oar applied, the mean rectum doses predicted by prior model dropped to 43.8±10.1Gy, from 49.5±9.0Gy in the average dose it predicted previously. The difference to GT pro-oar plans dropped from 6.6% to -0.6%. The same trend is observed for pro-ptv trade-off. This proves that the trade-off ΔZ can predict dose with trade-off for new patients.

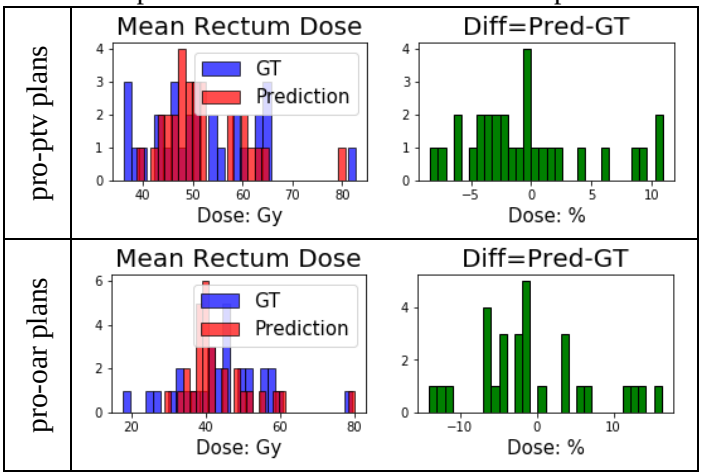

Figure 7. Histogram of predicted dose vs GT doses. It evaluates the accuracy of prior model with trade-off applied

An example of the input contour and predicted dose of prior model is shown in figure 8 below. Statistics of mean rectum doses are shown in table 1 below.

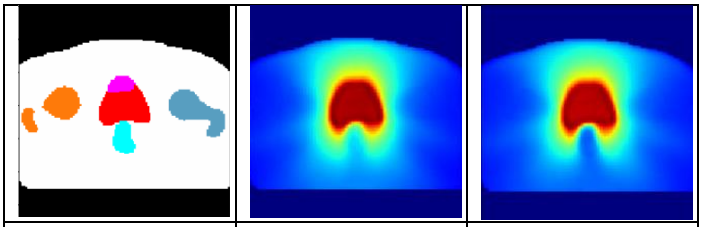

Figure 8. Model input (contours), the average dose predicted by prior model, and the rectum-sparing dose predicted by prior model with ΔZ

Table1:Mean rectumdose		Pro-ptv	Pro-oar
Ground truth doses		52.0±10.6Gy	44.2±12.2Gy
Post model inference	Prediction	51.6±9.9 Gy	46.2±12.4Gy
	Difference	-0.6±1.5%	2.4±1.8%
Prior model inference	Prediction	49.5±9.0Gy	
	Difference	-3.1±5.3%	6.6±7.9%
Prior model inference with ΔZ	Prediction	51.8±8.5Gy	43.8±10.1Gy
	Difference	-0.27±5.1%	-0.6±7.5%

4 Discussion

With pre-calculated ΔZs templated for different trade-offs, physicians can review doses with different trade-offs for a new patient immediately after contouring, and show the desired dose to dosimetrists. As trade-off selection occurs before dosimetry planning, back-and-force is minimized.

5 Conclusion

We proposed a DeepTuning framework that can predict doses with different trade-offs, showing great promise for improving planning efficiency

Automating Physics Plan Checks with Monaco Scripting

Paul Hill PhD[1]

[1]Department of Medical Physics, Cork University Hospital, Cork, Ireland

Abstract The Scripting Application Programming Interface (API) of the Monaco Treatment Planning System (TPS) allows code to be written which accesses many of the capabilities of Monaco and much of the data of the radiotherapy treatment plans. Scripts are created using the C# programming language and Microsoft Visual Studio and then imported into Monaco using the Manage Scripts Dialog. The API utilizes User Interface (UI) automation to provide access to Monaco functionality. Many of the functions which can be accessed through the Monaco UI are available through the API. A Script been created to automate a number of elements of the Physics Check of radiotherapy treatment plans. It performs checks on the validity of the dose calculation parameters, the treatment beam parameters, details of the treatment couch assignment and the values of the inverse planning optimizer inputs. The Script is in clinical use and is executed by the Dosimetrists prior to plan approval by the Radiation Oncologist. It has led to efficiency improvements in treatment planning as defects can be identified and then rectified early in the workflow.

1 Introduction

Radiotherapy treatment plans are developed by a multidisciplinary team consisting of Radiation Oncologists (RO), Medical Physicists, Dosimetrists and Radiotherapists. One of the critical tasks undertaken by the Medical Physicist is to perform the Plan Check of the treatment plan after it has been approved for treatment by the RO and prior to being sent to the treatment unit for delivery to the patient. This involves confirming the patient identity and prescription, validating that the multiple parameters of the Treatment Planning System (TPS) are correct, checking the dosimetry and preparing the plan for delivery. Guidelines exist to assist the physicist design the Physics Check process [1], in order to ensure the Quality of the treatment plan.

We use the Monaco TPS (Elekta, Stockholm Sweden) at Cork University Hospital. This allows for the generation of complex treatment plans using Volumetric Arc Therapy (VMAT) and Dynamic Multi-leaf Collimator (dMLC) technics. Version 6 of Monaco introduced a Scripting function. This provides an Application Programming Interface (API) which allows code to be created outside of Monaco, and then executed from within. It enables access to many Monaco functions including [2]:

- DICOM file import and export,
- Contouring auto-margins,
- Image Fusion
- Plan creation, optimization and calculation,
- Data extraction, including plan and beam details,
- DVH information,
- QA Plan generation, and,
- Report printing.

The scripting API uses User Interface (UI) automation to allow the script to manipulate the Monaco UI and access the data contained therein. The details of the API are contained in a dictionary "Index.chm" file provided by Elekta.

This work investigates how the process of Physics Plan Check could be automated with the Scripting capability. While the overall plan quality, suitability and correctness has to be assessed by a Medical Physics Expert (MPE) there are elements of the process which are suitable for automation. Some parameters in the TPS, for example the dose calculation grid size, just need to be checked that the value is set to the appropriate clinical value.

2 Materials and Methods

Monaco version 6.1.1 was used in this work. The Script was written using the C# language in the Microsoft Visual Studio 2019 Software Integrated Development Environment (IDE). The IDE was installed directly on to one of the Monaco calculation servers. The Script was compiled and linked using the API headers and Dynamic Linked Libraries (DLLs) which enable the script to communicate with the instance on Monaco running on the server.

Monaco provides configuration and access control to the Script via the Manage Script Dialog [2]. This allows the script to be imported into Monaco by selection of all necessary files. This Script is then available to be executed on any Monaco calculation server. To run any Script a user has to be a member of the Monaco Scripters group. The Manage Scripts Dialog also allows Scripts to be approved. These may then be executed by any Monaco user. This enables the testing of scripts which are not universally available and only when the testing is complete is the script available for all users.

An analysis of the API was carried out to determine which elements of the Physics Check process could be automated and produced the following list:

- Calculation properties including grid spacing, dose deposition type (medium / water) and algorithm;
- For each beam the description (clockwise or anti-clockwise for VMAT and gantry angle for dMLC), Treatment Unit, treatment couch inclusion and electron density assignment , bolus consistency and minimum number of segments;
- Consistency between the Inverse Planning Optimizer Target Penalty and the plan prescription;
- Dose Reference Point (DRP) location;
- Fractional DRP dose should be within tolerance of the Prescription.

These items defined part of the software requirements specification for the Script. In addition the requirements

were defined for how the results would be presented to the user through the UI. The graphical elements were added via Windows Presentation Foundation (WPF) and Extensible Application Markup Language (XAML). For each item to be checked the result was displayed as a pass ✅, fail ❌, or item not found ⚠.
Once complete, the Script underwent unit testing by creating a number of test plans in which each item was set to cause a pass or fail result and, where possible, not found.
Upon completion of unit testing the Script was made available to other members of the Monaco Scripters via the Manage Scripts Dialog. Two Senior Dosimetrists acted as beta testers by incorporating the Script in to their workflow for a period of several weeks after which the Script was approved for Clinical use.
The requirements, design, testing and configuration management of the Script were documented in our in-house Software Design Document [3].

3 Results

The Script was executed by the Dosimetrists prior to the plan being presented to the RO for approval. This was so that items which fail can be found early in the planning workflow and therfore can be remedied prior to approval. Otherwise, if found at the Physics Check, then, in general, the plan would need to be returned to planning for re-calculation, re-approval and re-export, which is time costly.
The Script runs in Monaco by driving the UI. It can be seen opening and closing windows and selecting tabs. For this reason is it is rather slow to execute with a typical VMAT plan requiring about 50 seconds. The user is presented with a visual indication in Monaco that a Script is running with a green (approved) or red (unapproved) animated text message as show in Figure 1.

Figure 1: The visual indication in provided in Monaco for Script execution. The animated text is shown on a green background for an approved Script and red for unapproved.

There are some restrictions on how the Script should be run. Monaco must be in full screen mode and on the main screen if the user has a multi-screen set up. The user must have only one instance of Monaco running on the particular server and requires write access to the patient plan. Monaco, and not MonacoSim, must be used.
A sample of the results presented to the user is shown in Figure 2. The appearance of the UI was designed to be similar in appearance to Monaco, using the same font style and colours.

Figure 2: A sample display presented to the user after script completion.

4 Discussion

The Script has been in Clinical use since early 2023. The feedback from users has been very positive. There was some initial skepticism but is now considered to be generally popular since it has been demonstrated to catch defects early and therefore save time.
A key advantage of moving the checks upstream in the workflow from Physics Check to before the plan approval stage is that any defects are discovered early in the process

and are therefore easier to remedy. Running the Script is repeated at Physics Check to confirm the result.

There are limitations in how Elekta have implemented the API. Not all elements of Monaco are exposed. For example the contents of the Dose Reference Points tab is not available in Monaco 6.1.1. It is expected that more items will become available in future releases. Also, unlike other TPS's with a Scripting Interface, it is not a simple task to iterate through the entire patient database.

The choice of UI automation as the Scripting architecture results in the Script execution times being long. However it offers enormous potential for workflow automation. Combined with an auto-contouring tool then a Script which offers 'single-click' plan creation is only a small number of lines of code. Upon open a patient and running the script a plan can be automatically created, optimized, calculated and saved with relative ease.

We are currently investigating further developments using the API including planning creation automation and plan complexity analysis.

5 Conclusion

We have used the Monaco Scripting API to automate a number of elements of the Physics Check process. The Script is executed prior to the plan being approved by the RO therefore defects are detected early in the planning process. It has been released to Clinical use and has led to significant time saving and workflow efficiency improvement. We expect to further develop the Script with future releases of Monaco as the number of Monaco items exposed through the API increases.

Optimization in radiotherapy integrating a multidisciplinary framework with GEANT4

E. Sergi[1], M. Severgnini[2], E Rigoni[1], and F. Longo[3]

[1]ESTECO S.p.A., Trieste, Italy
[2]SC Fisica Sanitaria director, Azienda sanitaria universitaria Giuliano Isontina, Trieste, Italy
[3]Department of Physics, University of Trieste and INFN Sezione di Trieste, Trieste, Italy

Abstract Radiotherapy is a complex treatment that requires optimization to deliver the right dose to the target while minimizing side effects.
This work [1] proposes a novel approach that combines optimization techniques from other engineering fields with Monte Carlo (MC) simulations to optimize RT plans. The coupling of GEANT4, an MC simulation toolkit with modeFRONTIER, an optimization platform, enabled the efficient identification of optimal linac parameters for tumor treatment.
This approach demonstrated improved accuracy and personalized treatment plans for RT, offering promising advancements in medical physics.

1 Introduction

Radiotherapy treatment (RT) is one of the most important cancer treatment; mathematically, it is a constrained multi-objective optimization problem that involves balancing 10-30 highly correlated criteria and constraints.
The solution to the problem appears simple, but achieving the best radiotherapy plan for a specific patient is a difficult challenge.
No single optimal solution can be found in multi-objective optimization problems, but we can find a set of different trade-offs, mathematically equivalent, called *Pareto optimal solutions*. A perfect multi-objective solution is impossible; a reasonable solution is to investigate a set of equally good compromises.
When dealing with dose calculation, different algorithms are available. Monte-Carlo algorithms are more accurate than conventional techniques: they reduce uncertainty in dose calculation and the uncertainty in overall delivered dose.
Our aim is to introduce the knowledge of optimization techniques from other engineering fields into medical physics to optimize a treatment plan.

2 Materials and Methods

GEANT4 [2] and modeFRONTIER have both been used to optimize a RT plan. modeFRONTIER is an integration platform for multi-objective and multi-disciplinary optimization, developed by ESTECO [3], an independent Italian software company highly specialized in numerical optimization, simulation process, and data management. It provides a seamless coupling with third-party engineering tools, enables the automation of the design process simulation, and facilitates analytic decision-making.
GEANT4 is an open-source Monte Carlo simulation toolkit for precise dose calculation.
We created models for patient and medical linac based on the `medical_linac` example models [4] in the GEANT4 distribution, an IAEA compliant phase space calculation, and two different phantoms, water and lung tissue with an ellipsoidal tumor.
The optimization was executed using the `MOGA-II` [5] algorithm. The objective was to find the linac parameters that would maximize the tumor dose while minimizing the related side effects.

3 Results

The coupling of modeFRONTIER and GEANT4 worked well; we were able to find the optimal configuration with a reduced number of initial particles in the MC simulation.
We analyzed two different problems.
The first problem is to retrieve a given photon momentum distribution in a phase space by changing the flattening filter geometry. The "real" and "optimal" geometries are then compared in terms of Percentage Depth Dose (PDD) and lateral dose profile using gamma index 3%/3mm analysis. A water phantom is used for this study, with 100 sensitive cubic elements for each direction. This is a single objective problem, as the goal is to find the flattening filter geometry that produces the best PDD and lateral dose profile.

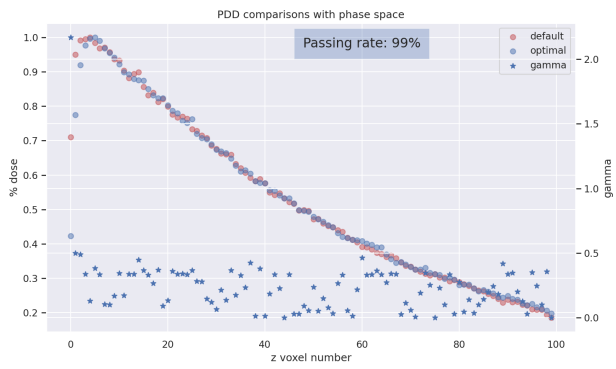

Figure 1: First problem: "real" and "optimal" geometries comparisons using γ-index 3%/3mm analysis for photon beam PDD.

The second problem involves a convex solid tumor inside lungs undergoing a simplified version of radiotherapy using four different gantry positions. The treatment is delivered all at once, without any dose fractionation. No ICRU (International Commission on Radiation Units and Measurements) volumes or dose constraints are defined. The problem is formulated as a two-objective optimization problem, with the objectives being to maximize tumor dose and minimize total dose to healthy lung tissue.
By utilizing a simplified TPS model, we retrieved the best configurations for tumor treatment. `MOGA-II` explored an area in the objective space not accessible in the initial designs. It also found a homogeneous Pareto front, with optimal designs distributed throughout the whole region.

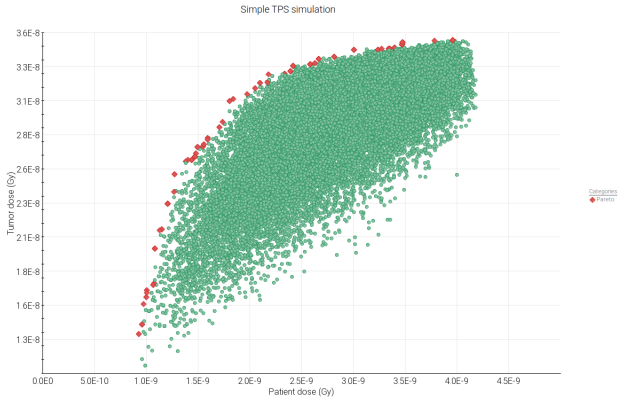

Figure 2: Optimization problem results with a well defined Pareto front (non-dominated results).

4 Conclusions

Medical physics benefits from the expertise in optimization derived from other engineering fields. Our procedure can be applied to optimize some linac components, such as the electron source.
RT plans benefit from the usage of MC algorithms, indeed they are more accurate than the conventional techniques and are suitable for a personalized treatment plan.
With its state-of-the-art algorithms for optimization, sensitivity analysis, and uncertainty quantification, modeFRONTIER is also a helpful tool for managing uncertainties in radiotherapy.

5 Forthcoming Research

To further enhance the efficiency and accuracy of the proposed radiotherapy optimization approach, the following research directions are planned:

- *Parallelization of* GEANT4: Leverage the parallel computing capabilities of GEANT4 to significantly reduce the computational time required for simulations, enabling the optimization of complex radiotherapy treatment plans more effectively.
- *Integration of GDML and DICOM*: Employ the GDML (Geometry Description Markup Language) and DICOM (Digital Imaging and Communications in Medicine) formats to seamlessly integrate linac and patient descriptions into the optimization framework. This will simplify the model setup and improve the accuracy of dose calculations.
- *Incorporating ICRU volumes and dose constraints*: Define the geometrical extent of ICRU volumes, representing organs at risk, and incorporate dose constraints into the optimization algorithm. This will ensure that the optimized treatment plan minimizes the risk of side effects to healthy tissues.
- *Investigating uncertainty quantification and robust optimization*: Address the issue of uncertainties in patient data and modeling assumptions by incorporating uncertainty quantification techniques into the optimization process. Additionally, explore robust optimization methods that can handle uncertainties and provide reliable solutions even in the presence of model imperfections.

These research endeavors aim to further advance the application of optimization techniques in radiotherapy, leading to more personalized, effective, and safe treatment plans.

Abstract Radiation therapy plan optimization is a time consuming and very complex process, and may not always result in an ultimate optimal solution. It is difficult to uniformly define what kind of plan is a high-quality plan when multiple complex standards need to be balanced. Manual plan evaluation is generally time-consuming and subjective according to reviewers' experiences, preferences as well as consideration of patient characteristics. We proposed an individualized automatic and objective plan evaluation method based on multiple-organ individually objective optimization (MIO). The proposed plan evaluation method is possible without manual intervention and captures overall plan quality using a plan scoring system. The scoring system is constructed based on the achievable dose limit for relevant OARs. In double-blind comparative experiments, the consistency between the results of the manual evaluation (standard practice) and the automatic plan evaluation system was 0.963, indicating its feasibility and efficacy. The proposed mechanism significantly reduces manual review time, the automatic plan evaluation MIO takes an average of 33 seconds, and the evaluation process takes an average of 17 seconds.

1 Introduction

Radiotherapy is one of the main treatments for cancer[1]. The effectiveness of radiotherapy depends on the quality of the treatment plan. A higher target dose ensures the tumor control probability(TCP), and limiting the normal tissue dose within a tolerated range is the key to reducing the normal tissue complications probability(NTCP).

However, plan optimization is a very complex process, and there often does not exist a unique optimal solution[2, 3]. It is difficult to uniformly define what kind of plan is a high-quality plan when multiple complex standards need to be balanced. Manual plan evaluation is generally time-consuming and subjective according to reviewers' experiences, preferences, and complicated clinical situations.

For different patients tumor geometry and location result in large variations of achievable organs-at-risk(OAR) dosimetry in the radiotherapy treatment planning process. This greatly increases the difficulty of plan optimization because we have no way of knowing whether the currently selected dose is optimal.

In recent years, many studies have conducted dose prediction based on images[4–6]. However, deep learning models based on retrospective data often have poor generalization, and it is difficult to collect huge data for training due to the preciousness and scarcity of clinical data.

We proposed an individualized automatic and objective plan evaluation method based on multiple-organ individually objective optimization (MIO). The proposed plan evaluation method is possible without manual intervention and was summarized to form a plan scoring system based on the achievable dose limit for relevant OARs.

2 Materials and Methods

Individualized plan evaluation uses MIO to obtain each patient's unique OAR distribution lower-bound. For each plan, beam angles, prescription doses, and structures were kept the same for all planners. In the initial phase, target structures were optimized to achieve the desirable prescription dose using V95 for the targets without consideration of any OAR. Then, each OAR, as well as the target, was added to the optimization process to generate a single-objective OAR plan. The optimization process stop until the target V95 no longer met the prescription objective

Compared to traditional fluence map optimization (FMO)[7, 8], the proposed method considers a single OAR at a time in each optimization process. The optimization function can be described as follows:

$$f = \sum_{n=1}^{N} p_n^T f_n^T + p^{OAR} f^{OAR} \tag{1}$$

Whre f_n^T is the objective function for the nth target volume, and p_n^T is the weight for that target. Similarly, f^{OAR} is the OAR to be optimized, and p^{OAR} is the corresponding penalty factor. This process was repeated for all OARs resulting in optimal dose distribution for each OAR. The difference in the fluence map of MIO results for two OARs is shown in Figure 1.

The OAR score is defined as the ratio of the area between the OAR DVH curve of the reference (clinical) plan and the DVH curve obtained from the single-objective plan. The weighted average of OAR scores (OAR_S) were calculated as the weighted sum.. The weights were determined by the MIO results. The target dose was scored using the Homogeneity Index score (HI_S), maximum dose score (MAX_S), and

[+] The authors contributed equally to this work.
[*] Authors to whom correspondence should be addressed.

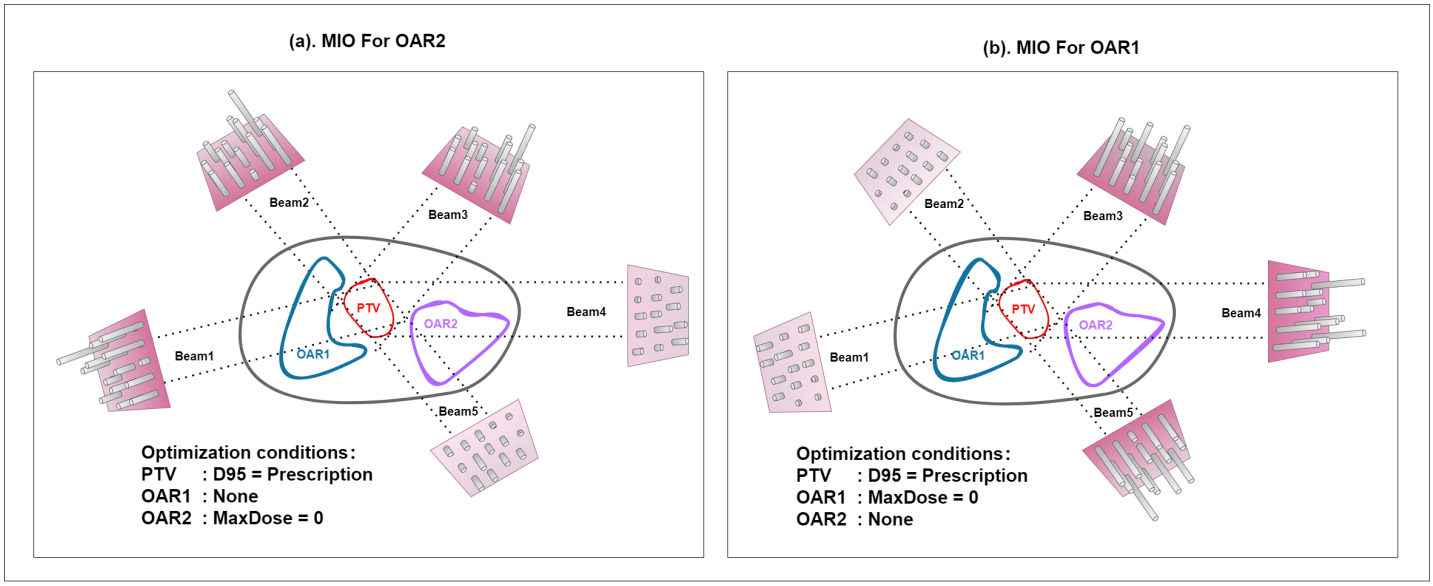

Figure 1: Difference in fluence map of MIO results for two OARs. The difference of the fluence map of the MIO plans when different OARs when included in the optimization process. If the beam passes through the optimized OAR, the fluence map will approach zero, which makes the surrounding dose larger, and the currently optimized OAR reaches the lowest dose.

minimum dose score (MIN_S). The final plan score was calculated as the average of the OAR_S for normal organs, and HI_S, MAX_S, and MIN_S for targets.

We evaluated the effectiveness of the algorithm through a set of head and neck cases. A double-blind comparison was designed. For the same patient, we asked three planners to generate three plans. These plans were evaluated by an expert oncology and ranked into the high-quality plans from low-quality plans. These plans were also evaluated by the MIO. The individual evaluation program did not include any knowledge of human evaluation results. The results of automatic evaluation were compared with the manual evaluation results.

3 Results

Figure 2 visualizes the MIO score results for two example patients. Longitudinal comparison of three plans from three planners in two patients. Differences in dose distribution may occur between different patients due to differences in the size and location of the target volume. Therefore, the MIO results of different patients must be different. This is the most important individualized index, and these differences can be included, in the OAR volume, target volume, and the positional relationship between OAR and target distinction. Finally, provides specific personalized quantitative indicators.

In a double-blind comparative experiment, the consistency between the results of the manual evaluation and the results of the automatic evaluation was 0.963. Most of the plan evaluation results were consistent with manual judgment, but manual evaluation of each plan took at least a few minutes to a few hours. However, the automatic plan evaluation MIO takes an average of 33 seconds, and the evaluation process takes an average of 17 seconds. It should be noted that only one MIO is required for N planned N assessments of one patient.

4 Discussion

We proposed an automatic plan evaluation method based on MIO, which can quickly and automatically score different plans. This algorithm can solve the problem of traditional manual evaluation being time-consuming and lacking objective standards and also allows the automatic evaluation of the merits of the plan in the automatic planning process. A scoring system consistent with experts can lead to higher-quality automated plans.

Although deep learning has developed rapidly in recent years, it still has many limitations, such as the need for huge data for training and poor personalization. In comparison, the method we proposed overcomes these shortcomings, but the application speed of the algorithm is slow. It is still slightly slower, and the advantages of both should be combined in the future.

5 Conclusion

The proposed plan evaluation method, based on multiple-organ individually objective OAR optimization, provided an objective, quantitative, and automated plan evaluation mechanism, which could greatly improve the quality and consistency of IMRT plans; streamline plan evaluation and evaluation efficiency in treatment planning workflow, and guide for planners to achieve optimal cancer treatment.

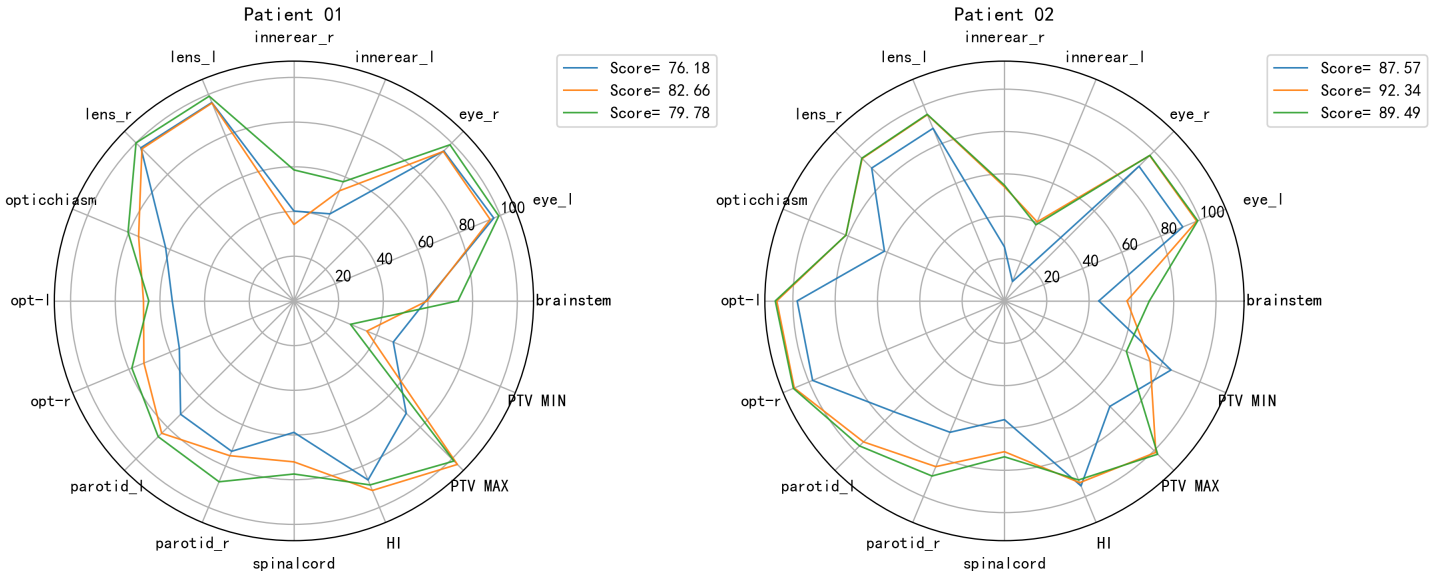

Figure 2: MIO results for each OAR in nine typical patients.

Dynamic Collimator Rotation Treatment Plan Optimization for O-Ring Treatment Systems

Michael K Fix, Werner Volken, Daniel Frei, Silvan Mueller, Gian Guyer, Daniel Schmidhalter, and Peter Manser

Division of Medical Radiation Physics and Department of Radiation Oncology, Inselspital,
Bern University Hospital, and University of Bern, Bern, Switzerland

Abstract In intensity modulated radiotherapy (IMRT) and volumetric modulated arc therapy (VMAT) static collimator angles are used per field or arc. While dynamic collimator rotation during beam on was investigated for C-arm linear accelerators, this was not investigated for O-ring ETHOS/Halcyon treatment systems. This work aims in the development of an optimization framework for treatment plans with dynamic collimator rotation during beam on for ETHOS/Halcyon systems. A previously developed in-house hybrid direct aperture optimization algorithm was first extended with a Monte Carlo (MC) model of the ETHOS/Halcyon treatment head including the double stack multi leaf collimator to calculate MC beamlet dose distributions and second with options for dynamic collimator rotation optimization for IMRT and VMAT. The framework was tested for a clinically motivated case showing improved dose sparing for organs at risk using dynamic collimator angle rotation compared with static collimator angle treatment plans, while the target coverage was the same.

1 Introduction

Currently, intensity modulated radiotherapy (IMRT) and volumetric modulated arc therapy (VMAT) are well-established state-of-the-art treatment techniques in radiotherapy [1,2]. More recently, there is an increasing interest in exploiting additional degrees of freedom in radiotherapy treatment planning to further improve treatment plan quality [3]. There is a variety of these techniques investigated ranging from using multiple arcs at different static table angles to dynamic trajectory radiotherapy (DTRT) using simultaneous dynamic gantry, table and collimator rotation during beam on leading to promising results in terms of treatment plan improvements [3–6]. While dynamic collimator rotation as a degree of freedom for dynamic collimator radiotherapy was investigated for C-arm linear accelerators, this was not yet investigated for O-ring ETHOS or Halcyon treatment systems.

Previously, we developed an in-house optimization framework within a treatment planning process to generate deliverable DTRT treatment plans for C-arm linear accelerators [7]. This framework consists of a hybrid direct aperture optimization (HDAO) algorithm, which combines a column generation algorithm with simulated annealing and is based on Monte Carlo (MC) generated beamlet dose distributions used to determine the aperture shape along with the Monitor Unit (MU) weight. However, this HDAO cannot be directly applied to ETHOS/Halcyon treatment systems, as those system consists of a different beam defining system including a unique double stack multi leaf collimator (MLC).

The aim of this work is the development of an optimization framework for VMAT and IMRT treatment plans with dynamic collimator rotation for ETHOS/Halcyon treatment systems to improve treatment plan quality compared to plans with static collimator rotation angels. For this purpose, first a MC model for an ETHOS/Halcyon treatment system was implemented and commissioned for an ETHOS unit to be used to generate MC beamlet dose distributions for the HDAO. Second, the HDAO algorithm was extended in order to handle the double stack MLC and the dynamic collimator rotation in the optimization. Finally, the developed framework was tested for a clinically motivated head and neck case.

2 Materials and Methods

In a first part of this work, an MC model of the beam defining system for an ETHOS/Halcyon treatment system consisting of the target, the primary collimator, the monitor chamber, the secondary collimator, the double-stack MLC and the leaf box cover as illustrated in Figure 1 was implemented into our in-house developed Swiss Monte Carlo Plan (SMCP) [8] following the information provided by the vendor (Varian, a Siemens Healthineers Company).

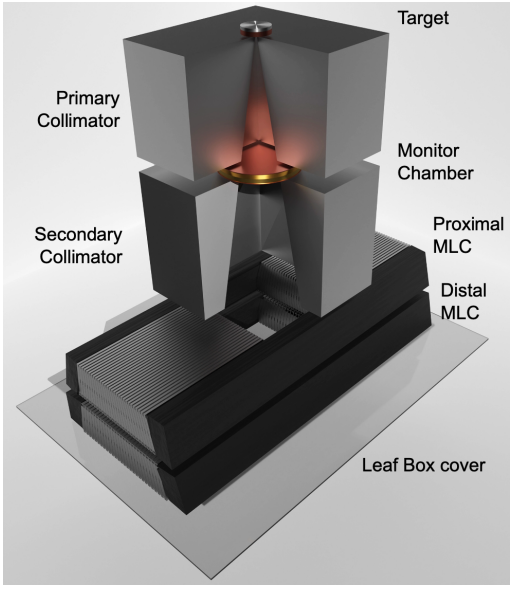

Figure 1: Illustration of the beam defining components for the ETHOS/Halcyon treatment system as implemented in the SMCP.

For the commissioning of the model, the energy and the lateral fluence distribution of the initial electron beam impinging on the target were tuned to match measured dose distributions. For this purpose, depth dose curves and lateral dose profiles in five depths ranging from 1.3 cm to 15 cm

were measured for square MLC shaped field sizes ranging from 1 x 1 cm^2 to 28 x 28 cm^2 at a source to surface distance (SSD) of 100 cm in units of cGy/MU on an ETHOS treatment system. For the validation the analogous set of dose distributions at an SSD of 90 cm were measured and compared with the corresponding calculated dose distributions using the commissioned MC model.

The implemented MC model was used in our HDAO algorithm. However, this HDAO so far is not able to handle the double stack MLC of an ETHOS/Halcyon system. This double stack ETHOS/Halcyon MLC consists of a proximal part with 29 leaf pairs and a distal part with 28 leaf pairs. In the following these are referred to as the physical MLC leaves. The width for each individual physical MLC leaf is 1 cm in the isocenter plane. The positions of the physical 57 MLC leaf pairs can be described by a set of 2 x 57 numbers. In general, the combination of two field shapes individually defined by the proximal and the distal MLC parts can be described with 56 so-called pseudo-MLC leaf pairs with a width of 0.5 cm in the isocenter plane, i.e. any combination of proximal and distal MLC leaf patterns (physical aperture) can be represented unambiguously by a pseudo leaf pair pattern (pseudo aperture). An example of such a conversion from a physical to a pseudo aperture is illustrated in Figure 2.

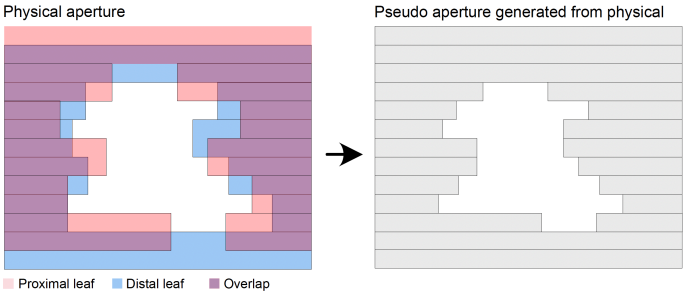

Figure 2: Illustration of the conversion from physical leaf positions to pseudo leaf positions. The graphics on the left shows the combination of a proximal and a distal MLC leaf pattern (physical aperture), while the graphics on the right-hand side shows its representation using the pseudo-MLC leaves (pseudo aperture).

Consequently, 56 x 56 beamlets with a size of 0.5 x 0.5 cm^2 each were generated using the commissioned MC model and serve as a base for the beamlet dose calculation resulting in the dose influence matrix applied during optimization. During the HDAO, the optimization algorithm keeps track of two sets of numbers representing the physical aperture (2 x 57 numbers) as well as the pseudo aperture (2 x 56 numbers). Both sets are always synchronized to guarantee that beamlet selection based on pseudo apertures is in compliance with the corresponding physical apertures.

In addition, the HDAO was extended to include the dynamic collimator rotation angle in the treatment planning process with different approaches for IMRT and VMAT.

In the case of IMRT, a set of 12 equi-angular beam directions are provided as input for the HDAO. This setup corresponds to our standard IMRT setup template of the ETHOS planning system. The number of apertures was limited to a total of 100, based on previous investigations with the HDAO. Next, beamlet dose distributions per beam directions were calculated for different collimator angles. This was done for a set of discrete collimator angles {-80°, -60°, -40°, -20, 0°, 20°, 40°, 60°, 80°} referred to as *'optimized collimator angle'* method (*oca*) leading to an increased search space of promising apertures for each beam direction. This newly developed method was compared with using a static static collimator angle of 10° for all apertures and all beam directions referred to as *'static collimator angle'* method (*sca*).

In the case of VMAT, the *oca* method would allow large collimator angle rotation changes between adjacent control points resulting in excessive collimator movement. In addition, this would also need an enormous amount of beamlet dose calculations. Thus, an approach was implemented in which the gantry-collimator path is predefined and provided as input to the HDAO. For this purpose, we implemented a '*predefined collimator angle*' method (*pca*). In this *pca* method a A* path finding algorithm is applied with a maximum gradient of 4°/5° (collimator/gantry) to a gantry-collimator whitespace area map to find the gantry-collimator path that maximally reduce the whitespace area. For this map, first the area between the PTV structure is extended by an isotropic margin of 0.5 cm. Then, the conformal MLC opening (whitespace area) is determined as a function of the gantry and collimator rotation angle settings leading to a two-dimensional gantry-collimator map. The resulting path was then passed to the HDAO for optimization.

Finally, this developed HDAO framework was tested for a clinically motived head and neck case and treatment plans for a 12 field IMRT and a two full arc VMAT technique with and without dynamic collimator rotation were generated. For the optimization the objectives for the intensity modulation optimization were based on those used for the clinically delivered treatment plan. The optimization utilizing a static or a dynamic collimator rotation used the same set and values for the objectives and priorities as well as the same objective function. For all these comparisons the normalization was such that 95% von the PTV ($D_{95\%}$) receives the prescribed dose. Resulting treatment plan qualities using either a dynamic collimator angle or a static collimator angle were compared by means of the dose distributions and dose volume histogram parameters.

3 Results

An MC model of the ETHOS/Halcyon radiotherapy beam was successfully implemented in the SMCP. The commissioned MC model for an ETHOS treatment system agreed in general within 1% (global) or 1 mm for all depth dose curves and lateral dose profiles in units of cGy/MU for

all square field sizes considered in the validation. Figure 3 shows some exemplary results of this validation.

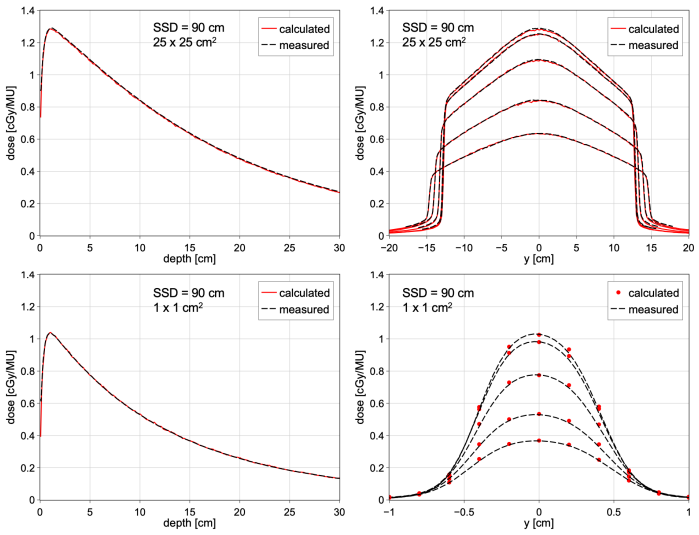

Figure 3: Absolute dose comparisons of calculated dose distributions with the corresponding measured dose distributions in homogeneous water at an SSD = 90 cm for field sizes of 25 x 25 cm² (top row) and 1 x 1 cm² (bottom row) using the commissioned MC model. Depth dose curves and lateral dose profiles in five depths (1.3 cm, 2 cm, 5 cm, 10 cm, 15 cm) of water in y-direction are shown for each field size. The agreement is generally within 1% or 1 mm.

In Figure 4 the results for the clinically motivated head and neck case are presented utilizing the 12 field IMRT technique.

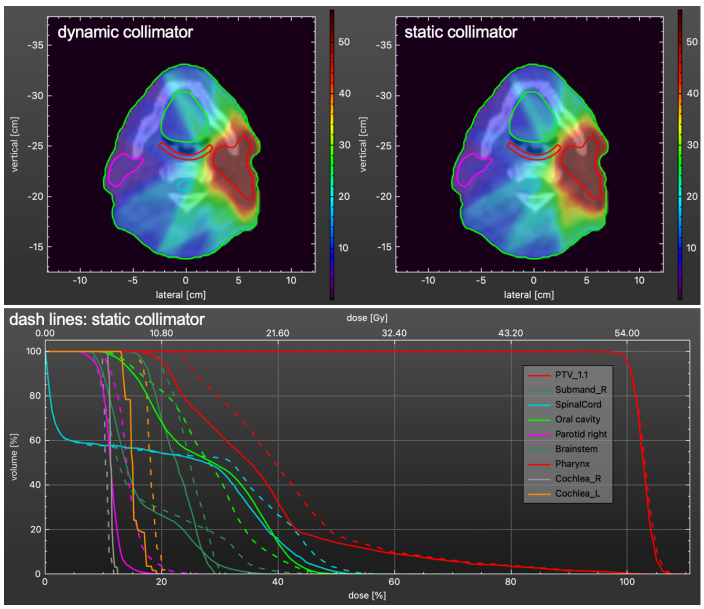

Figure 4: Dose distributions and DVH comparisons for IMRT treatment plans using either the dynamic collimator angle approach or the static collimator angle approach for a clinically motivated head and neck case. For this comparison the 'optimized collimator angle' (oca) method was used to determine the collimator angle for each individual aperture of the beam directions.

Both treatment plans result in a very similar target coverage, while improved dose distributions were achieved for the treatment plan with dynamic collimator rotation when compared with the treatment plan using a static collimator rotation of 10° for all apertures.

The results for the two-arc VMAT treatment plans are illustrated in Figure 5. Again, the target coverage was very similar for the two treatment techniques. For the plan using a static collimator rotation angle per arc the values of 9° and 29° were used (one value per arc). The OAR sparing improvements for the treatment plan including the dynamic collimator rotation vs. the treatment plan using static collimator angles was less pronounced for the VMAT technique when compared with the IMRT delivery modality. The dose volume histogram parameters for the comparisons are summarized in Table 1.

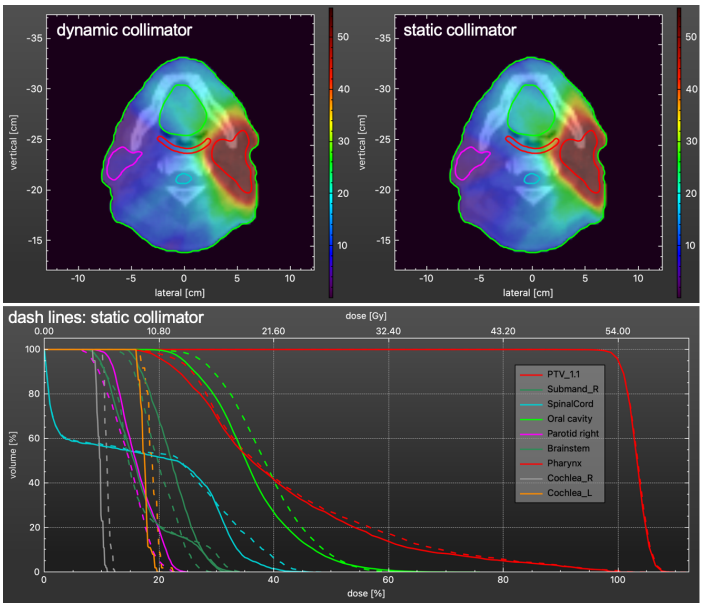

Figure 5: Dose distributions and DVH comparisons for the two-arcs VMAT treatment plans using either the dynamic collimator angle approach or the static collimator angle approach for the clinically motivated head and neck case already shown in Figure 4. For this comparison the predefined collimator angle (pca) method was utilized, where the A algorithm was used to determine the collimator rotation angle as a function of the gantry angle.*

4 Discussion

We have successfully implemented and commissioned an MC model of the beam defining components of an ETHOS treatment system. The validated MC model is now available within the SMCP for accurate dose calculation. The level of accuracy is similar to the results shown by Laakkonen et al. [9]. In addition, this model was successfully integrated in our in-house optimization framework, which was extended to allow optimization for an ETHOS/Halcyon system including the double stack MLC as well as for dynamic collimator angle rotation.

While the results of this work focused on an ETHOS treatment system, the developed framework is also suitable for Halcyon treatment systems, as the beam defining system components are the same. However, the MC model would have to be commissioned for the different systems.

The currently used clinical ETHOS/Halcyon treatment systems do not allow dynamic collimator rotation during beam on for VMAT. However, the generated treatment plans take into account all mechanical and dosimetric influencing parameters and contributions in the final dose calculation and consequently such VMAT treatment plans can be considered as potentially deliverable treatment plans. Although in this study only one clinically motivated case was investigated, the results demonstrate potential for dynamic collimator rotation treatment plans to improve OAR sparing when compared with treatment plans using static collimator rotation angles. However, a larger number of clinically motivated cases has to be investigated to determine the potential dosimetric benefit of dynamic collimator rotation radiotherapy for ETHOS/Halcyon treatment systems.

5 Conclusion

We have successfully implemented an optimization framework for dynamic collimator rotation optimization for ETHOS/Halcyon treatment systems based on MC generated beamlet dose distributions. The results suggest potential benefits for OAR sparing when dynamic collimator rotation is applied. The framework can now be used to investigate the potential benefit of dynamic collimator radiotherapy for a larger patient cohort.

Abstract Radiotherapy for head and neck cancers is challenging, due to the complexity and heterogeneity of the anatomy. In order to improve this process and make it more accurate, MRI-based planning has been assessed in several studies. However, compared to brain and prostate, head and neck area may have anatomical and tumor type variations from one patient to another, leading to limitations in the existing solutions, mostly based on learning. To address this issue, a direct physical-based method is proposed in this work, to obtain quantitative information which would lead to a more personalized treatment, through the proton density. This method uses an ultra-short echo time sequence to measure the MR signal almost without any decay. The dosimetry on a reference CT and on the synthetic CT generated with this method were compared for nasopharyngeal, oropharyngeal, laryngeal and oral cavity squamous cell carcinoma patients treated by radiotherapy. A 125 HU MAE was obtained between the CT and the sCT and a dose difference of 1.5% of the 70 Gy prescription dose was computed as a mean of the Planning Tumor Volumes median dose. The maximum dose for several organs at risk showed a percentage of dose difference below 1% for 5 out of 6 organs. The mean global gamma index for a 3%/3mm criteria was 0.21 ± 0.05 with a 93 ± 2.8% gamma pass rate. The proton density method allowed to generate a synthetic CT with only one dedicated sequence, giving results comparable to the CT-based dosimetry and to the literature for head and neck radiotherapy.

1 Introduction

MRI's excellent contrast between soft tissues is of great interest for radiotherapy planning to improve normal tissue and tumor delineation. But for dose calculation electronic density is needed and is not directly accessible with MRI, unlike CT. This difficulty can be overcome with a synthetic CT created from MR images. Several methods allow to build a synthetic CT: statistical methods such as atlas registration[1] and deep learning[2] and physical-based methods derived from quantitative MRI such as density assignment[3] and proton density measurement[4].

The electronic density depends on tissue characteristics such as the mass stopping power and the mass attenuation coefficient, so these two values have been evaluated for different atoms and for a wide range of energies. It has been found[4] that these values have a different evolution for the hydrogen atom than the other atoms for energies between 0.2 and 8 MeV[4]. Quantitative MRI can provide hydrogen concentration through the measurement of proton density, which is possible with specific sequences.

This work presents a pilot study aiming to build a synthetic CT using MRI proton density measurement with a patient-specific workflow.

2 Materials and Methods

In order to compare a routine CT-based dosimetry with a dosimetry based on our proton density method, a protocol has been conducted on 26 patients with head and neck cancers, to be treated by radiotherapy at the comprehensive cancer Center Léon Bérard in Lyon.

This protocol is divided into two parts, a conventional injected CT scan performed on a Siemens Somatom Go Sim (Siemens Healthineers, Erlangen, Germany) and a 11 minutes MRI acquisition protocol performed on a Siemens 3T Magnetom Vida (Siemens Healthineers, Erlangen, Germany). The MRI protocol includes 7 minutes of clinical routine sequences for the contouring of the tumor volumes (manual) and the organs at risk (automatic) and an additional 4 minutes for the sequence dedicated to the sCT generation for the treatment planning.

To reduce large variations in the position of the patient, the same immobilization material was used for CT, MRI and radiotherapy: a five-points fixation mask and a radiotherapy table. To have high quality MR images and to fit with the radiotherapy table and mask, a flexible anterior Body coil and the lower part of a Head coil were used.

Proton density (PD) was obtain from the magnetization at the origin M_0, considering a very low T1 and a low flip angle, we can write:

$$M_0 = G \circ PD$$

with G the coils sensitivity maps[5] and ° the Hadamard product.

To determine the best algorithm for coil sensitivity correction, we used a calibration phantom (SpinSafety-T04, Rennes, France). The phantom tubes were filled with a D_2O dilution in water for which we knew the theoretical proton density and were able to draw linear regression with the pixel's intensities. In-line (Prescan and B1-filter) and post-processing (SENSE, ESPIRiT and adaptive reconstruction) algorithms were compared. The sequence used to obtain the magnetization at the origin, is an ultra-short echo time (30 µs) spiralVIBE. These regressions also showed the linear relationship between proton density and MRI pixels intensity. Before any other steps, the MR images were registered on the CT with a Matlab® algorithm.

The CT and the sCT were compared with the computation of the Mean Absolute Error (MAE). CT images-based dose calculation and distribution were computed using MONACO software (Elekta®) using a set of dose-volume constraints for the organs at risk (OAR) and Planning Target Volumes (PTV). Dose were then recomputed on

sCT images, keeping the same deliverable segments. The results are compared with several indexes.

Firstly, the dose-volume histograms were extracted for each patient, the range, mean, standard deviation and percentage of dose difference were computed for several OARs and for PTVs. Comparisons between sCT and CT-based dosimetry were done using a Bland Altman analysis.

Secondly, the gamma index[6] was computed. It evaluates the distance difference and the dose difference for each point of the reference dose planning on the CT with the sCT-based planning. A dose difference criterion δD (DD in %) and a distance to agreement criterion δr (DTA in mm) are set for the evaluation of the gamma index, in this work 1%/1mm, 2%/2mm and 3%/3mm gamma indexes were evaluated. The gamma pass rate $\gamma_{\%}$ was also computed and evaluates the percentage of gamma indexes bellow 1.

3 Results

From the images of 26 patients, the images of two patients were not considerate, because the MRI acquisition box was misplaced leading to a part of the face truncated.

The algorithm with the best results for the coil sensitivity correction was the Prescan, Figure 1 shows the correspondent linear regression, compared to SENSE algorithm.

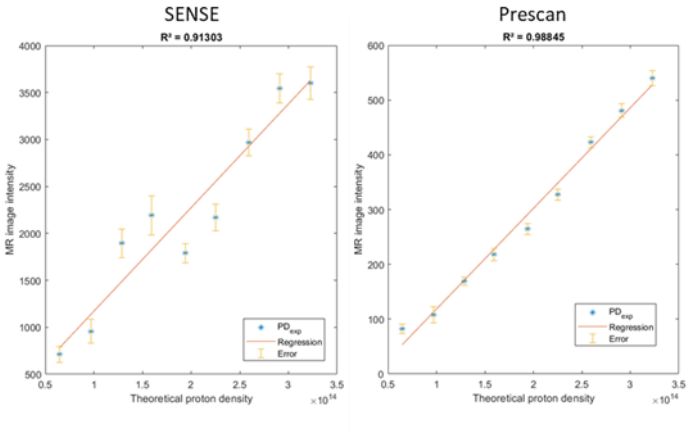

Figure 1: linear regression between MRI intensity corrected with SENSE algorithm (left) and Prescan algorithm (right) and theoretical proton density for 9 tubes with different D_2O concentrations

The mean MAE between the sCT and CT of the patients was 124.6 HU ± 23.1 HU which, as a percentage of the total range, is equivalent to 4.2 % ± 0.8 %. An example of a sCT is given Figure 2, as a comparison to the CT.

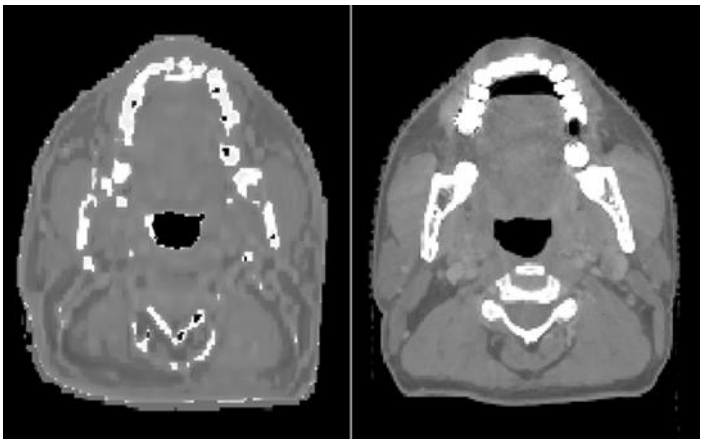

Figure 2: sCT (left) and CT (right) of a cavum patient

The dose-volume histograms showed a low difference between CT and sCT-based dosimetry. For the PTV 54.25 Gy (i.e the PTV for which the prescribed dose was 54.25 Gy) and the PTV 70 Gy, the difference between the mean median dose were 0.2 ± 0.2 Gy (0.57% of the prescription dose 70 Gy) and 0.0 ± 0.5 Gy respectively. For the OARs, the results are presented in the Table 1 as the CT-based dosimetry mean minus the sCT-based dosimetry mean of the maximum dose.

Organs	Brainstem	Spinal cord	Monolateral parotid
Dose difference in Gy (% of 70 Gy)	0,46 (0,66 %)	0,38 (0,54 %)	0,86 (1,23 %)

Table 1: absolute dose difference between CT-based mean of the maximum dose and sCT-based mean of the maximum dose for several OARs.

The Bland Altman analysis showed a low bias for most of the OARs (between -0.39 and 0.4 Gy) and for the PTVs (-0.04 Gy), the organ POST showed a bias of 1 Gy. The variability was very low for the tumor volumes (3.17 %), it was higher for some organs at risk such as the brainstem (20.94 %), the lips (22.70 %) and POST (21.05 %).

The mean gamma indexes were below 1 for every DD/DTA criteria, and with low standard deviation. For the tightest criteria of 1%/mm, the mean gamma was 0.21 ± 0.052, with a gamma pass rate of 93 ± 2.8 %. The maximum gamma pass rate was 98 ± 1.5 % for the 3%/3mm criterion. An example of a gamma index map is given Figure 3 for each criterion.

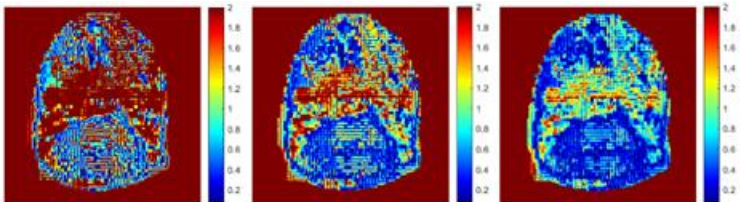

Figure 3: gamma indexes map for 1%/1mm (left), 2%/2mm (middle) and 3%/3mm (right) criteria, for a larynx patient

4 Discussion

The UTE spiralVIBE sequence is a sequence with a relatively short acquisition duration (4 minutes), allowing to generate a synthetic CT only based on the intensities of the pixels, the short echo time also allows to capture the signal short-T2 tissues such as the bone. This sequence is also less sensitive to B_1 field inhomogeneities. On the other hand, being a Work In Progress, this sequence may not be available yet on all systems and machines. Also, the fat inside the bone and the body fat proton densities are hard to dissociate, leading to low HUs for the bone, which is visible on the sCT. A solution would be to use a different regression model for bone or to use another MRI sequence to obtain a T2* map on which the segmentation would be easier.

The dosimetry demonstrated that the results were consistent, the differences with the reference CT-based dosimetry being very low. The MAE obtained are similar to the literature for the head and neck region, Guerreiro et al.[7] report a MAE of 116.3 HU with a multi-atlas-based method and Johansson et al.[8] report a MAE of 137 HU with a voxel-based method.

The acquisition protocol overall duration was only 11 minutes with the clinical sequences and the UTE sequence, which is compatible with the clinic. The use of the immobilization mask reduces the registration shifts, and allows to obtain images in the treatment position. The sCT generation is a fast process, even with the registration step, it required around 3 minutes per patient. The drawbacks of the radiotherapy immobilization material are the difficulty to fit within usual head and neck coils and the need for an adapted MR coil set up and patient elevation. In our specific case, the table on which the patient was laid was elevated of about 5cm to fit within the lower part of the head coil. The loss of quality compared to a regular fit inside the coil, due to the distance from the coil, was widely offset by the presence of shim coils. They improve a lot the quality of the images, compared to the use of a body coil only. Due to the immobilization mask, the patient cannot move too much but they still can swallow which induces artifacts. The spiraled acquisition of the UTE sequence in known to be less sensitive to this type of artifacts.

The dosimetry results obtained with our method can be compared to the literature. First, the dose difference of the PTVs is close to the results of the literature, with a mean of 0.27% of the prescription dose for the density assignment method of Karotki et al.[9]. For the OARs, Kazemifar et al.[10] obtained a 1% dose difference for the maximum dose of the brainstem with a deep learning method, which is higher than the 0.6% we obtained.

Then, the gamma index also gave results comparable to the literature. Guerreiro et al.[7] obtained 94 % ± 0.7 % and 98.4 % ± 0.3 % gamma pass rates for a 2%/2mm and a 3%/3mm criterion respectively, our gamma pass rates were very similar, with a slightly higher standard deviation. Johansson et al.[8] obtained a 94 % gamma pass rate for a 1%/1mm criterion, which is also very close to our 93 %.

MRI planning allowed equivalent dosimetry with to the CT and was not much longer for the patients. For this work, the organs at risk contouring was done automatically on CT images, as commonly used in the routine. The possibility to contour these volumes on an MR image could allow an MRI only workflow, which would be much easier for the patients: an 11 minutes protocol would be enough for volumes contouring and dose planning, avoiding extra-radiations for the patients and allowing more accuracy in delineation[11,12] for the medical staff. Compared to deep learning methods which cannot adapt to every anatomy, this work could also open the gate for a more personalized treatment with sequences allowing dose painting for example. The drawback is the pixels intensity-based segmentation, it is more sensitive to classes overlapping especially between bone and air.

5 Conclusion

This study shows that proton density quantification with MRI allows to build a synthetic CT with a direct method. The dosimetry shows results comparable to other methods in the literature and to the reference CT-based dosimetry. This method is a first step towards personalized treatment that could be adapted to other anatomical area with the proper UTE sequence and a coil setup compatible with the immobilization material.

Abstract Breast cancer is widely treated with IOeRT, (Intra Operative electron RadioTherapy) in the case of partial breast irradiation treatments, yielding satisfactory results; one of the main limitations of this technique is the absence of a Treatment Planning System (TPS) that could significantly enhance proper coverage of the target volume during irradiation. In this contribution, we present an IOeRT TPS that has been developed using an in-house fast GPU-based Monte Carlo (MC), and an ultrasound imaging system. This tool aims to provide the best irradiation strategy (electron beam energy, applicator position, and bevel angle) within the limited amount of time allowed to keep the patient on the surgery bed, and facilitate the optimization of dose prescription and delivery to the target volume. The study was conducted in-silico, exploiting MC simulations of a breast cancer treatment. Ultrasound-based input was employed to compute absorbed dose maps for different irradiation strategies, and a quantitative comparison was performed analysing dose maps and the corresponding Dose Volume Histograms. The system demonstrated the capability to identify the optimal strategy within a few minutes. The overall computation time was found to be compatible with clinical implementation. The impact of ultra high dose rate irradiations on a possible additional sparing of the Organs at Risk was modelled as well, when optimizing the biological dose, integrating the benefits from minimally invasive surgery techniques.This long awaited planning tool will boost the treatment efficacy, overcoming the limits identified within the clinical trials carried out so far, and pave the way for the first implementation of the FLASH effect into the IOeRT clinical workflow.

1 Introduction

Among the different cancer treatment modalities available today, Intra Operative Radiation Therapy, delivered with electrons (IOeRT), allows to achieve a very high dose conformity to the target volume maximising the local treatment efficacy and thus decreasing the risk of local cancer recurrence [1]. It is a technique that involves precise delivery of a dose of ionizing radiation directly to the tumour bed after the surgical tumor mass removal. Currently, IOeRT irradiations are mainly performed by a dedicated mobile linear accelerator close to the surgical beds, with energies between 4 and 12 MeV. Within IOeRT, whenever needed and possible, temporary beam modifiers, such as the Radio Protection Disc (RPD) used for the treatment of Partial Beast Irradiation (PBI), are used to protect the underlying healthy tissues during the irradiation and the beam is passively collimated by means of a PMMA hollow tube (called applicator).

Despite the technique high efficacy, the planning technology has not evolved since its conception, being outdated in comparison to the current state of the art in other external Radiotherapy (RT) techniques and therefore slowing down the IOeRT clinical potential.

The absence of proper imaging, treatment planning and applicator docking or position checking is directly related to the underdosage or geographical miss of the Clinical Target Volume (CTV) as reported by the ELIOT trial [2]. The treatment planning, up to now, was not foreseen in the clinical workflow for two main fundamental reasons: the lack of 'post-surgery' imaging, needed to allow for the dose calculation, and the time needed to produce dose maps that are needed in the optimisation process. Such planning tool becomes additionally interesting in view of the recent experimental evidence of Organs At Risk (OARs) sparing in presence of treatments delivered at Ultra High Dose Rates (UHDR) (>40 Gy/s, FLASH effect [3]). The use of monoenergetic high-intensity pulses of electrons (needed to deliver as fast as possible the whole dose) makes IOeRT the current best candidate for the first clinical implementation of the FLASH effect. In this contribution we explored the possibility to use a fast GPU-based Monte Carlo (MC) software, FRED (Fast paRticle thErapy Dose evaluator) [4–6], in combination with an ultrasound (US) imaging input (PTV) to perform a full IOeRT treatment plan optimisation in the limited amount of time allowed by the surgical procedure. The case of PBI was taken as an example for this feasibility study, as it represents the largest fraction of patients treated with IOeRT nowadays.

The obtained results are discussed also in view of the possible applications to FLASH therapy.

2 Materials and Method

The IOeRT planning involves rapid intra-operative imaging and fast MC simulations, performed with FRED, for the computation of absorbed dose maps when exploring various irradiation configurations.
Within FRED, particles interactions are described with the precision level available in bleeding edge MC tools used for medical physics applications, with the advantage of reducing the simulation time up to a factor 1000. In this way, it is possible to performa full MC plan recalculation in few minutes on a single GPU (Graphics Processing Unit) cards.
S.I.T. Sordina IORT Technologies S.p.A., provided an intra-operative imaging acquired using 3D real-time ultrasound system, resulting in the clinical workflow illustrated in Fig. 1. This system is able to provide the positions of the tissues, post-tumor resection and of the protective disk whenever implanted.
The acquired imaging is the starting block for the exploration of different treatment configurations, such as beam energies, applicator positions, dimensions, and bevel angles. MC simulations are then compared for target volume coverage and optimal OARs sparing through dose maps and Dose Volume Histograms (DVHs) analysis.
As patient related US imaging data are not yet available, to simulate real conditions, we used a CT image of an anthropomorphic RANDO male phantom with a silicone breast prosthetic application, modified to account for the expected US resolution. All the voxels belonging to the patient were assigned to the water Hounsfield unit (HU) while outside the patient the air HU was used. For the plan optimisation and evaluation it is crucial to have a proper definition of the PTV and of the OARs. We defined the ROIs for the study of the PBI optimisation according to the clinical workflow characteristic of these treatments. According to the US expected spatial resolution, Regions Of Interest (ROIs) with a depth of no more than 7 cm (equal to the US optimal viewing) have been defined. The PTV was approximated as a spherical region with a mean radius of 2.5 cm, positioned at a depth of 1.3 cm from the skin, while the RPD as a cylinder (radius of 3.9 cm) of a 3 mm thick layer of PTFE (HU=950), followed by 3 mm of stainless steel (HU=10000). The skin was introduced with a thickness of 5 mm. The Pectoral Muscle was structured as a cylindrical-shaped region (1.2 cm thick, mean radius of 3.9 cm) positioned just after the RPD, while the breast region was defined to encompass all the tissues between the Skin and the RPD surrounding the PTV. All these ROIs are shown in Fig.2, panel A. In addition to that, also the surgical breach and the tissue deformation needed to insert the applicator were accounted for in the geometrical setup.

3 Results

The best plan selection involved computing DVHs, as well as maximum and mean dose values absorbed by each ROI. Based on the dimension, position and thickness of the PTV considered in our simulations and on the clinical experience of PBI treatments, we defined 8, 10 and 12 MeV as options to be investigated for the beam energy and applicator diameters ranging from 40 to 70 mm to simulate the possibility to consider a small or large safety margin. An automated applicator position scan around the surgical breach was also performed to determine the best applicator position. For this study, the dose map calculation and optimization assumed a dose prescription of 20 Gy to 90% of the PTV according to the standard IOeRT procedure. Fig.2, panel B and C, shows the dose map distributions obtained for the energy and applicator dimensions scan. All the dose maps were normalized to fulfill the dose prescription. As can be observed looking at the dose maps, 8 MeV beam does not provide an adequate PTV coverage defined as, here and in the following, the fraction of the PTV volume that receives 95% of the goal dose (D95). The values of D95 for 8, 10 and 12 MeV are respectively 92%, 96% and 97%. At 12 MeV a significant increase of the dose absorbed by the pectoral muscle region is observed, while at 10 MeV a proper PTV coverage is obtained, with a reduced dose to the pectoral muscle. These results have been confirmed by the DVHs and mean/max dose values analysis. For what concern the applicator diameter scan the D95 values obtained are 93%, 96%, 96% and 97% for the 40, 50, 60 and 70 mm respectively demonstrating that when using a 40 mm internal diameter, it is not possible to achieve the required PTV coverage, as the applicator diameter is approximately equal to the PTV mean radius. The dose absorbed by the Breast region and to the skin grows as expected when using larger applicators, accordingly with the geometry and positioning of the ROIs. Finally, the optimisation of the applicator position was also performed by means of an automated scan around the surgical breach. The beam centre, impinging on the phantom along the y direction, was moved from the centred position in a (x,z) grid with 10 mm steps. Fig. 2, panel D, shows the dose maps in Gy units for the centered and worst-case plans.
Once all the MC simulations are performed the best plan selection algorithm implements the calculation of mean and maximum doses in the OARs and returns the optimal configuration ensuring the proper PTV coverage while lowering the dose to the OARs as much as possible. For what concerns the optimization process time we were capable to optimize the treatment in few seconds, and thus in a time window completely compatible with the few minutes available during the surgery. As an example, the simulation time needed to explore three different beam energies and, for each energy, nine different applicator positions, is $\sim$ 1 minute. PBI treatment aligns well with FLASH effect requirements, being compatible with the high-dose rates used to deliver

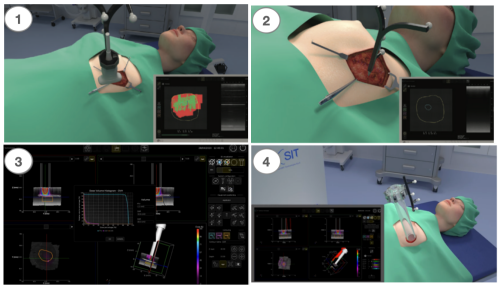

Figure 1: IOeRT procedure: after the tumor mass removal and positioning of the RPD disc (1) by using a US probe, which is referenced in the space by means of an optical tracker, the surgeon acquires US images; (2) the surgeon identifies the surface to be treated and regions of interest (PTV and OARs); (3) different treatment configurations are explored looking for the optimal one. The whole process takes less than 2 minutes. Image guided docking happens at the end and the dose is recalculated in the final position (4).

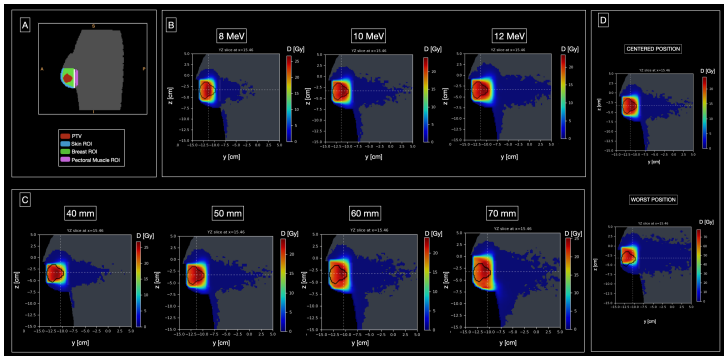

Figure 2: Panel A: Visualisation of anthropomorphic phantom CT. The CT has voxels dimension of 0.2 cm in all the directions. The ROIs are also highlighted. Panel B and C: Plan comparison with different beam energies and applicator dimensions. Dose maps obtained from the IOeRT plan with an 8, 10 and 12 MeV electron beam collimated by a 50 mm diameter applicator are reported on panel B, whereas the ones obtained by changing only the applicator dimension (ranging from 40 to 70 mm) with a fixed beam energy equal to 10 MeV are shown on panel C. Panel D: Dose maps comparison between the centered (upper) and worst-case (bottom) plans, performed with 10 MeV electron beam collimated by 50 mm applicator.

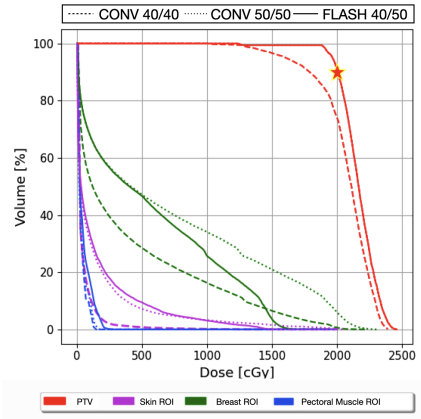

Figure 3: Biological effective dose volume histograms for the PTV (red), Breast ROI (green), Pectoral Muscle ROI (blue) and Skin (purple) for the simulations performed in conventional regime (CONV) with a 40 mm (dashed line, 40/40) and 50 mm (dotted line, 50/50) surgical breach and applicator dimension, and in FLASH regime with a small surgical breach 40 mm, and a larger applicator diameter 50 mm (solid line, 40/50).

20 Gy in a single fraction. In our study we implemented the FLASH-modifying factor (FMF) model that was introduced by Bohlen et al. in [7]. On the basis of the results obtained from mini-pig skin treatments [8] we selected values of FMF^{min} and D_{Th} equal to 0.65 and 6 Gy, respectively. According to the dose absorbed by each voxel in the full treatment, an FMF re-weighed dose has been calculated to evaluate the FLASH potential. In IOeRT the FLASH effect can be exploited to combine a minimally invasive surgery technique, which avoids postoperative complications, with the very precise delivery of IOeRT irradiation, thus reducing the probability of tumor local recurrence. Fig.3 shows the comparison of 3 different DVHs: the dashed line represents the "current clinical workflow", i.e. a small applicator exactly matching the surgical breach of 40 mm (CONV 40/40), the dotted line represents the correct PTV treatment, i.e. large surgical breach and thus applicator dimension equal to 50 mm (CONV 50/50), while the solid line describes the FLASH IOeRT minimally invasive treatment, i.e. small surgical breach (40 mm) and a larger applicator dimension equal to 50 mm (FLASH 40/50). As can be seen, all the OARs, in FLASH configuration, have reduced effective doses, when compared to the conventional one, with the additional advantages of minimizing the surgery impact without causing significant damage on the patient skin thanks to the FLASH effect sparing, while ensuring the correct PTV coverage.

4 Discussion

The obtained results confirm the feasibility of the developed tool for an online treatment optimization. Absorbed dose maps can be quickly generated and studied selecting a plan that achieves the necessary PTV coverage while minimizing OAR doses. The results emphasize the importance of an automated procedure to identify the best treatment position. Through image-guided docking of the applicator, ensuring the treatment alignment with the plan, the impact of geographical misses will be reduced, enhancing the treatment efficacy. This approach can also be used to explore and assess the advantage of delivering beams at ultrahigh dose rates, leveraging the FLASH effect finally helping in avoiding invasive surgical procedures while maintaining treatment efficacy [9].

5 Conclusion

The ability to compute and optimize an IOeRT plan in a few minutes using a single GPU card has been demonstrated. This streamlines the preparation, recording, and verification of IOeRT procedures, bringing it closer to the level used for external beam RT. IOeRT plan optimization addresses a current limitation of the technique, specifically the risk of underdosage of the PTV due to the restricted surgical breach when RPD is necessary. The proposed clinical workflow enables radiation oncologists and breast surgeons to assess the actual need for RPD insertion, evaluate dose distribution, and ensure PTV coverage by adjusting the applicator diameter. The software tools also support exploring the potential of UHDR irradiations. For PBI, the FLASH effect presents an opportunity to redefine the workflow for IOeRT treatments, allowing direct applicator placement on part of the patient's skin or eliminating the need for RPD and finally improving the patient's quality of life.

Abstract Radiotherapy (RT) is crucial for treating deep-seated tumors; options include photon RT, particle therapy (PT) with protons or heavier ions like ^{12}C. Very High Energy Electron (VHEE) beams (100-200 MeV) were proposed for deep tumors, but clinical implementation faced challenges. Recent advancements in compact C-band electron acceleration and FLASH radiotherapy have renewed the interest in this option. FLASH, demonstrated in pre-clinical studies, reduces healthy tissue toxicity while maintaining cancer-killing efficacy whenever the dose rates are radically increased (~40 Gy/s) with respect to current conventional radiotherapy (~0.1 Gy/s or less). This study explores the potential impact of electron beam therapy for the treatment of deep-seated tumors focusing on the stereotactic treatment of pancreatic cancer. Results are presented and compared against conventional radiotherapy performed with a VMAT approach.

1 Introduction

Electrons of 'very' high energy (VHEE, E above 50 MeV) have been already explored in the past for the treatment of deep-seated tumors [1]. The obtained results showed a tumour coverage and Organs At Risk (OARs) toxicities comparable to advanced proton (PT) or photon radiotherapy (RT) only at the cost of implementing multiple fields and/or very high electron energies (above 100 MeV). Challenges in deploying such beams, combined with limited therapeutic gains, hindered the technique development. Recent advancements in compact, high-gradient electron acceleration and experimental evidence of organ sparing in Ultra-High Dose Rate (UHDR) irradiation modalities, the so-called "FLASH" regime, have the potential to reshape this landscape. Compact accelerators, a few meters long, could deliver required electron energies for stereotactic treatments, capitalizing on FLASH's organ-sparing benefits. This potential could allow the simplification of irradiation geometry, also reducing the number of fields needed for patient treatment.

2 Materials and Methods

To evaluate the potential of VHEE treatments implementing the FLASH effect, we compare the results obtained optimizing treatment plans with electrons of energy below 130 MeV in the case of three patients (PT1, PT2, PT3) affected by a pancreatic cancer, with the plans delivered using photons according to Volumetric Modulated Arc Therapy (VMAT) technique, implemented using 2-3 arcs. All the patients underwent a treatment with very high dose per fraction, the so-called Stereotactic Body Radiation Therapy (SBRT) condition, with 6 Gy or more absorbed dose per session delivered in target lesions that are of few centimeters in size. Treatments, carried out at the Campus Biomedico Hospital, were carried out using a TrueBeam Linear Accelerator, produced by Varian.

In this study, we employed FRED [2] Monte Carlo (MC) software, specifically designed for GPU (Graphics Processing Unit) operation. This facilitated the simulation of absorbed dose in electron treatment with full MC accuracy, all accomplished within a few hours.

FRED requires CT information, the electron's origin points relative to CT position, and beam specifications (energy, lateral and angular spread) at the production point to calculate the absorbed dose maps. An Intensity-Modulated Radiation Therapy (IMRT) -like configuration was employed to plan the geometry of the electron fields, in order to define their number and their respective directions.

In our simulations, we adopted beam characteristics consistent with conventional electron linear accelerator solutions with energies exceeding 50 MeV [3]. The beam exhibits a transverse size of ~ mm and a divergence of ~mrad. Furthermore, we limited our analysis to the relatively low energy range of VHEE, specifically, 70 to 130 MeV; we assumed an active scanning-like beam delivery technology [4], akin to the approach presently employed in proton therapy (PT).

Once absorbed dose maps were obtained with the full MC simulation approach for each PB in the treatment plan, the fluence of each PB was optimized to ensure coverage of the required Planning Target Volume (PTV) while sparing organs at risk (OAR). Specifically, an optimization was implemented to do this by minimizing a voxel-based objective function, defined below:

$$\chi^2 = \sum_{i \epsilon PTV} \omega_i \frac{(d_i - D_{PTV})^2}{d_i^2} + \sum_{i \epsilon OAR} \omega_i \frac{(d_i - D_{OAR})^2}{d_i^2} g(d_i - D_{OAR})$$

where the weights are adjusted euristically to match the dosimetric constraints.

To reduce the computational cost, we adopted two different minimization methods: Steepest Descent, as observed in [5] and Quantum Simulated Annealing [6].In the end, the evaluation of the FLASH effect potential was performed after the treatment optimization. Once the dose maps were obtained, the Flash Modifying Factor (FMF) [6] was introduced to assess the reduction in radiation-induced toxicity.

3 Results

To evaluate and compare the effectiveness of VHEE treatment plans, we used the common tools available and used in radiotherapy: Dose Volume Histograms (DVHs) and isodose maps have been produced to verify the dosimetric constraints on OAR and PTV and finally ensure the clinical acceptability of the plan.
The first patient (PT1) underwent homogeneous stereotactic treatment, requiring a V(95%) coverage greater than 95% for plan approval, accepting "hot spots" below 106% of the prescribed dose. In contrast, the second and third patients (PT2, PT3) received heterogeneous stereotactic treatment, accepting target coverage of 100% of the dose in at least 95% of the volume and allowing "hot spots" up to 126%, promoting the destruction of tumor cells through necrosis. The common goal for all three cases was to achieve adequate PTV coverage while simultaneously limiting the dose to various OARs, including the duodenum, as shown in Figures 1 and 2 and referring to Table 1, we can observe the dosimetric constraints.
From these preliminary studies, it has been observed that VHEEs are competitive compared to advanced techniques such as VMAT, demonstrating good target coverage while limiting the dose to various organs at risk, such as the duodenum. The selection of these three cases was not random, as they involved the use of high doses over a few sessions, making them suitable candidates for studying the effectiveness of the FLASH effect in sparing various OARs. Specifically, by selecting parameters to trigger the FLASH effect, modeled according to [7], an increase in OARs dose sparing, especially in the duodenum, has been be observed. Such outcome has the clear potential of enhancing the treatment's efficacy leading to either a dose escalation in the PTV or improving the duodenum sparing.

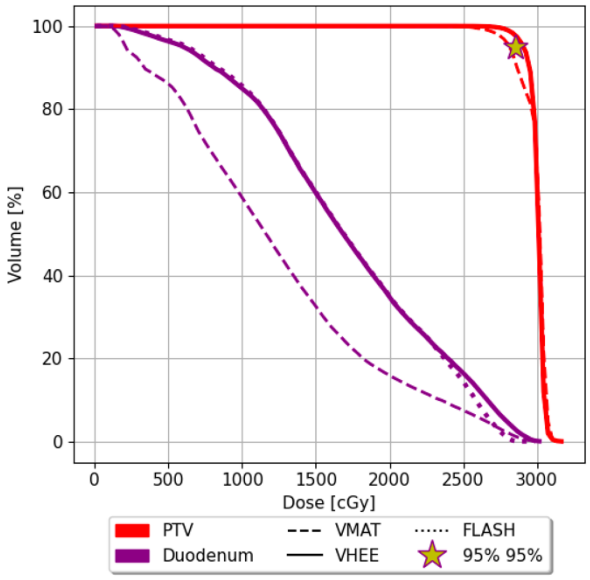

Figure 1. Analyzing the variations in PT1 treatment utilizing VMAT and VHEE, both with and without the FLASH effect. Specifically, we are studying the FLASH effect as outlined in [7], employing a D_{th} of 22.5 Gy and an FMF_{min} of 0.8. The reduction in dosage, facilitated by the implementation of the FLASH effect, is depicted by the dotted curve.

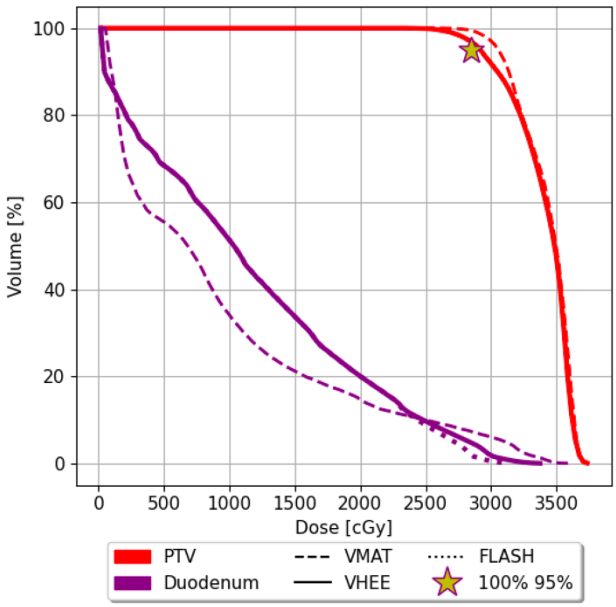

Figure 2. Analyzing the variations in PT2 treatment utilizing VMAT and VHEE, both with and without the FLASH effect. Specifically, we are studying the FLASH effect as outlined in [7], employing a D_{th} of 22.5 Gy and an FMF_{min} of 0.8. The reduction in dosage, facilitated by the implementation of the FLASH effect, is depicted by the dotted curve.

PT1				
Organ	Dosimetric constraint	VMAT	VHEE	FLASH
PTV	$V_{95\%}$>95%	97 %	98 %	98 %
Duodenum	D_{max}<33 Gy	30 Gy	30 Gy	28 Gy
PT2				
Organ	Dosimetric constraint	VMAT	VHEE	FLASH
PTV	$V_{100\%}$>95%	96%	95%	95%
Duodenum	D_{max}<35 Gy	33 Gy	34 Gy	31 Gy

Table 1. Dosimetric endpoints are either expressed as the fraction of volume (V_{XX}) that absorbs a given amount of dose (XX Gy), or as the value of the maximum absorbed dose (and the associated volume) and are shown for all the OARs considered in a pancreas treatment.

4 Discussion

The results presented in this contribution demonstrate how it could be possible to obtain clinically acceptable plans with VHEE with a limited number of fields and energy below 130 MeV. The implemented field configurations, including the number of fields and directions, are similar to those used in techniques such as IMRT. The analyzed cases were treated with stereotactic radiotherapy techniques, which are widely used today to treat small-sized lesions, utilizing high doses over a few treatment sessions. Given these considerations, it was observed that by using only VHEE, without introducing the FLASH effect, it is possible to achieve adequate coverage of the PTV while simultaneously limiting the dose to surrounding OARs. This makes the treatment plan competitive compared to plans obtained with commonly used techniques such as VMAT.
Furthermore, since the analyzed cases are excellent candidates for studying the effectiveness of the FLASH effect, it was noted that delivering the plan using UHDRs allows for better sparing of OARs compared to photons. In all three cases, it was crucial to preserve the OAR closest to the PTV, the duodenum, as an excess dose to it would have rendered the treatment ineffective. As observed, implementing the FLASH effect resulted in a lower dose to the duodenum whose size will finally depend on the experimental characterization of the FLASH effect sparing that is currently ongoing in a worldwide campaign.

5 Conclusion

The research here-before reported, explores the treatment of pancreatic tumors using VHEE. A comparison between VHEEs and VMAT plans revealed that VHEE can achieve performance levels similar to state-of-the-art irradiation techniques, even without additional sparing from the FLASH effect.
The findings suggest that, assuming reasonable conditions for triggering the FLASH effect, it could be effectively utilized to mitigate the impact on OARs surrounding the PTV. Across all cases, the FLASH effect demonstrated a clear potential for significantly improving the therapeutic window of External Beam Radiation Therapy (EBRT) treatments of pancreatic cancer.

Abstract Since its first presentation at ICCR 2013, the Reconstruction Toolkit (RTK) has become a reference software for tomographic reconstruction of computed tomography (CT) images. In this period, RTK has become a remote module of the Insight Toolkit (ITK), thus enabling improved continuous integration and Python wrapping. New functionalities have also been developed, including simulation of Forbild phantoms, handling of cylindrical detectors and new iterative reconstruction algorithms for conventional CT, single photon emission CT (SPECT), four-dimensional (4D) CT and spectral CT. This article summarizes these eleven years of developments to today's RTK v2.

1 Introduction

The Reconstruction Toolkit (RTK) was first presented at the XVII-th international conference on the use of computers in radiotherapy (ICCR 2013) in Melbourne, Australia [1]. Initially, RTK was an open-source and cross-platform software for fast circular cone-beam CT reconstruction based on the Insight Toolkit (ITK) [2], "an open-source, cross-platform library that provides developers with an extensive suite of software tools for image analysis" (https://www.itk.org). RTK has been and keeps being a tool for researchers working in radiotherapy and radiology as well as a sofware used by companies for their cone-beam CT scanners. This paper summarizes the new features of RTK which have been developed in the past eleven years.

2 Software design

2.1 ITK remote module

The change of major version number for RTK, from version 1 to version 2, was motivated by a complete refactoring of RTK's code to make it compatible with ITK's modular architecture. The architecture of each module is defined by the ITKModuleTemplate repository (https://github.com/InsightSoftwareConsortium/ITKModuleTemplate). ITK is split into several modules with a dependency graph. Core modules are distributed in the `Modules` directory of the main ITK source repository, https://github.com/InsightSoftwareConsortium/ITK, *external* modules can be manually added to an `Modules/External` directory of ITK source directory and *remote* modules are external modules which are described in the ITK source repository and which are automatically downloaded when activated. The description of remote modules is provided in a `CMake` text file in the `Modules/Remote` directory of ITK's main source repository. RTK's module file was added in February 2019 and it is since one of ITK's remote modules. From the user perspective, RTK compilation has to be activated during ITK compilation by turning on the CMake option `Module_RTK`.

2.2 CudaCommon module

More recently, in June 2022, the modular architecture of ITK has also enabled the extraction from RTK of the code to manage ITK images on the graphics processing unit (GPU) using the Compute Unified Device Architecture (CUDA, NVidia). The CudaCommon module, available at https://github.com/RTKConsortium/ITKCudaCommon, can now be used by all users without RTK even if it is still managed by the RTK consortium. The main feature of this module is to offer an `itk::CudaImage` class which inherits from `itk::Image`. An `itk::CudaImage` object has a GPU buffer, in addition to the inherited central processing unit (CPU) one, to or from which the image data is transferred depending on which processing unit is used for the calculation. The data transfer from one unit to the other is automatically managed by triggering a data synchronization when calling a class member which may modify the data buffer.

2.3 Continuous integration

RTK relies on *GitHub actions* for testing every change to the repository before integrating it to the `master` branch. To that end, ITK provides reusable GitHub Actions workflows in a dedicated repository https://github.com/InsightSoftwareConsortium/ITKRemoteModuleBuildTestPackageAction/. Compilation and testing are executed by Linux, Windows and MacOS runners provided by GitHub's infrastructure. For CUDA, the RTK consortium currently manages self-hosted Linux and Windows runners but RTK will switch to CUDA-enabled Github runners as soon as they are made available.

2.4 Python wrapping

ITK offers the infrastructure to wrap selected parts of remote modules for their use in Python software. Since ITK heavily relies on templates to be able to, e.g., manage images of any dimension using pixels of any type (int, float, etc.), the wrapping code specifies which image types are compiled for Python. A large part of the CudaCommon and RTK modules has been wrapped. The user can either compile the wrapping or download pre-compiled binaries distributed via the Python Package Index (PyPI, https://pypi.org/). Both CPU only and CPU+GPU packages of RTK are distributed. The distributed CUDA packages are wrapped for a specific CUDA version number which is appended to the package name. Currently, the distributed packages are `itk-rtk`, `itk-rtk-cuda116` and `itk-rtk-cuda121` and the latter depends on `itk-cudacommon-cuda116` and `itk-cudacommon-cuda121`. New versions of the packages are distributed after every release of ITK base packages to ensure compatibility. The last ITK version is v5.4.0 and the corresponding CudaCommon and RTK releases are v1.1 and v2.6, respectively.

3 New features in RTK v2

3.1 Forbild phantoms

Tomographic reconstruction is often evaluated on numerical phantoms which are described by simple geometric shapes (ellipsoids, cones, parallelepipeds, etc.). The most famous one is the Shepp-Logan phantom, made of ellipsoids only, which was already available in RTK v1. RTK has since implemented the use of a larger set of geometrical shapes described by the Forbild file format. A separate GitHub repository (https://github.com/RTKConsortium/Forbild) pre-process the original Forbild files using gcc's preprocessor (to apply `#include` and `#define` directives) and Python (to calculate mathematical expressions), thus producing a single file understandable by RTK. These files (currently `Abdomen`, `Thorax` and `Head`) can be input to RTK to compute projection and reference CT data, as used for example in [3] to evaluate several reconstruction algorithms. Figure 1 illustrates the Forbild head and thorax phantoms.

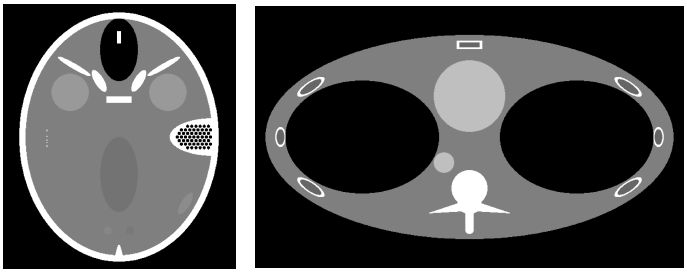

Figure 1: Central axial slice of the head (left) and thorax (right) Forbild phantom generated with RTK. Gray windows: $[0, 100]$ HU (left) and $[-100, 100]$ HU (right).

3.2 Cylindrical detector

RTK was initially developed for x-ray cone-beam CT with flat panel detectors which are commonly used in image-guided radiation therapy. Diagnostic CT scanners, used for acquiring treatment planning CT images, use cylindrical detectors with an axial axis (Figure 2). RTK is now capable of simulating and reconstructing projection data of cylindrical detectors, as illustrated in, e.g., [4].

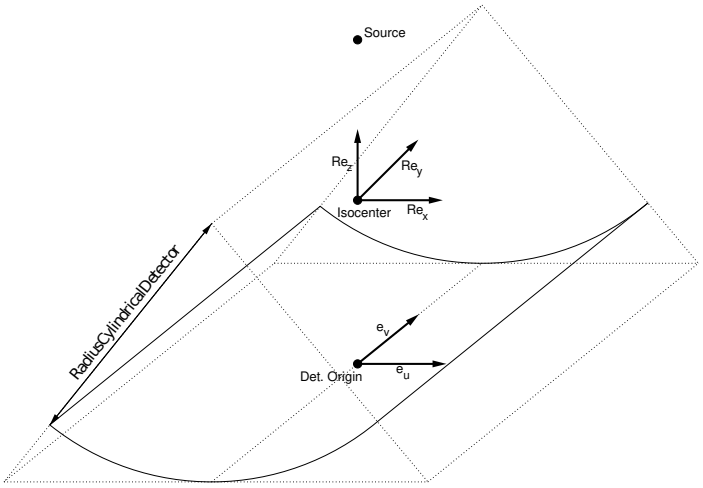

Figure 2: Schematic illustration of RTK's geometry with a cylindrical detector (from RTK's documentation, http://www.openrtk.org/Doxygen/DocGeo3D.html).

3.3 Iterative reconstruction

Several iterative reconstruction algorithms have been developed in RTK since v1. Those include conventional least square minimization with quadratic Tikhonov regularization using conjugate gradient minimization as well as less smooth regularizers, e.g., total variation, L1-norm of the image or L1-norm of the wavelet decomposition of the image. Several of these algorithms are also used by four-dimensional (4D) CT reconstruction algorithms to improve image quality, as illustrated in Figure 4.

3.4 Single photon emission CT (SPECT)

RTK has also been extended to handle projection data acquired with a SPECT scanner. New projectors (and adjoint backprojectors) have been implemented to model the patient attenuation (given a known attenuation map) and the resolution of the collimator [5]. For example, these projectors have been used to reconstruct respiration-correlated 4D SPECT images using ordered subset expectation maximization (OSEM) in [6]. Figure 3 shows sinograms of a sphere in the left lung of the Forbild thorax phantom without and with attenuation, where the attenuation map has been scaled such that the attenuation of water is $0.2\ \mathrm{cm}^{-1}$.

Figure 3: Parallel projections of a 1 cm sphere located at the center of the left lung of the Forbild thorax (Figure 1) without (left) and with (right) attenuation.

3.5 Four-dimensional CBCT

Four-dimensional (4D) CBCT has been a major axis of development of RTK since its debut. Early versions included filtered backprojection respiration-correlated 4D CBCT using the breathing signal extracted from the projections [7]. Several reconstruction algorithms have been developed since RTK v1 for reconstructing higher quality 4D CBCT images using iterative reconstruction techniques. The most advanced algorithms are the RecOnstructiOn using Spatial and TEmporal Regularization (ROOSTER) [8] and its motion-aware version [9]. The two algorithms alternate between conjugate gradient minimization and several constraints or regularizations: positivity, time-averaging outside a motion mask, 3D spatial total variation (TV) denoising and one-dimentional (1D) temporal TV denoising. The motion-aware version used a priori knowledge of breathing motion to improve the 1D TV denoising. Figure 4 shows coronal slices of several 4D CBCT images reconstructed with RTK.

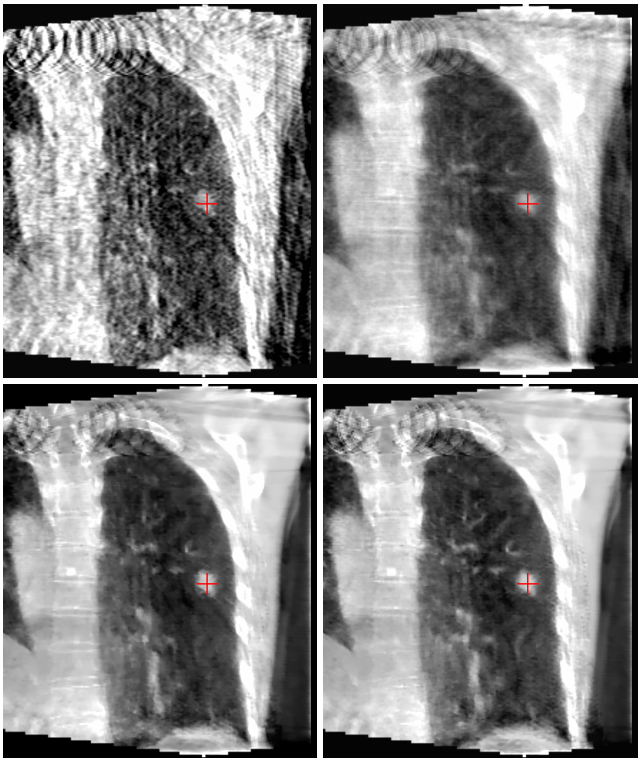

Figure 4: Coronal slice of the end-exhale CBCT frame of 4D CBCT images reconstructed with RTK from the same dataset, using filtered-backprojection (top left), unregularized conjugate gradient optimization (top right), ROOSTER [8] (bottom left) and MA-ROOSTER [9] (bottom right). Figure adapted from [9].

3.6 Spectral CT

Spectral CT is becoming increasingly popular in diagnostic CT. Dual-energy CT scanners are commercialized by all major vendors and scanners with photon counting detectors are also commercialized by some vendors. Spectral CT images can be processed in many ways. The first solution is to reconstruct each energy bin CT image and do image-based processing. However, the bin CT images will suffer from beam-hardening. An alternative is to process the acquisition in the projection domain if projection images are acquired with the same geometry, e.g. with a dual-layer detector or a photon counting detector. For example, material decomposition [10] can result in decomposed sinograms (Figure 5) and each sinogram can be reconstructed separately in material CT images using filtered backprojection or iterative algorithms.

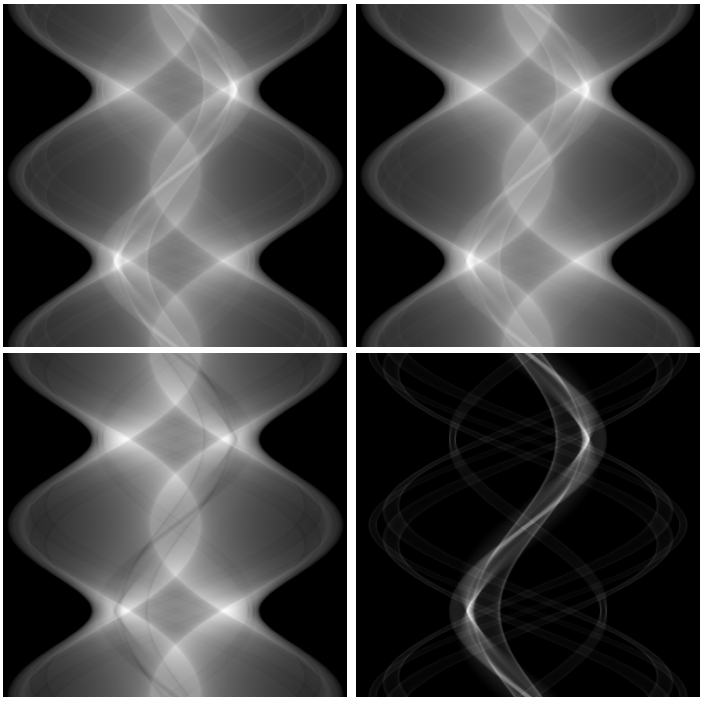

Figure 5: Log-transformed simulated X-ray projections of the Forbild thorax phantom (same slice as in Figure 1) at 80 kV (top left) and 120 kV (top right) and the corresponding water (bottom left) and bone (bottom right) sinograms of the material decomposition.

Alternatively, projection images can be decomposed and reconstructed jointly, in one-step. Such processing has a high computational cost but can significantly improve image quality, particularly if the number of energy bins of the scanner is larger than the number of sought material CT images. Two-step and one-step reconstruction algorithms have been implemented in RTK and evaluated on patient images obtained on a prototype photon counting scanner [11], as illustrated in Figure 6. Image quality improvement is a trade-off between spatial resolution and image noise can be improved depending on the selected regularization parameters.

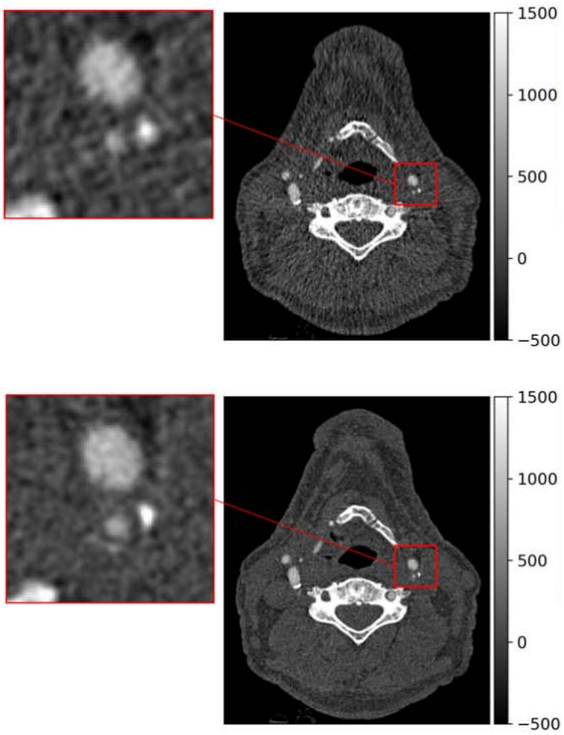

Figure 6: Virtual monoenergetic CT image at 40 keV obtained from RTK's two-step projection-based (top) and one-step (bottom) material decomposition of a prototype photon-counting CT angiography patient dataset. Figure adapted from [11].

4 Conclusion

Since its first public release in 2012 and its presentation at ICCR 2013, RTK has become a reference software for tomographic reconstruction of CT images. Thanks to funding from research projects and industrial partners, RTK keeps being improved and will remain an open-source research and development tool used and developed by an ever-growing international community.

Validation of an Open Source Contouring Tool

Haley Clark[1,2]

[2]Department of Physics and Astronomy, University of British Columbia, Vancouver, Canada

Abstract While radiotherapy increases in sophistication, and software complexity continues to grow, there remains a lack of validated open source software for routine radiotherapy tasks. This work presents a validation of the geometric accuracy, positional precision, and interoperability of the open source DICOMautomaton manual contouring subsystem. Using 2D and 3D contour arrangements, we demonstrate that DICOMautomaton is sufficiently accurate for radiotherapy purposes.

1 Introduction

The complexity of treatment planning systems (TPSs) continues to increase, with commercial proprietary TPSs now commonly supporting specialized use-cases including adaptive radiotherapy, multi-criteria optimization, and automated segmentation [1]. Despite escalating sophistication, manual contouring or manual contour refinement nevertheless remains a crucial step in the radiotherapy process, even for the state-of-the-art [2].

In contrast to commercial offerings, non-commercial open source TPSs as a whole tend to be more focused in scope and, for various reasons, do not report validation of the implementation. This is especially true for 'infrastructure' software, where scientific novelty is deprioritized and opportunities to report validation are limited. Compared with autosegmentation tooling, which has exploded in popularity in recent years [3], the number of robust, validated, and open source manual contouring tools are limited.

The aim of this work is to validate the manual contouring subsystem of the DICOMautomaton [4, 5] open source project. While the set of features provided by the contouring subsystem is modest, it is capable of providing high-quality contours; can be composed with other subsystems (e.g., image registration, surface mesh extraction, 3D constructive geometry, and dosimetric analysis); supports reading and writing of contours in standards-compliant formats; and is extensible. The DICOMautomaton contouring subsystem is designed to interoperate with, and complement, other software, thus providing a validated open source tool to complete a crucial step in the radiotherapy process.

2 Materials and Methods

For region-of-interest (ROI) contouring to be useful for radiotherapy planning or dosimetric analysis, the provided tools must be versatile enough to contour a wide range of tissue (c.f. optic nerves vs liver), and the resulting contours need to be both dimensionally accurate and precise.

DICOMautomaton contouring supports any planar image modality (e.g., CT, MR, PET, US). Images are backed by a volumetric image mask from which contours are extracted. The underlying mask resolution (and thus minimum supported contour feature size) is user configurable. Increasing mask resolution increases the time need to extract contours, so the user is encouraged to adjust resolution to accommodate the nature of the specific target(s). For this work, synthetic CT images with mask images comprising 512x512 pixels are used. All masks used isotropic voxels with width 0.5 mm.

Contouring brushes with 2D and 3D extent are supported. Brushes can be manually dragged across an image to draw/erase contours, and both straight and right-angle sweeps are supported. Brushes support 'dynamics' which cause a contour to grow or shrink while lingering, mimicking the dynamics of paint spray. Brush sizes can range in size/extent continuously. The ability to use the available contouring tools to produce geometrically accurate contours is measured. To simulate realistic conditions when manually contouring, brush dynamics are enabled, and a visual guide of the brush is provided.

Circular/spherical targets with radii ranging from 5-50 mm are created and evaluated for concentricity against ideal circles/spheres using orthogonal projection fitting. All fits were allowed 200 iterations to converge and were considered fully converged when a tolerance of 0.001 mm was reached. Radii and maximum radial deviations are assessed against the idealized target radii. Brush sweeps are performed for circular and spherical brushes with 10 mm radius along the cardinal directions and diagonally; radii are similarly assessed. Sweeps can be used to provide interpolation in 3D, but dedicated contour interpolation is also provided. The accuracy is confirmed by interpolating between two 2D circles on different image planes to produce a cylinder; the interpolated portion is compared to the manually contoured portions. This is done once with 30 mm radius and once with 10 mm radius.

2D boundary contours are extracted from masks using a *marching squares* algorithm [6]. By inverting this algorithm, resulting in a new algorithm which we refer to as '*receding squares*,' it is possible to convert between mask and contour representations bidirectionally. Relaxing the requirement for the conversion to be exact, it is possible to convert from contours to a mask with a single pass using an error-correcting algorithm as follows: (1) for each pixel ($v_{i,j}$) in an image, starting in the top-left corner, determine the position and intensity of the adjacent pixels to the left (v_{i-}

$_{i,j}$), top ($v_{i,j-1}$), and top-left diagonal ($v_{i-1,j-1}$); (2) for each contour, find the locations where contours intersect the line segments connecting $v_{i,j}$ to the left, top, and diagonal pixels; (3) assuming linear interpolation will be used for marching squares, and that the left, top, and diagonal pixel intensities are already fixed, determine three separate estimates of the $v_{i,j}$ pixel intensity which will exactly reproduce the contour intersections, (4) finally, take the median of all estimates to yield a final estimate for the $v_{i,j}$ pixel intensity. Note that various boundary conditions can be applied when pixels have no top, left, or top-left diagonal neighbours; contour orientation and overall can be selectively honoured by counting crossings and transitions; and the estimate can also be clamped to the mask intensity range (e.g., [0:1]).

Accuracy of the receding squares algorithm is characterized by manually generating a contour mask (a circle with 50 mm radius), performing marching squares to extract the contour, performing receding squares on the contour to recover the mask, extracting a contour from the recovered mask, and then comparing the two contours geometrically.

Positive and negative margins (i.e., expansions and contractions) are supported via extensible morphological operations [7]. Accuracy is confirmed by applying -0.5, 0.5, 1.5, 3, and 5 mm margins to a spherical region-of-interest (ROI) with 30 mm radius and comparing the radial change vs expected.

The primary export format is DICOM with RTSTRUCT modality. Because individual contour sizes can easily exceed format length restrictions, e.g., >65534 bytes for explicit value representation (VR) transfer syntax of the contour data 3006,0050 element, many clinical systems now default to an *implicit* VR transfer syntax. This imposes additional consistency constraints across implementations, which need to share a common dictionary of elements. Furthermore, consistency and alignment of the coordinates systems used by images and contours is critical for radiotherapy purposes. Therefore, interoperability with other implementations needs to be explicitly confirmed; we do so here by importing into the Varian Eclipse TPS (v18.0) and MIM Maestro (v7.2.10), confirming the DICOM file interpretation is consistent, and then confirming contour geometry. DCMTK [8] (v3.6.7) is used to provide additional verification that files are in accordance with the DICOM standard.

Finally, an 'undo-redo' buffer is provided which allows the user to quickly jump. The validity of this mechanism is confirmed by comparing checksums of the underlying masks.

3 Results

Contour geometrical accuracy measurements were made for 2D and 3D circles/spheres with nominal radii 5, 10, 15, 30, and 50 mm. All fits converged, and fitted radii for 2D and 3D brushes were all within 0.002 mm of expected. ROIs with 3D extent correctly extended in- and out-of-plane to the expected image slice. Effective radii extracted from areas and perimeters computed directly from contours (i.e., using a vertex and edge representation) agreed with the nominal radii within 0.005 mm.

Cardinal axis-aligned brush sweeps were all accurate to within 0.005 mm, whereas diagonal sweeps were accurate within 0.02 mm. Axial interpolation between two 2D circles of either 10 mm or 30 mm radius separated by 5 empty image slices resulted in a perfect cylinder in both cases, with all interpolated 2D contours sharing the exact radii and location of the bounding contours.

For receding squares, the 'edit contours' feature was used to invoke receding squares, followed by marching squares to attempt to recover the original contour. Contour measurements are listed in table 1. Measured radii were equivalent to < 0.01 mm; areas differed by 0.003%, equivalent to roughly ¼ of the volume of a single voxel; and perimeters differed by 0.8%. The fitted centres differed by 0.01 mm.

Contour	Fitted Radius (mm)	Area (mm^2)	Perimeter (mm)
original	50.00	7853.81	314.18
recovered	50.00	7853.55	316.88

Table 1: Contour dimensions, original vs recovered via receding squares algorithm.

Results of applying margins to a 2D contour with 30 mm radius are shown in table 2. Though the input was a single contour, margins correctly expanded in 3D axially an appropriate number of slices. The maximum discrepancy in all cases was within ± 0.1 mm.

Margin (mm)	Expected Radius (mm)	Fitted Radius (mm)	Discrepancy (mm)
-0.50	29.50	29.54	0.04
0.50	30.50	30.46	-0.04
1.50	31.50	31.43	-0.07
3.00	33.00	32.93	-0.07
5.00	35.00	34.96	-0.04

Table 2: Geometric accuracy when applying margins.

Synthetic CT images and contours produced by DICOMautomaton were imported into Eclipse and Maestro TPSs. 2D and 3D circles/sphere contours with nominal radii 5, 10, 15, 30, and 50 mm were imported, and radii and centroids were measured and compared between software to confirm geometric accuracy and positional precision. All three systems agreed within 0.05 mm for radii (n.b. limited resolution due to the use of manual measurement tools) and

within 0.01 mm for centroids. Contours were then exported and imported back into DICOMautomaton, confirming bidirectional compatibility.

DCMTK's 'dcmpschk' and 'dcmdump' tools were used to confirm that encoding, syntax, structure, and content of the contour and image files were consistent with the DICOM standard. No errors or warnings were produced.

Finally, the 'undo-redo' buffer was confirmed to be functional and lossless.

4 Discussion

Validation is necessary to ensure software accuracy and functionality, but is often either not performed, or not reported for open source projects. The aim of this work was to validate the open source DICOMautomaton contouring subsystem for the purposes of radiotherapy.

All geometric accuracy and precision tests exhibited discrepancies that are considered to be clinically insignificant, including basic use of 2D and 3D brushes, sweeps, and axial interpolation between 2D contours.

The receding squares algorithm was found to recover the original contour's radius and area to within 0.003%. Due to the relaxed constraint for exact inversion, the recovered contour's perimeter was 0.8% larger. This is an expected result since the single-pass algorithm is not able to simultaneously satisfy three independent constraints (left, top, and top-left diagonal). The small amount of extra perimeter represents sub-millimetre variations or surface ripple and is acceptable for clinical radiotherapy. Note that increasing mask resolution will both reduce this variation, and also improve geometric accuracy for all discrepancies reported in this work.

Application of positive and negative margins resulted in accurate growth or reduction, with a maximum discrepancy of less than 0.1 mm from expected. Use of morphology-based margins is more straightforward compared to directly applying margins to contours (i.e., in vertex and edge representation) due to the topological complexities, including computing intersections and handling degenerate situations (e.g., abutting or thin contours). The morphology-based margins implementation provided by DICOMautomaton was found to provide accuracy sufficient for use for radiotherapy purposes.

Two third-party commercial TPSs were used to confirm DICOM interchange conformance. Geometrical accuracy and consistency of the coordinate systems was also confirmed. Open source tools from the DCMTK suite were used to provide verification against the DICOM standard.

The rationale for using predominantly circular or spherical contouring targets for geometric assessment is as follows: (1) the mask underlying contours is rectilinear and line segments that comprise circular contours span 360° angles, so circles/spheres exercise local-neighbour pixel intensity arrangements with non-zero gradient; (2) circles/spheres have a extreme relationship between area/volume and perimeter/surface area, simplifying detection of discrepancies; (3) circles/spheres have a well-defined position and extent, which can be used to simultaneously evaluate accuracy and precision, and the centroid corresponds to the geometric centre, simplifying the process of position extraction; and (4) the sweep of a circle/sphere in any direction has a consistent diameter, which simplifies assessment. While the tools provided by DICOMautomaton are capable of making intricate and sharp contours, they are comparatively harder to evaluate.

The receding squares algorithm demonstrated accurate inversion of the marching squares algorithm and reproduction of the underlying mask. Like marching squares, it can be accomplished in a single scan over image pixels and still yield accurate results. However, because the algorithm carries forward discrepancies from left-to-right and top-to-bottom (and thus compensating discrepancies arising from inconsistent intensity estimations), it is not 'embarrassingly parallel' like marching squares. In practice, multiple scans may be preferable to handle contour overlap (e.g., deciding whether an inner concentric circle is 'within' or 'outside' of a contour). Re-running receding squares in a reverse orientation (i.e., from bottom-right to top-left) can also improve accuracy. Both marching and receding squares algorithms trivially generalize to 3D voxels and surface meshes.

ROI volume was not compared in this work. Accurate estimation of the volume of a ROI requires extrapolation, and the spacing and resolution of adjacent mask image planes can impact the extrapolation. Furthermore, the volumes reported by the benchmark software (Varian and MIM) differ. While DICOMautomaton supports volumetric analysis, a detailed comparison is beyond the scope of this study.

5 Conclusion

The contouring subsystem provides rudimentary but effective tooling, generates geometrically sound contours, interoperates according to widely supported standards, and can thus fulfill a crucial step in the radiotherapy process. DICOMautomaton is free/libre and open source software. Contributions are welcome.

Abstract This work was carried out within the Ependymomics project, focusing on the analysis of multi-omics data of children and teenagers with epndymoma. In this paper, we present preliminary results of the harmonization of multicentric brain T1 MRIs from 14 sites in France. We aimed to mitigate image properties heterogeneity using an unsupervised deep learning GAN-based CUT model. Using T1-weighted MRI (n=217 subjects), we tested the model (i) by using different references, and (ii) with a single or multiple slices as input references. Qualitative evaluation of harmonized images, as well as the use of image quantitative metrics, show that the method efficiently reduced the inherent variability of images, with before and after variance values of $2,81e^{11}$ and $1,15e^{3}$ respectively. Our next step will be to evaluate the impact of these harmonization strategies on tumor-derived radiomics, and the resulting improvements in the performance of radiomics models predicting patient outcomes (progression free survival).

1 Introduction

Projects including multimodal medical images as a data source (amongst others histopathology, genomics, or clinical variables) to build models predictive of patient outcomes, typically face challenges associated with recruiting larger cohorts of patients in numerous clinical centers over a long period, to reach a reasonable number of patients for model training and evaluation. The main advantage of such a recruitment is that a larger cohort of patients is available to support stronger statistical significance of findings, and can allow for more efficient training and validation of models. The drawback is that collected images can display a high level of heterogeneity in terms of overall quality and properties (e.g., signal-to-noise ratio, contrast levels, axial versus sagittal, voxel size, textures...). This is due to the fact that the various centers in which patients were imaged relied on different scanners (vendor, model, generation) and with different acquisition and reconstruction protocols. Scanner and/or protocol variability can affect both the stability and the discriminating power of radiomic features and predictive models[1]. The Ependymomics project aims at building models predictive of the risk of relapse and outcomes in pediatric ependymoma patients,(the third most common brain tumor affecting children [2]), with a high rate of relapse of approximately 40 % after surgery and radiotherapy [3, 4], by exploiting imaging, dosimetry, clinical, genomics, and histopathology data. The imaging datasets collected in this context consist of MRI sequences including T1, T2, and FLAIR. The cohort exploited in the project contains 345 patients and was collected in 14 different centers in France. The goal of this paper is to present our preliminary evaluation of a method for harmonizing the images of the ependymomics cohort, focusing on the post-contrast T1-weighted images. The method uses a modified Generative Adversarial Network (GAN)[5] image synthesis, namely the Contrastive Unpaired Image to Image Translation (CUT) algorithm [6]. The evaluation of the performance of the harmonization will be reported here using a set of overall image metrics. Future work will consist of evaluating the harmonization using tumor radiomics features, and the potential impact on the predictive models, including all sequences.

2 Materials and Methods

2.1 Harmonization procedure

Based on the domain adaptation approach, our objective is to increase the similarity of characteristics between the images of the data set, through a style translation, while preserving their clinically relevant informative content. Thus, in the context of our multi-center study, we aim to evaluate the performance of the generative model for mitigating the effects of the acquisition shift. Based on two subsets of data, an input source domain X (raw images) and a target domain Y (reference images), the harmonization model used here learns to translate an image from one domain to the other. In other words, it aims to translate images from X to appear like an image from Y generating a "fake y" = $\bar{y}$, i.e. the harmonized images. In our application, we use this method to transform images so they appear as if they had been acquired in the same configuration (scanner model, acquisition protocol, reconstruction settings) as the chosen reference.

2.2 Dataset and pre-processing

The data were collected from the NETSPARE (Network to Structure and Share Pediatric data to Accelerate Research on Ependymoma) database, which stores all relevant data from 345 children and adolescents with ependymoma since 2000 in France. After the curation of the images, 217 patients from 14 imaging centers were included in the present analysis. For each patient, the post-gadolinium T1-weighted sequence was selected. These images were acquired using scanners from Siemens, Philips, and GE, using different acquisition protocols at each center with varying acquisition parameters (1.5 or 3 Tesla, slice thickness ranging from 1.5 mm to 4 mm, and matrix sizes from 68×65 to 512×512 pixels).
We applied some commonly performed pre-processing steps[7], such as conversion from DICOM to NIFTI format, cropping to a size of 512×512, normalization to [-1, 1] based on minimum and maximum intensity values, and matching to the percentile of the quantile range [1%, 99%].

2.3 CUT Model

The CUT model is based on a CycleGAN [8] used in the context of unpaired data. Unlike CycleGAN, the CUT model requires learning the mapping in one direction and avoids using inverse auxiliary generators and discriminators. This can simplify and shorten the training. To summarize, the training needs a set of images from each domain. Given a dataset of unpaired instances $X = \{x \in X\}$, $Y = \{y \in Y\}$. The objective is to learn a pixel-level adapter $G(x \in X)$ to a reference subset Y and generate a new set of data $\bar{Y}$. The generator function G is broken into two components, an encoder *Genc* followed by a decoder *Gdec*, which are applied sequentially to produce output image $\bar{y} = G(z) = Gdec(Genc(x))$. To achieve our goal of content conservation and style transfer, two loss functions are used: the content conservation of the source domain (X => $\bar{Y}$) is ensured through the PatchNCE loss ((L_{NCE}), and the style translation from the reference domain (Y => $\bar{Y}$) is ensured through the GAN loss ((L_{GAN}).

Strategy 1	Strategy 2	Strategy 3	Strategy 4
Reference 1		Reference 2	
3 slices	1 slice	3 slices	1 slice

Table 1: 4 strategies for harmonization performance assessment

2.4 Comparison of harmonization strategies

Four different strategies were compared to assess the performance of each method. The first main parameter concerns the choice of an image of the reference domain. A typical reference should be a good-quality image within / external of X or can be synthesized images, with desirable properties, i.e. higher contrast, greater sharpness, and lower noise or blur levels. Therefore, for our work, we defined certain criteria for selecting and testing several references within the dataset, to train the model, namely: recently acquired, isotropic, 3 Tesla, and with high contrast. The second parameter was to use either a single slice or several (in our case, 3 at different locations, middle, top, and bottom of the patient's brain) in the reference volume to feed the network. Therefore, the model was trained for each chosen reference using either 1 or 3 slices (**Table 1**). All experiments were implemented in PyTorch 1.13 with the Adam optimizer using the same training hyper-parameters, and they were trained and tested on an NVIDIA GeForce RTX 3090GPU (24G) with a batch size of 1. The training was performed for 400 epochs, and a learning rate of 0.0002 using a ResNet-9 inspired architecture.

2.5 Evaluation

First, a qualitative (visual) assessment was carried out to appreciate the magnitude of the harmonization and to ensure that the harmonized images were visually satisfying, with no obvious artifacts, noise, or distortions of the clinically-relevant contents. A statistical analysis (quantitative evaluation) was then carried out to assess the model's performance in reducing variability after harmonization, relying on 15 image metrics (including first-order statistical measures as well as second-order statistical and filter-based measures) extracted before and after harmonization, as it was proposed previously to quantify the batch effect in MRI and to detect artifacts [9]. t-distributed stochastic neighbor embedding (t-SNE) [10] was then used to project the 15 metrics into a 3D space and to visualize the difference of image properties before and after harmonization. The reduction of variance was measured to compare the four different strategies.

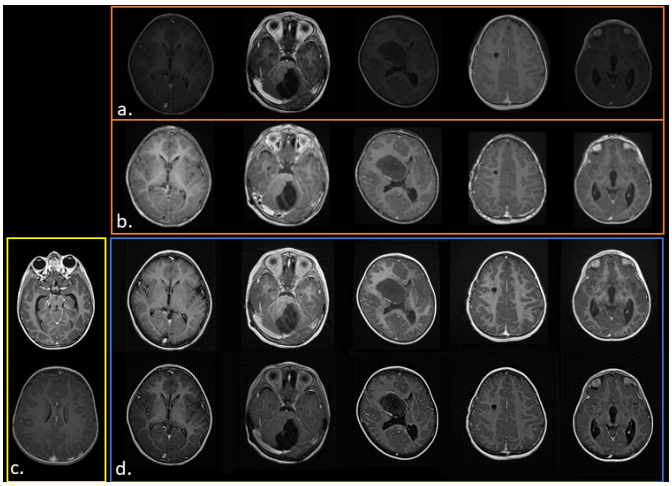

Figure 1: Qualitative analysis of the CUT model on T1-weighted source images of 5 different patients towards the two references (c.) from different centers. (a.) Raw images. (b.) The pre-processed non-harmonized images. (d.) The harmonized images.

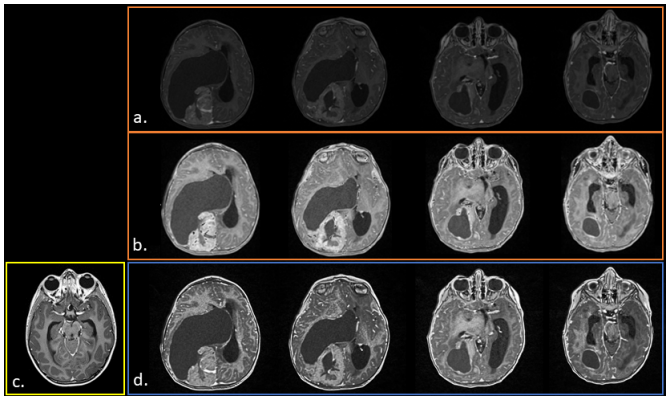

Figure 2: Qualitative analysis of CUT model on 4 slices of a single patient. (c.) The reference, (a.) the raw source image, (b.) pre-processed images, (d.) the harmonized images.

3 Results

Figure 1 gives an overview of the model results, showing five 2D axial slices of five different patients from different centers. The two first lines represent the raw and the pre-processed images, respectively, and the last two lines correspond to the generated (harmonized) images with each of the two chosen references. It is worth noting that the harmonized images are generated without artifacts or distortions, for both references. It can also be appreciated visually that all generated images have a more similar appearance to the chosen reference than before harmonization. According to clinician collaborators, the style transfer was successfully achieved without altering the clinically relevant content of the images (position tumor, organs...). The same observation is made for the results represented in **Figure 2**, which displays the harmonized images for a single patient with a large tumor over 4 slices of the volumes. The t-SNE results are shown in **Figure 3**, highlighting a clear separation of the data in three-dimensional space, for all the strategies using different references and one (middle of the head) or more slices of

Strategies	1	2	3	4
σ^2 before harmonization	$2.81e^{11}$			
σ^2 after harmonization	$2.38e^{8}$	$7.44e^{4}$	$2.23e^{4}$	$1.15e^{3}$

Table 2: Variance (σ^2) after/ before harmonization by strategy.

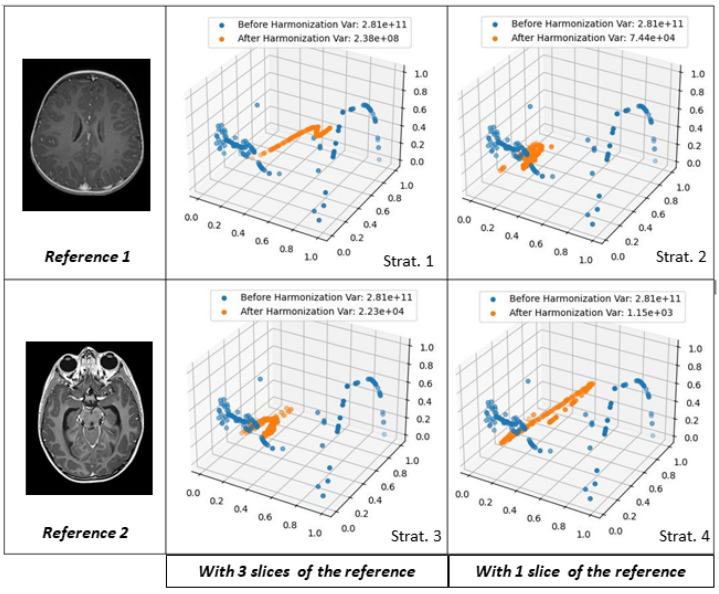

Figure 3: T-SNE analysis based on the 15 metrics extracted from images, before and after harmonization.

each. It can be seen that the values of the metrics extracted before harmonization (blue points, each point is an image) have a much greater dispersion. After harmonization (orange points), the observations are much more clustered, displaying reduced dispersion. In other words, there is less variation and more similarity in the data after harmonization. For each strategy, the variance (σ^2) before and after harmonization was calculated to assess the model performance (**Table 2**). Strategies 2 ($\sigma^2 = 7.44e^4$) and 4 ($\sigma^2 = 1.15e^3$) led to a high decrease in variance, suggesting that the use of one slice from a reference as an input for training the model is more efficient than using 3. Furthermore, the use of reference 2 led to stronger variance reduction (strategies 3 ($\sigma^2 = 2.23e^4$) and 4 ($\sigma^2 = 1.15e^3$)) than reference 1.

4 Discussion

In this paper, we presented preliminary results of our contribution to the Ependymomics project where the major challenge is the large heterogeneity of data gathered from different sites, subjecting it to the problem of acquisition shift. Research shows that this heterogeneity adversely affects radiomic studies and predictive models[11] supporting the hypothesis that an image harmonization step could help in training predictive models if the information is contained in the images but is "hidden" due to the heterogeneity of image properties. The purpose of our work was to evaluate the ability of a harmonization model based on image synthesis to reduce variability

within a heterogeneous MRI dataset. The CUT model used here, was implemented for two objectives: style translation and content preservation, ensured thanks to a GAN and a PatchNCE loss functions, respectively. To assess the performance of the CUT model in terms of reducing variability within a dataset, a quantitative analysis was carried out using image quality measurements extracted before and after the harmonization. This was done for 4 strategies (i.e., 2 different references chosen, and for each reference, using 1 or 3 slices as input) for model training. In all experiments, the variance values decreased by several orders of magnitude (from $2.81e^{11}$ before to between $2.38e^{8}$ and $1.15e^{3}$ after harmonization), showing that the CUT model can reduce the variability of image characteristics. This applies even to very small reference domain training sets consisting of a single 2D reference image slice (Figure 3: strategies 2 and 4), where the model achieved its best performance. The choice of reference is also an important factor in achieving optimum model performance. Given the variance values, we found that the model performed better with reference 2 ($\sigma^2 = 1.15e^{3}$) than with reference 1 ($\sigma^2 = 7.44e^{4}$). This may be explained by the fact that the model performs better with a reference whose image characteristics are closest to those of the dataset.

A very recent study [12] has developed a similar approach and added a gradient difference loss (GDL) to reinforce the structure preservation of source images while allowing flexible contrast translation from the reference. To improve our results, we intend to investigate the addition of this loss. Furthermore, one of the limitations of our work is that the evaluation of the CUT model has been done just at the level of the image, in future work, we will include an evaluation at the level of tumor radiomic characteristics, as well as a study of the potential impact of harmonization on the predictive modeling stage, including other MRI sequences.

5 Conclusion

This paper presents preliminary results of image harmonization of multi-center imaging data from the ependymomic cohort, focusing on T1-weighted sequences. This is an image-to-image translation approach transferring the style of a reference image from a target domain to heterogeneous images from a source domain. We evaluated the model performance in reducing variability within a dataset through a t-SNE analysis of image quality metrics extracted before and after image harmonization. This analysis showed that variability was significantly reduced after harmonization, with better efficiency when using a single slice of mid-brain volume as a reference than when using multiple slices. This approach showed promising results and could be used as image pre-processing for radiomic studies. In future work, we aim to add further losses, which could increase the structural correspondence between generated and source images, as well as apply the model to different MR image sequences in the database. We will also evaluate the impact of the CUT harmonization on radiomics predictive modeling of outcomes.

Performance evaluation of a Pix2Pix synthetic Xray image generator for preclinical applications

Vasilis Eleftheriadis[1], Paneta Valentina[1], Eleftherios Fysikopoulos[1] and Panagiotis Papadimitroulas[1]

[1]BIOEMISSION TECHNOLOGY SOLUTIONS, BIOEMTECH, Athens, Greece

Abstract In this work, we evaluate a pix2pix conditional generative adversarial network as a potential solution for generating adequately accurate synthesized morphological X-ray images by translating standard photographic images of mice. Continuing our previous work, we expanded our dataset to 940 paired photographic/X-ray mice images and used data augmentation and transfer learning techniques to improve the performance and generalization of our model. We explore how the expansion of the training dataset affects the models' performance and use five image quality metrics to quantitatively evaluate the models' performance in the present dataset and compare the results to visual inspection by experts to assess the metrics' ability to evaluate image-to-image translation tasks. In conclusion, a combination of metrics is essential for generated image quality evaluation, and we propose an ensemble of the used metrics as an essential methodological step to evaluate the performance of image-to-image deep learning models.

1 Introduction

Scintigraphy is a high throughput alternative to 3D high-end molecular imaging systems and biodistribution ex vivo studies in monitoring the interaction of radioisotope- or fluorescence-labeled pharmaceuticals on animal subjects. It can effectively be used to track a new tracer and study the accumulation from zero point in time post-injection.

Image-to-image translation is a generative deep learning (DL) technique that utilizes generative adversarial networks (GANs), conditional generative adversarial networks (cGANs), and convolutional neural networks (CNNs) to learn complex mapping functions between input and output images to translate a source image into a target image while preserving certain visual properties of the original.

In our previous studies [1, 2] we presented a potential solution for generating adequately accurate synthetic morphological X-ray images by translating standard photographic images of mice using a well-known cGAN for image-to-image translation (pix2pix) [3]. Such an approach would benefit both imaging and targeted radionuclide therapy studies. The results showed that the network predicts an X-ray image with sufficient accuracy and that the calculated metrics are comparable with those presented in literature. In this study, we expanded our dataset, and we used data augmentation and transfer learning techniques to improve the generalization of our method. In addition, we performed a thorough evaluation of the performance comparing different metrics.

2 Materials and Methods

A dataset of 940 input/ground truth image pairs consisting of a photographic image and the corresponding X-ray scan of the same anesthetized mouse has been acquired. The photographic images were captured using commercial imaging devices by BIOEMTECH (eyes-series – www.bioemtech.com).

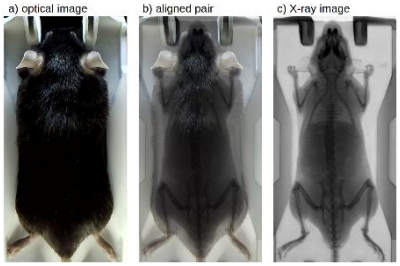

Figure 1: a) Indicative optical image acquired by BIOEMTECH eyes-series imaging devices, b) Corresponding X-ray image, c) Aligned pair.

These scanners, featuring a standard photographic sensor, provide an optical image of the animal (Fig. 1a) [4]. Both systems are adequate for mice imaging providing a useful field of view (FoV) of 50×100 mm^2.

The study involved 86 white and 88 black Swiss albino mice. We acquired 5 input/ground truth images of each animal in different poses upon the hosting bed, leading to a total of 940 input/ground truth images. The mice were divided into two groups to form the training and testing datasets. A group of 76 white and 78 black mice was used to collect 823 paired images for training, while a group of 10 white and 10 black mice was used to collect 117 paired images for testing. Except mouse color, the method was evaluated against different animal hosting beds (plastic bed with white color; plastic bed with black color), which leads to different backgrounds in the input image. The image pairs were properly aligned before training, having a resolution of 512×1024 pixels, corresponding to the 50×100 mm^2 FoV (Fig. 1b). Additionally, to ensure the validity of the training and testing sets, the mice used for training were separate from the individual mice used in the test set.

In this study, we utilized the PyTorch implementation of the pix2pix algorithm [3] and used the cross-entropy loss function. We trained all models for 200 epochs. For our transfer learning experiments, we first trained models on a subset of the dataset and then finetuned those on data from specific scanners using the weights of the pretrained models. For data augmentation we used the open-source Python library Albumentations [5]. By using different geometric and photometric transformations we managed to expand our training dataset up to 5175 paired images. We evaluated the performance of the pix2pix models in the present dataset using five commonly used image quality metrics: (a) mean squared error (MSE), (b) normalized root mean squared error (NRMSE), (c) peak signal-to-noise ratio (PSNR), (d) structural similarity index measure (SSIM) and (e) Fréchet inception distance (FID). Furthermore, we propose and evaluate our models' performance with a novel

weighted average ensemble performance evaluation metric (WAEM) which combines these five metrics.

$$WAEM = \frac{a}{MSE} + \frac{b}{NRMSE} + c \cdot PSNR + d \cdot SSIM + \frac{e}{FID}$$

3 Results

Model performance for increasing dataset size, starting from 50 to 5175 images, is presented in Fig. 2 through the 5 metrics used in this study. By visual inspection of the generated images, none of these metrics was adequate to individually be used to identify the best performing model. The weighted combination of the used metrics (WAEM), relying on a greater extent on FID, was found to be the metric which most consistently agrees with visual inspection and is also included in Fig. 2.

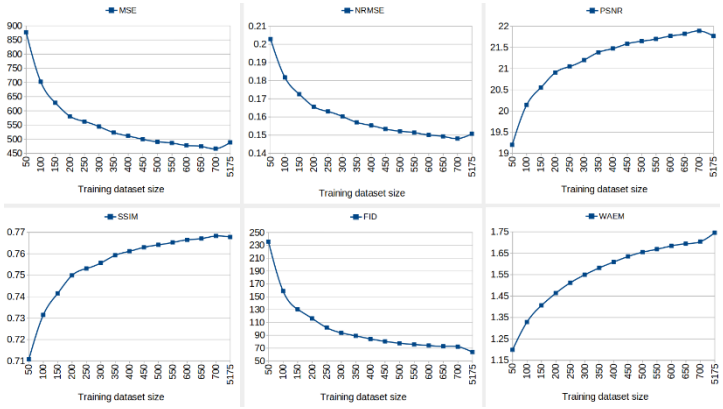

Figure 2: Graphs of the 6 metrics used in this study for the performance evaluation of the pix2pix models. The X-axis represents the size of the training dataset.

Fig. 3 shows indicative optical to X-ray translations of the same optical image in the test dataset for different training set sizes for visual comparison. The increase of the dataset using data augmentation (Fig. 2 & 3) was found to boost performance, while transfer learning techniques did not improve the generalization of our model, in our case study.

4 Discussion

Increasing the training dataset size with real input/ground truth pairs of images (up to 700 in the graph) the performance of the pix2pix models is improved according to all evaluation metrics. Nevertheless, when we further increase the training dataset size using data augmentation to 5175 images, four out of five metrics (MSE, NRMSE, PSNR and SSIM) show a drop in the model's performance. In contrast, FID metric gets even lower values implying that the final model with the augmented training dataset performs better. Fig. 3 depicts the visual resemblance of the generated images to the ground truth that drastically improves by increasing the training dataset size either with real images and/or using data augmentation. We identified FID as the most indicative metric for image-to-image translation. However, we observed that when 2 models have similar FID scores the models that translate the photographic images into synthetic x-rays that resemble the ground truth better are the ones that score better on the rest of the performance evaluation metrics (MSE, NRMSE, PSNR and SSIM), independently of which model had the best FID score. Our proposed weighted metric (WAEM) was found to clarify these cases and gave a straightforward measure of performance.

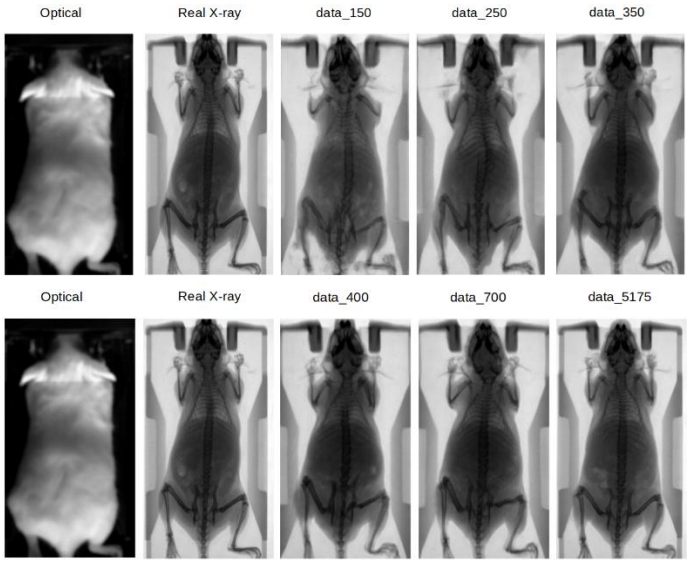

Figure 3: Indicative optical to X-ray translations of the same optical image in the test dataset for different training set sizes.

5 Conclusion

In the present work we evaluate the performance of pix2pix for image-to-image translation in our case study, in terms of dataset size, data augmentation, transfer learning techniques and the performance metrics themselves, that proved to be the most challenging issue. Our proposed weighted average ensemble performance evaluation metric (WAEM), which combines the five metrics used in this study (and are the most frequently used metrics in this field) could help researchers evaluate the performance of image-to-image DL models according to their case/dataset too.

Abstract This work discusses a dose verification procedure tailored for online adaptive MRI-guided RT workflows specific to the Unity MR-Linac system. The methodology was implemented as a fully automated pipeline using Python-based scripting available in the RayStation treatment planning system. The pipeline input consisted of adapt-to-shape (ATS) plan, including target and organs-at-risk (OARs) contours, and dose maps, as well as 3D image data acquired for treatment verification (VER) step as part of the online workflow and data collected during beam-on delivery (BON). The automated analysis algorithm relies on deformable image registration (DIR) between ATS and VER/BON image series to propagate contours (no need for extra contours generation) and facilitate dosimetric analysis. Contours derived on VER/BON are representative for intra-fraction motion and can be used to quantify dosimetric changes. 100 treatment fractions were investigated for liver, pancreas, oligometastases and lung SBRT cancer patients. 620 contours and their associated DIRs were evaluated by expert reviewers. 98% of the DIR-generated contours were found to be clinically acceptable. The results showed a significant correlation between DICE values and intra-fraction motion. The 3D dose verification tool on both VER and BON datasets detected significant dosimetric changes which were not apparent during the online treatment sessions. This analysis holds potential as a valuable tool for assessing plan quality and can streamline the decision-making process during the verification stage of the online adaptive workflow.

1 Introduction

Online adaptive MRI-guided RT procedures are rapidly advancing, integrating both anatomical and functional imaging information. They extend capabilities such as gating using real-time multi-planar imaging, the ability to rapidly adjust treatment plans for sudden target baseline shifts, and synchronous contouring by multiple users. Opportunities for improvement exist, especially regarding plan dose verification before and during treatment delivery. This aspect is particularly crucial in sites affected by organ motion, such as the upper gastrointestinal (UGI) area (including the liver, pancreas, and esophagus) and the lung. Previous studies have investigated dose reconstruction using delivery log files and 2D cine image series in prostate treatment [1]. Offline, post-treatment procedures for recomputing dose on additional datasets have also been reported [2]. In this study, we propose a fast and automated procedure to assess plan quality given various degrees of intra-fraction motion on any verification 3D scan at any point in the online adaptive workflow. The methodology also facilitates (a) the implementation of reinforced online adaptive strategies, including the generation of bespoke clinical goals between subsequent treatment fractions and/or (b) dose accumulation.

2 Materials and Methods

The Unity MR-Linac (Elekta) workflow is streamlined to include the acquisition of 3D imaging for planning, DIR-based contours mapping, and/or manual re-contouring of targets and organs-at-risk (OARs), generation of a fully-optimized treatment plan, real-time motion monitoring via 2D cine imaging in multiple planes, 3D verification scans, and treatment delivery [3]. For UGI sites as well as for lung patients, the treatment sessions are on average 60 minutes long, and can extend up to 90 min for the single fraction cases of 24-30 Gy due to prolong beam-on time [3].

The automated dose verification pipeline was developed using RayStation's Python-based scripting environment and validated for 21 patients, including liver treated with 1/3/5 fractions, as well as pancreas, abdominal oligometastases, and lung patients who received 5-fraction SBRT treatments.

The pipeline input comprised the adapt-to-shape (ATS) plan, including 3D planning images (i.e., time-averaged or navigator-triggered in exhale phase of the breathing cycle), contours, and 3D dose maps, as well as 3D image series from the verification (VER) step of the online workflow and similar data acquired during treatment beam-on delivery (BON). The automated analysis involved the sequential execution of the following steps: (a) data sorting and import from the RayStation data repository (data received from Online Monaco and Unity-MR console), (b) image and plan nomenclature update to facilitate robust data processing, (c) deformable image registration (DIR) based on image intensity between the ATS image data and VER/BON data, (d) contours mapping via DIR from ATS to VER/BON, (e) addition of site and prescription specific clinical goals , (f) transfer of contours rigidly from VER/BON to ATS to reflect any potential changes due to setup or intra-fraction motion, (g) dosimetric and similarity analysis for all relevant ROIs, and (h) generation of a summary report including dosimetric evaluation of clinical goals and assessment of DIR performance.

The DIR and contours mapping processes were visually validated by independent reviewers. Dose invariance was assumed between the ATS and VER/BON datasets, thus avoiding the need for dose recomputation. This assumption was validated by performing dose recomputations in

Offline Monaco for select cases covering the full range of clinical scenarios investigated.

3 Results and Discussion

The retrospective analysis involved 100 treatment fractions, encompassing the evaluation of 620 DIR-generated ROIs. Over 98% of the contours were accurately propagated within the region relevant to the treatment volume, with minor deviations having a negligible impact on the accuracy of reconstructed dose. Additionally, 30 plans were recomputed offline to confirm that the agreement between the ATS and BON/VER data was within 1%, which falls within the tolerance of Monaco's dose in magnetic field computations based on Monte Carlo.

The DICE similarity metric, readily available via RayStation scripting, was utilized to detect intra-fraction motion relevant to plan dosimetry. DICE was evaluated for both full organs and fractional volumes within the treatment region, defined as a 4 cm extension from PTV. The DICE values for fractional volumes proved to be more sensitive. ROI similarity analysis between ATS and VER/BON within the treatment region strongly correlated with intra-fraction changes in OARs, flagging dosimetric discrepancies. It is possible to define site-specific DICE thresholds to trigger user investigation into the DIR quality. The dose verification analysis detected outliers not initially identified during the online sessions (Fig. 1). These discrepancies were not necessarily specific to a given site or prescription.

In the ATS to BON analysis, relevant to the evaluation of dose-of-the-day, the large bowel emerged as the OAR with the highest level of variation, with roughly 33% and 40% of set clinical goal value for liver and pancreas 5-fraction cases, respectively. Duodenum, stomach, and small bowel ranged from 6% to 25% variations in the clinical goal values for liver and pancreas 5-fraction treatments. The largest change from all cases investigated was for a single liver case – duodenum dose varied by roughly 60%.

For the 2 lung cases investigated, the maximum variations between ATS and BON clinical goal values for OARs (heart, esophagus, bronchus) across all treatment fractions were found to be within 10%.

The maximum dose variation between the VER and BON analysis for UGI sites was found to be within ±100 cGy for the target and all OARs. The change for the mean dose for healthy liver (liver minus GTVs) was more modest, within ±20 cGy. The above findings underscore the need for a dose verification analysis on the VER data set to support the clinical decision-making process regarding whether to pass or fail an ATS plan immediately prior to treatment delivery. In contrast, the analysis on the BON data acts as a post-delivery data generation process to assess how the plan was delivered and generate data that can be used to link multiple treatment fractions. We are currently investigating the automated generation of updated clinical goals based on a given online plan, which can be propagated as the reference for subsequent treatment fractions. This type of data can reinforce the adaptive process from the online sessions.

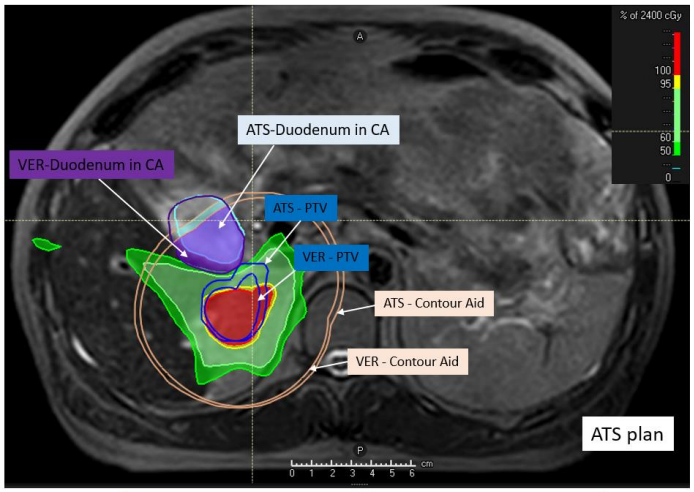

Figure 1. Example of the ATS-VER analysis highlighting intra-fractional changes which led to an increase in dose delivered to the duodenum.

4 Conclusion

We developed and validated a dose verification automated analysis pipeline for UGI and lung cancer patients treated with SBRT on the Unity MR-Linac system. The study demonstrated the importance of such an analysis in aiding the online adaptive process and facilitating future advancements in methodology for further adapting online treatments (reinforced adaptation). If efficiently implemented within the MR-Linac workflow, it can serve as a robust on-demand tool for quickly assessing patient setup and intra-fraction motion. Currently, we are initiating a pilot study to deploy and evaluate the dose verification pipeline as an online clinical tool.

Optimizing the contrast to noise ratio for tumor tracking in the lung using dual energy imaging strategies for soft tissue enhancement

Nawal Alqethami[1], Wentao Xie[1], Prasannakumar Palaniappan[1], Felix Ginzinger [2], Philipp Steininger [2], Marco Riboldi[1]
1. Department of Medical Physics, Ludwig-Maximilians-Universität, Munich, Germany
2. medPhoton GmbH, Salzburg, Austria

Abstract: Lung tumor tracking using x-ray encounters challenges, primarily due to shadowing effects from bony anatomy. This study addresses the experimental optimization of the soft tissue contrast and noise reduction in Dual Energy (DE) imaging-based tumor tracking relying on fast energy switching. DE Cone-Beam CT(CBCT) projections were acquired on a mobile CBCT scanner with a modified CIRS phantom in static mode at two energy settings (80-120 kV) and (60-120 kV) to study the effect of various energy gaps. Tumor inserts with different materials (adipose tissue, breast, muscle, and liver) were tested, by selecting projections with maximal overlap with the bony anatomy. Deformable registration was utilized to correct the misalignment between frames. We specifically investigated (i) the optimal weight in the weighted logarithmic subtraction (WLS) to enhance the soft tissue target and (ii) the optimal image filter to reduce noise. Median filters (MF) of different kernel size and anti-correlated noise reduction (ACNR) were considered.
The impact of (60-120 kV) setting demonstrated higher CNR, emphasizing its superior bone suppression and soft tissue enhancement in comparison with (80-120KV).
The result indicates optimal weighting factors of (0.65-0.7) for (60-120 kV) and (0.75-0.8) for (80-120 kV), aiming at maximal contrast to noise ratio (CNR) in the target. For a smaller energy range, smaller kernel size was deemed appropriate, with an optimal MF size of 11 pixels for the (80-120 kV) and a size of 9 pixels for (60-120 kV). The best noise suppression was achieved with ACNR+MF.
In conclusion, the study showed the effectiveness of using DE imaging and WLS to optimize the CNR to advance lung tumor tracking capabilities.

1 Introduction

X-ray based tumor tracking in the lung encounters a significant hurdle, primarily caused by the interference of high-density structures, notably bony anatomy. The presence of superimposed shadows cast by these bony structures poses a limitation on the contrast of lung lesions in images, frequently leading to missed tracking opportunities (1).
The visual attributes of bones take on a distinctive pattern, showcasing reduced contrast in comparison to the surrounding soft tissues when high kilovoltage peak (kVp) settings are employed. Conversely, a shift to lower kVp settings alters the appearance of bones, resulting in an increased contrast relative to the surrounding soft tissues (2).
In response to these challenges, the application of Dual Energy (DE) imaging comes into play. This advanced technique involves the acquisition of two images at different x-ray energies, followed by a weighted logarithmic subtraction (WLS). The outcome is a third image intentionally designed to cancel either bone or soft tissue selectively (3). Despite its effectiveness in mitigating bone interference, the DE method often yields images with a perceptible increase in noise.
This study aims to evaluate the efficacy of the DE and WLS approach. The primary objective is to gauge its success in suppressing the visibility of bones while concurrently enhancing the visual representation of soft tissue. Moreover, the study will incorporate various noise reduction methods, contributing to the continual improvement of tumor tracking capabilities within the lung.

2 Materials and Methods

DE-Cone-Beam CT (CBCT) projections were acquired using the mobile ImagingRing (IRm) developed by medPhoton GmbH (Salzburg, Austria) (Figure 1A). Images were acquired using the dynamic CIRS MRI-Linac Phantom (Sun Nuclear, Melbourne, Florida) in static mode.
The phantom was adjusted to incorporate cylindrical inserts of different target materials with about 30 mm in diameter and 50 mm in length, taken from the CIRS Model 062 Electron Density Phantom. These materials include adipose, breast, muscle, and liver tissues (Figure 1C).
In addition, pork ribs were attached on the phantom to simulate a more intricate representation of the human anatomy as illustrated in Figure 1B.
The acquisition process resulted in a set of eight DE-CBCT scans with the X-ray generator operating in pulsed mode and the detector set to 0.3 mm pixel spacing.
Each target material underwent two scans, with the first scan employing settings of 80 kV (15 mA, 17 ms) and 120 kV (15 mA, 12 ms), while the second scan using 60 kV (15 mA, 17 ms) and 120 kV (15 mA, 12 ms).

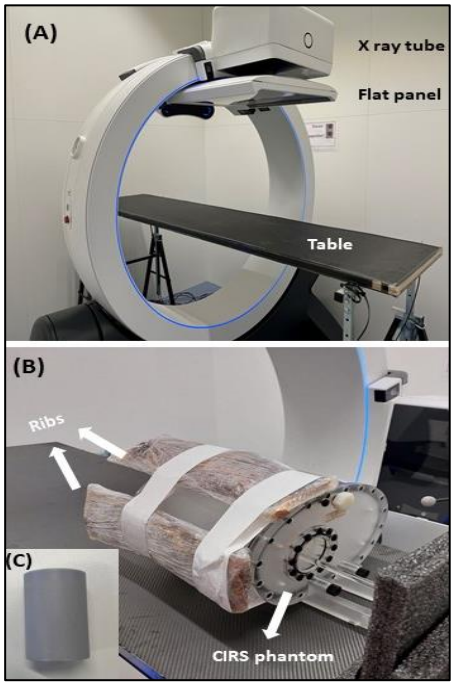

Figure 1: Experimental setup. Panel (A) shows the mobile ImagingRing (IRm). Panel (B) depicts the experimental setup of the phantom and the ribs with panel (C) showing the CIRS liver insert.

Each scan consisted of X-ray frames with alternating energies, capturing a complete 360° rotation within 120 seconds, with a 165 ms and 84 ms interval between consecutive frames respectively.
From each experimental study, two frames were manually selected which contained the maximum overlap between the ribs and the target.
To rectify the misalignment between frames, a deformable registration was employed, followed by images WLS calculated as in equation (1), using a range of weighting factors (w_{st}) within the interval [0.5, 0.95] with 0.05 spacing:

$$I_{DEst} = ln\ I_H - w_{st}\ ln\ I_L \quad (1)$$

In this equation, I_{DEst} refers to the DE soft tissue image, with I_H representing the input from high energy (HE) image, and I_L representing the input from low energy (LE) image.
Separate regions of Interest (ROIs) for bone and soft tissue were segmented, while avoiding sharp intensity transitions (e.g., bone edges). Subsequently, the CNR between the two ROIs was computed, and the optimal weighting factor was identified as the one yielding the lowest CNR to eliminate the bone. Figure 2 illustrates the segmentation employed for CNR calculation in the evaluation of the optimal weighting factor.
It was observed that the WLS process resulted in a compromise in image quality. In response to this trade-off, two noise reduction methodologies were applied to enhance image quality and increase the CNR for the soft tissue target.

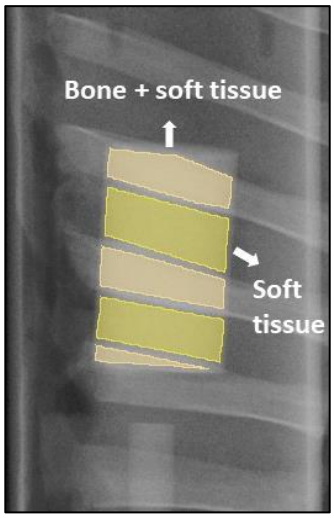

Figure 2: The segmentation used to the calculate the CNR

The CNR for the soft tissue insert was calculated between the segmented insert and the background, obtained by expanding the segmentation as illustrated in Figure 3.

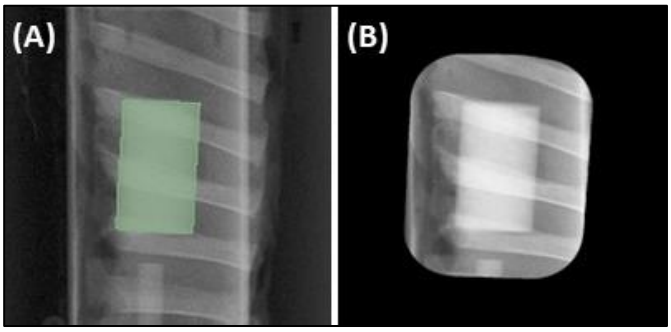

Figure 3: Panel (A) shows the tumor insert segmentation. Panel (B) represents the expanded segmentation region to include the background.

Different competitive approaches were applied for filtering the resulting DE image. The first approach was based on Median Filtering (MF) (4).A range of filter sizes, spanning from 9 to 11 pixels, was tested, with the final selection being guided by the achievement of a higher soft tissue CNR value combined with minimal image blurriness.
The second approach incorporated the anti-correlated noise reduction (ACNR), a technique to reduce noise in material specific images generated by WLS. (5) (6). This method relies on the fundamental observation that there exists a high correlation between the noise present in soft tissue and bone images.
To address noise reduction in the soft-tissue image, the ACNR algorithm applies a high-pass filter to the complementary image, precisely the bone-only image (I_{DEB}).

This filtering operation eliminated the bone component from the complementary image, leaving only the residual noise. Subsequently, the original DE soft-tissue image (I_{DEst}) and the high-pass filtered bone image (I_{DEB}^{HPF}) were combined using a weighted subtraction, incorporating a parameter denoted as w_n in equation (2):

$$I_{DEst}^{ACNR} = I_{DEst} - w_n \, I_{DEB}^{HPF} \quad (2)$$

A Wilcoxon matched-pair test was used to investigate potential variations in the CNR between the specified energy ranges of 80-120 kV and 60-120 kV. Additionally, both the Friedman test and the post-hoc Nemenyi test were utilized to systematically evaluate the statistical significance of differences observed among various noise reduction techniques in comparison with the DE-enhanced input images. These tests were essential for investigating the significance in CNR performance associated with different energy ranges and filter type.

3 Results

Figure 4 depicts an example of the original frame before and after the WLS using a combination of different weighting factors for both (80-120 kV) and (60-120 kV).
For the (80-120 kV) energy range, the optimal weighting factor, determined through quantitative CNR values and visual assessments, ranged between 0.75 and 0.8. On the other hand, for the (60-120 kV) energy range, the results indicated that the optimal weighting factor is within the range of 0.65 to 0.7, across all material tissues tested in the study.

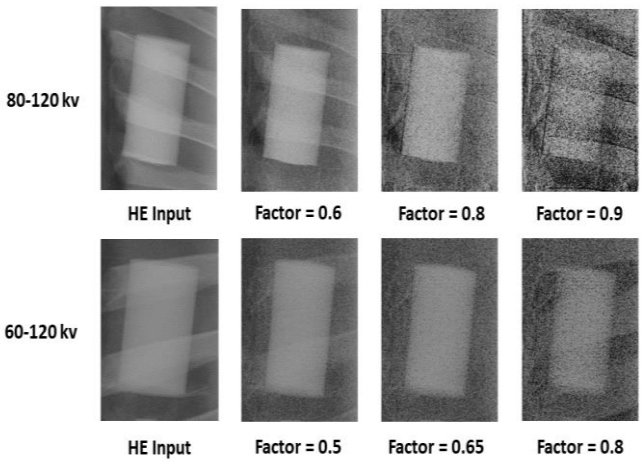

Figure 4: Weighted logarithmic subtraction for the breast target

The noise reduction techniques including MF and ACNR were carried out, with the ACNR parameter (w_n) in equation (2) optimized to the optimal weight of 0.95. This aimed at achieving a balance in the noise reduction process, and the contribution to the enhancement of the image. Furthermore, an investigation into a composite approach, including MF + ACNR, was conducted, and the outcomes are visually presented in Figure 5.

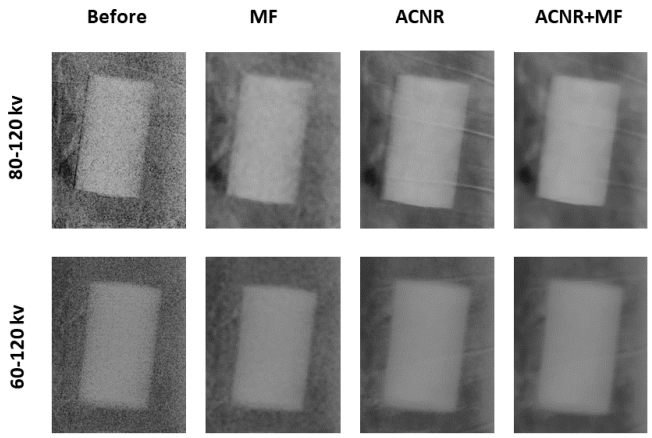

Figure 5: Result of MF, ACNR, and MF+ACNR applied on (80-120 kV) using w_{st}= 0.8 and (60-120 kV) using w_{st}= 0.65

The CNR was computed for both HE input frame and the LE input frame. The HE input frame yielded a superior CNR value compared to the LE input frame. Consequently, the HE frames CNR were chosen for subsequent comparison with the CNR values obtained using different noise reduction techniques.
The obtained p-value in the Friedman test, which stands at 1.81 x 10^{-5}, indicates a statistically significant difference across the various techniques.
The mean ranks resulting from the post-hoc Nemenyi test are plotted in Figure 6.

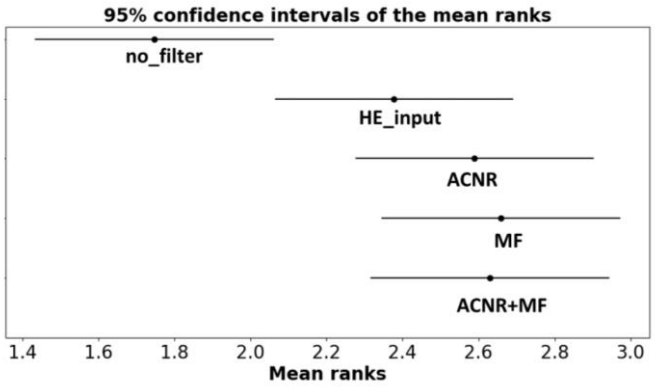

Figure 6: A plot of the mean ranks from smallest to largest for all noise reduction techniques compared to the HE input

Table 1 shows the p-values of the one to one comparison, with the asterisk marks indicating significant result at 95% confidence.

	HE Input	No filter	MF	ACNR	ACNR+MF
HE Input	1.000	0.687	0.084	0.319	0.014*
No filter		1	0.001*	0.014*	0.001*
MF			1	0.900	0.900
ACNR				1	0.687
ACNR+MF					1

Table 1: p-values of the Nemenyi test, with * indicating a statistically significant difference at 95%

The median CNR value for the HE input is presented in Table 2 for comparative analysis before and after the implementation of various noise reduction techniques.

	HE Input	No filter	MF	ACNR	ACNR+MF
80-120kv	2.19	1.52	2.33	2.44	2.49
60-120kv	2.77	2.04	3.25	2.97	3.01

Table 2: Median CNR values before and after introducing noise reduction methods

The difference in CNR between the energy ranges of 80-120 kV and 60-120 kV was statistically significant (Wilcoxon matched pair test), with a p-value of 0.017.

4 Discussion

The quantitative CNR values incorporated with visual assessments revealed that the (80-120 kV) energy range exhibits optimal weighting factors ranging between 0.75 and 0.8. Conversely, for the (60-120 kV) energy range, our results demonstrate that the optimal weighting factors fall within the range of 0.65 to 0.7 with the result being consistent across all material tissues used in this experiment.

The assessment of various noise reduction techniques within this study revealed distinct performances in CNR. Without the use of a filter, the outcome obtained the lowest CNR value when compared to the HE input, indicating potential limitations in terms of reduced image quality and increase in the noise. ACNR+MF exhibited best results, outperforming other techniques and displaying a higher CNR value compared to the HE input, suggesting its effectiveness in elevating image quality.

It is notable that for MF enlarging the filter size leads to an increase in image blurriness. A correlation was observed, indicating that a smaller energy range requires a correspondingly smaller filter size. Specifically, for the (80-120 kV) range, an optimal MF size of 11 pixels was deemed appropriate. In contrast, for the (60-120 kV) range, a size of 9 pixels was considered suitable for optimal image quality.

5 Conclusion

The study tested the effectiveness of utilizing DE imaging and WLS, highlighting their efficacy in optimizing the CNR for the advancement of lung tumor tracking capabilities. The observed variations in optimal weighting factors for the two energy ranges attributed to differences in the attenuation characteristics of tissues at various energy levels. A smaller weighting factor will be optimal as the gap between the two energy ranges is greater. (7)

A comprehensive assessment of various noise reduction techniques to reduce the image noise resulting from WLS process was carried out. Among the techniques examined, ACNR+MF emerged as the top performer, possessing a higher CNR value than the HE input.

The outcomes of the study conducted between the energy ranges of 80-120 kV and 60-120 kV, emphasizing the impact of energy range variation on the observed CNR values. Notably, the 60-120 kV range, characterized by a greater energy separation, exhibited higher CNR, showcasing greater bone suppression and soft tissue enhancement. (7)

Future work will focus on optimizing imaging protocols to achieve superior bone suppression and enhanced soft tissue visibility while minimizing patient dose on full rotation DE-CBCT scans. Non-linear methods to achieve WLS are currently being tested, aiming at soft-tissue enhanced images (3). The exploration will also include motion studies in tumor inserts with different size and shape.

Abstract : We aimed to verify patient setup accuracy using a combination of virtual laser-based SGRT systems (LUNA 3D, LAP, Germany). The experiments were divided into (1) skin-surface guidance with virtual laser and (2) mold-surface guidance with optical laser. The humanoid head phantom setups were analyzed into vertical (mm), lateral (mm), longitudinal (mm), and rotational (yaw in degree). In the virtual laser-based SGRT results, the displacement in the lateral direction is less than 0.5 mm, and the displacement in the longitudinal direction is more pronounced. In comparison, the vertical direction shows a difference of about 1 mm. The mold-based optical laser system showed vertical and longitudinal direction errors up to 2 mm. The SGRT system with the virtual laser can provide accurate alignment information of a large area and the area of interest set before treatment, providing accuracy of treatment and stable treatment setup.
Keywords: SGRT, virtual laser, optical laser, head phantom

1 Introduction

Radiotherapy technology has generally been developed along the two axes of efficient intensity modulation and image-guidance technologies.

In recent years, surface-guided radiation therapy (SGRT) has begun to replace traditional laser-based setups. It is even used as an alternative to patient motion management in image-guided radiation therapy (IGRT). Also, the installation of non-invasive and non-radiographic devices for managing patient setup posture before and during treatment using optical surface imaging technology has been expanding. Patients move against their will during treatment, which can lead to significant errors in high-precision treatments such as intensity-modulated radiation therapy (IMRT) or stereotactic body radiation therapy (SBRT).

Since the setup using an optical laser-based system uses ink or pen directly on the patient's skin to draw lines according to the laser projected from 3 directions (frontal & bilateral), the systemic error of the laser system itself and the random error of the radiotherapist still affect the quality of the patient's treatment. In addition, if a tattoo is applied to the patient's skin, it cannot be erased, and if the line drawn with ink is smeared or erased by sweat or water, CT simulation may have to be repeated.

One of the most popular treatment areas for SGRT is the breast, and studies have shown that tattoo-based treatments can reduce cosmetic and psychological burdens, as well as improve reproducibility and accuracy of patient positioning. These results have been confirmed by studies that have expanded the application to the chest, abdomen, pelvis, and head and neck.

In this study, we aimed to verify patient setup accuracy using a combination of virtual laser and optical camera using dicom information from the CT-based treatment plans.

2 Materials and Methods

The equipment used in the experiment was a C-arm type linear accelerator (iX, Varian, USA) and an SGRT system (LUNA 3D, LAP, Germany) with a virtual laser function. To realize accurate equipment performance, once the equipment was installed, calibration was performed using a cubic phantom and plate for calibration (Figure 1). The calibration of the virtual laser is crucial in the calibration process of SGRT equipment, especially in checking the agreement with the precisely calibrated CBCT.

To evaluate the performance of the LUNA 3D system, CT simulation was performed using a head phantom (Edward model 605, CIRS, USA) with and without a thermoplastic mask (Figure 2). CT scans (LB, Canon, Japan) were performed at 1 mm thickness to reconstruct 1 mm CT slices to minimize the effect of the resolution of the fine reference surface.

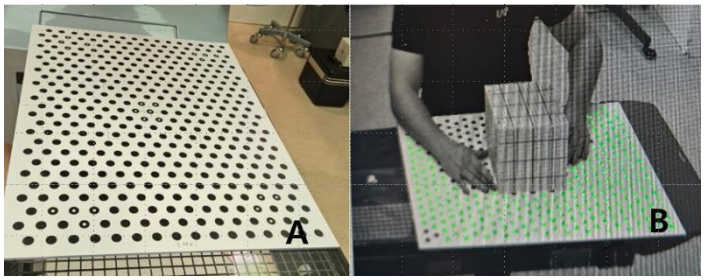

Figure 1: LUNA 3D system calibration (A) SGRT calibration plate (B) cubic phantom for SGRT calibration

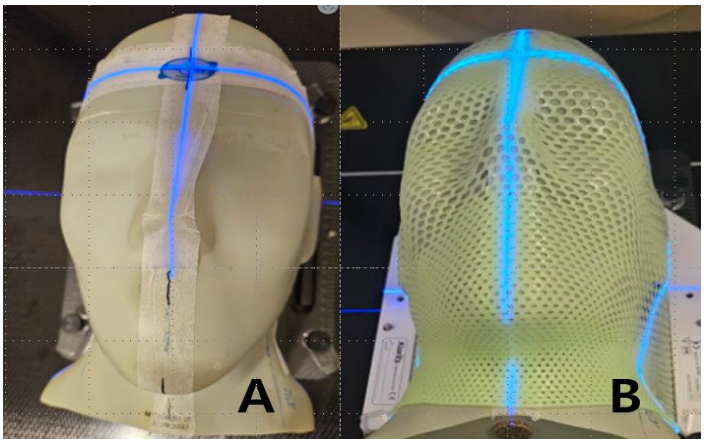

Figure 2: CT simulation using a head phantom (Edward model 605, CIRS, USA) without (A) and with (B) a thermoplastic mask

A volumetric modulated arc therapy (VMAT) treatment plan was established for the phantom plan, and the dicom

RT plan and dicom RS files were generated and imported into the LUNA 3D server.

The experiments were divided into (1) skin-surface guidance with virtual laser and (2) mold-surface guidance with optical laser. The phantom setups were analyzed into vertical (mm), lateral (mm), longitudinal (mm), and rotational (yaw in degree). The calibrated cone beam CT (CBCT) was used as a baseline to analyze the errors. The CBCTs were acquired in half fan mode with a scan condition of 512 x 512 pixels and a slice distance of 2 mm (Figures 3 and 4). Each setup was performed three times; the average and deviation were calculated, and the magnitude was analyzed by calculating the composite value of the error. The region of interest (ROI) of the skin surface was set to the whole frontal surface of the phantom. The virtual laser was referenced to the setup by matching the coordinate axis of the isocenter set during calibration with the value provided by the SGRT system based on the dicom information of the CT image (Figure 5).

3 Results

Table 1 shows the results of calculating the displacement by taking a CBCT after setting up the humanoid phantom based on the virtual laser-based skin-surface guidance. As you can see from the results, the displacement in the lateral direction is less than 0.5 mm, and the displacement in the longitudinal direction is more pronounced. In comparison, the vertical direction shows a difference of about 1 mm. The magnitude of the three directions showed results in the range of 1 to 1.5 mm. In all three measurements, the displacement in the yaw direction was less than 0.1 degrees.

SG+VL*	Vt[1] (mm)	Lt[2] (mm)	Lg[3] (mm)	Mg[4] (mm)	Yw[5] (°)
1st	0.3	0.5	1.4	1.5	-0.1
2nd	-0.6	-0.3	-1.0	1.2	0
3rd	-1.0	0	-0.2	1.0	-0.1

Table 1: Skin-surface guided setup using the virtual laser (SG+VL). The acquired CBCT images were used to analyze the deviations: Vt[1] (vertical), Lt[2] (lateral), Lg[3] (longitudinal), Mg[4] (magnitude), and Yw[5] (yaw). Table 1 shows the results of calculating the displacement using an SGRT system after CBCT imaging correction.*

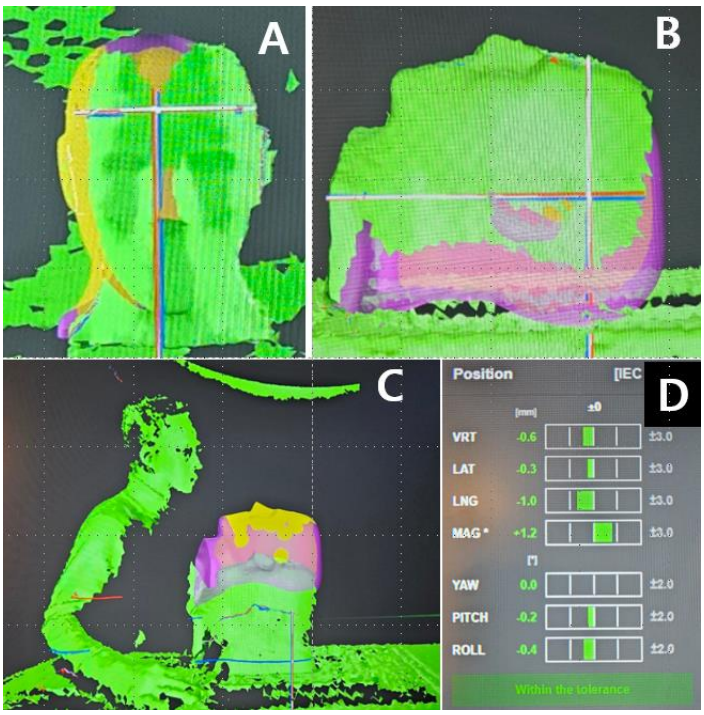

Figure 5: SGRT setup screen with the virtual lasers(blue lines) and patient dicom center (red lines) (A) frontal view, (B) left lateral view, (C) red crosslines to blue crosslines matching operation, and (D) mismatching results based on the virtual lasers and the phantom's dicom center

MG+OL*	Vt[1] (mm)	Lt[2] (mm)	Lg[3] (mm)	Mg[4] (mm)	Yw[5] (°)
1st	0.0	0.0	2.0	2.0	-0.1
2nd	2.0	0.0	1.0	2.2	-0.6
3rd	1.0	0.0	2.0	2.2	0.0

Table 2: Mold-surface guided setup using the optical laser (MG+OL). The acquired CBCT images were used to analyze the deviations: Vt[1] (vertical), Lt[2] (lateral), Lg[3] (longitudinal), Mg[4] (magnitude), and Yw[5] (yaw). Table 2 shows the results of calculating the displacement using the CBCT system after a mold-based surface-guided setup.*

On the other hand, the results of the optical laser-based mold-surface guided setup error are shown in Table 2. As shown in Table 2, the error in the lateral direction was zero in all three cases, but the errors in the vertical and longitudinal directions were up to 2 mm. The magnitude was about 2 mm, and the vertical and longitudinal directions were complementary, just like the virtual laser-based setup.

4 Discussion

In radiotherapy, stable patient positioning is more fundamental than any other technique, but it is common to all modalities and is essential for successful treatment.
In recent years, this has been the subject of active research, particularly in the breast deep-inspiration breath hold (DIBH) technique, which is synchronized with breathing, and patient motion management interfaces for high-precision radiotherapy such as frameless stereotactic radiosurgery. Traditional vendors in this SGRT market include VisionRT's AlignRT, C-RAD's Catalyst, and Varian's IDENTIFY, and their use is expected to expand as insurance coverage becomes available. Technically, many variables are utilized to evaluate the quality of an instrument, including data compatibility with the instrument, surface information acquisition and processing speed (CPU, GPU, etc.), treatment area, accuracy and reproducibility, and image resolution. Therefore, when introducing SGRT equipment, the equipment's characterization and quality evaluation are essential, and validation of new functions is necessary before use.

In this study, the functions of LAP's virtual laser with new functions were analyzed compared to the general optical laser system, and the significance of the research process was described.
1) After hardware installation of the SGRT solution and virtual laser calibration, cross-validation with a well-commissioned CBCT is necessary.
2) Comparison and verification of surface generation according to the resolution of dicom CT images is necessary.
3) Verify the correlation between the response speed of the patient's interfractional motion and the drive of the treatment device.
In the initial process of this study, we found a systematic error in the calibration of the virtual laser, which showed a difference of 1.7 mm in the same direction as CBCT, which was corrected. In addition, we found a slight difference in the 3D surface generated depending on the resolution of the reconstructed CT image, which may be important to note when using dicom images as a direct reference surface, and we believe that further research is needed. Finally, we found a delay in positional detection during the setup process based on the virtual laser, and sufficient research is needed for treatments based on real-time monitoring, such as motion tracking. This study aimed to compare the effectiveness of surface guidance based on a virtual laser to the mask molding surface guidance of an optical laser. We confirmed its usefulness with CBCT as a baseline.

5 Conclusion

In this study, the usefulness of the virtual laser-based SGRT system was compared to the conventional SGRT with the optical laser system to check the accuracy and reproducibility. By utilizing the virtual laser system, which is not adopted in the conventional SGRT system, it was possible to improve the accuracy of the setup through the information of the alignment during the patient setup, which suggested the possibility of reducing the setup time and additional imaging dose. We believe that the SGRT system, with the function of the virtual laser, can provide accurate alignment information of a large area and the area of interest set before treatment, which can provide accuracy of treatment and stable treatment setup.

Preliminary evaluation of a software application for target tracking without fiducials during Cyberknife treatment of pancreas

James Bedford, Simeon Nill and Uwe Oelfke

Joint Department of Physics, The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, London, United Kingdom

Abstract Cyberknife is an effective treatment for pancreatic cancers but visualization of the planning target volume (PTV) on the orthogonal kV imaging system is usually accomplished by means of fiducial markers. Insertion of the markers can lead to complications, so this study aims to visualize and track the pancreatic PTV without fiducials, using in-house software CKImage v1.1. The PTV delineated on the planning computed tomography scan is projected onto digitally reconstructed radiographs (DRRs) in the image planes to define the region of interest. The acquired kV images are filtered and the average image is subtracted from the individual images to remove stationary features such as bony anatomy. Rigid registration is then used to determine the offset of the actual pancreas from that defined on the DRR. The method is applied to a high-contrast test object to verify the performance of the software, and also retrospectively applied to four patients with pancreatic cancer. In each case, the results are compared with the actual position of the PTV as determined using Cyberknife itself, using fiducials for the patient cases. The median accuracy of tracking with CKImage for the 177 image pairs acquired of the high-contrast test object is 0.8 mm (range 0.0 – 21.8 mm). The median accuracy of tracking for the 1249 image pairs acquired of the pancreas patients is 4.1 mm (range 0.2 – 16.1 mm). There is much scope for improvement in the method, but the novel imaging approach shows promise for minimally invasive treatment of pancreas cancer.

1 Introduction

The Cyberknife system (Accuray Inc., Sunnyvale, CA) consists of a short waveguide 6 MV linear accelerator mounted on a robotic arm, and with a choice of fixed cone collimator, variable iris collimator or high resolution multileaf collimator, is ideal for intracranial or extracranial stereotactic radiotherapy. The planning target volume (PTV) is tracked accurately using two orthogonal kV imaging systems, mounted at 45° to the horizontal plane [1].

The Cyberknife system has great potential for treatment of pancreatic cancer, where stereotactic ablative body radiotherapy (SABR) is currently of considerable interest. The imaging system of the Cyberknife can be used to track the respiratory motion of the target volume in real time, thereby minimizing margins and dose to surrounding critical structures. However, the pancreas is currently not explicitly visible on the kV images, and fiducial markers are therefore inserted to enable tracking. Although this is a successful approach, insertion of the markers can lead to clinical complications, so tracking without fiducial markers is a desirable research goal.

Other authors have reported on tracking pancreas using kV images without fiducial markers. For example, Zhou et al. [2] train a deep learning prediction model for each patient to predict the contour location based on the digitally reconstructed radiograph (DRR). They then test the method on further orthogonal DRRs and are able to predict the location of the clinical target volume (CTV) to within 1 mm accuracy. The scenario described is well-defined, so high accuracy is to be expected, but the results are promising for markerless tracking. A related work studies inter-patient organ-at-risk deformation in the organs surrounding the pancreas [3].

These studies form the basis of a more general and challenging study of mapping 3D organ models onto 2D kV images in the presence of organ motion [4]. For the pancreas gross tumor volume (GTV), the surface of the volume is predicted with a median accuracy of 1 mm, maximum error of 5 mm and dice similarity coefficient of around 90%. Similar results are obtained for the other abdominal organs, but with a maximum error of around 10 mm. Accuracy is approximately 1 mm worse when setup errors are included. This is therefore a more general model which is capable of transforming 3D organ structures according to 2D images, which is very relevant to the Cyberknife scenario.

The increasing experience of magnetic resonance (MR)-guided treatment is also a possibility for radiotherapy of pancreatic adenocarcinoma [5]. Stemkens et al. [6] report a study of 4DMR pancreas imaging in which they produce 10 k-spaces at the 10 phases of the breathing cycle. They use deformable image registration to quantify the motion of the pancreas and duodenum. Grimbergen et al. [7] treat 13 patients using stereotactic ablative body radiotherapy (SABR) to 5 x 8 Gy in the MOMENTUM study. Motion is minimized using an abdominal corset. Interfraction motion is found to be stable, and breathing amplitudes are in the order of 1-4 mm, these amplitudes being quantified in each of the three cardinal directions.

These studies are the motivation for the present work, which aims to develop a software system capable of tracking pancreas without fiducial markers with sufficient speed and accuracy that it can be used in real time to track pancreatic target volumes during treatment on the Cyberknife. In this paper, the software is described, the methods outlined and benchmarking tests reported in which the current speed and accuracy of the system are evaluated for a small retrospective cohort of pancreatic cancer patients.

2 Materials and Methods

The image processing for this project, was performed using in-house software CKImage v1.1. This was written in multithreaded Java (Oracle Corporation, Reading, UK) for maximum flexibility and platform-independence. The graphical user interface (GUI) for this software is shown in figure 1.

Although eventually, the goal is to use the software in a real-time context, at present it is operated in an offline retrospective approach. When a patient is loaded, the software reads the patient data file structure that is normally used for providing patient information to Accuray. The planning computed tomography (CT) scan and outline set are read and the PTV delineated on the planning CT scan is projected onto the DRRs in the image planes to define the region of interest. The DRRs themselves are created by the Precision software (Accuray Inc.) using bone suppression, where necessary, so as to remove confounding bony anatomy from the DRRs, leaving the soft tissue.

The acquired kV images are filtered using a band-pass cosine-shaped filter to increase the image sharpness without excessively accentuating the high-frequency noise, and the average image is subtracted from the individual images to remove stationary features such as bony anatomy. This is most effective when there are many images in the sequence being analyzed. A rectangular bounding box is defined which encloses the PTV projection with a margin of 30 mm, and the image intensities of the DRR and treatment images are equalized in this region. Rigid registration is then used to determine the offset of the actual pancreatic PTV projection from that defined on the DRR using a quadratic penalty function in the bounding box. An additional term in the penalty function increases with increasing mis-registration of the DRR and treatment images, thereby discouraging large, implausible shifts. At present, only shifts are used in this process, without rotations. Geometric considerations are then used to convert 2D shifts to 3D.

Computationally, the GUI class responds to user requests in the GUI and SwingWorker threads are used to accomplish more demanding tasks. For the tracking process, the application thread filters the images, using one thread per pair of images in the set of images to be processed. The registration process is carried out sequentially with respect to the set of images, but multiple threads are used to register each pair of images. The superoinferior position of each image pair is synchronized as a shift in anatomy in this direction is reflected equally in both images. These shifts are dealt with by multiple threads, and the independent orthogonal shifts, one for each image, are dealt with sequentially within those threads (figure 2).

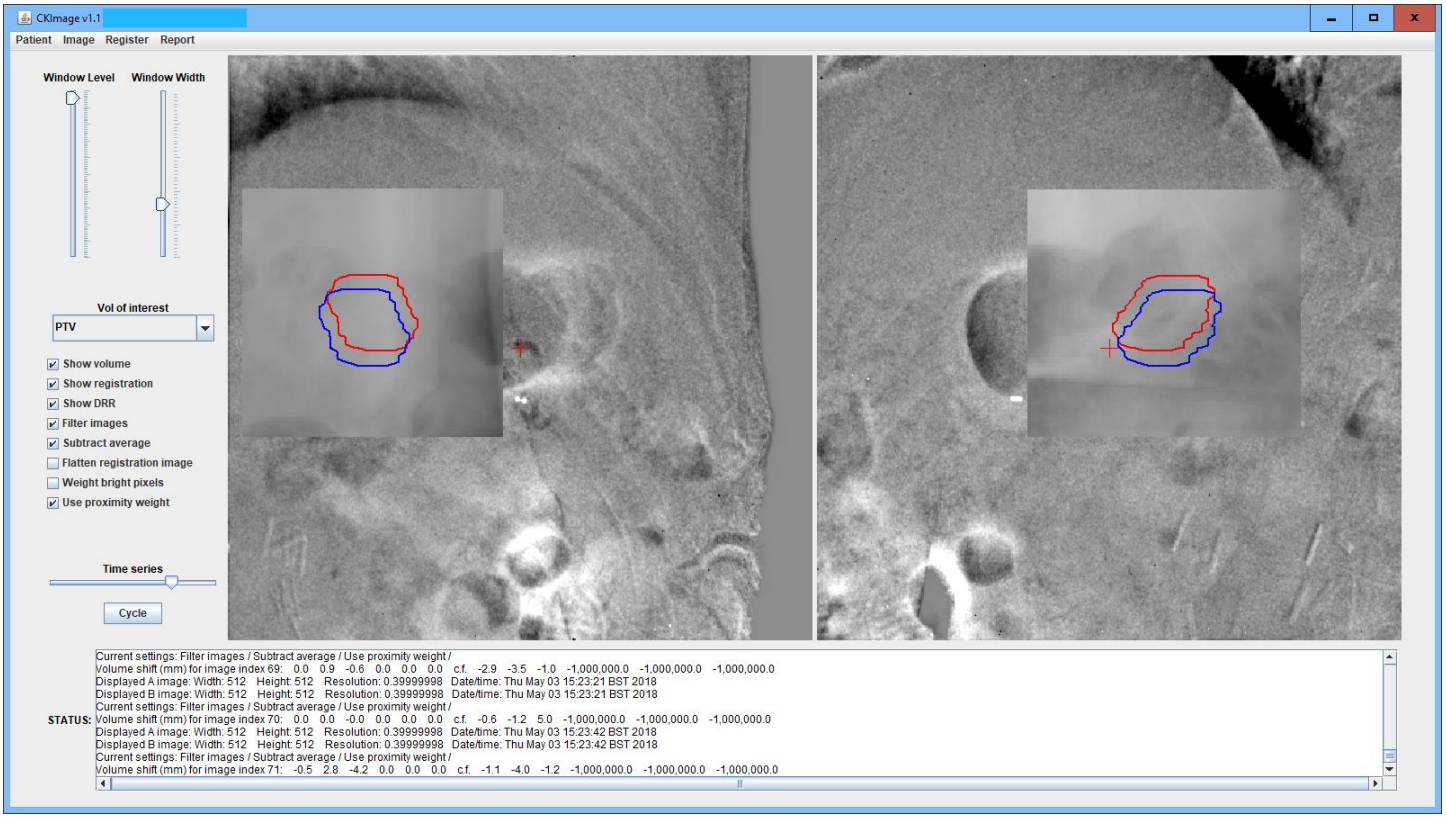

Figure 1. Graphical user interface for the CKImage software. The outlines of the planning target volume from the planning scan are shown in red and the corresponding matched regions in the treatment images are shown in blue. The digitally reconstructed radiographs are shown around the planning target volume. The results are reported in the status panel for each of the images in the time series as lateral, anteroposterior and superoinferior offsets of the imaged volume of interest with respect to the volume of interest projected onto the digitally reconstructed radiograph.

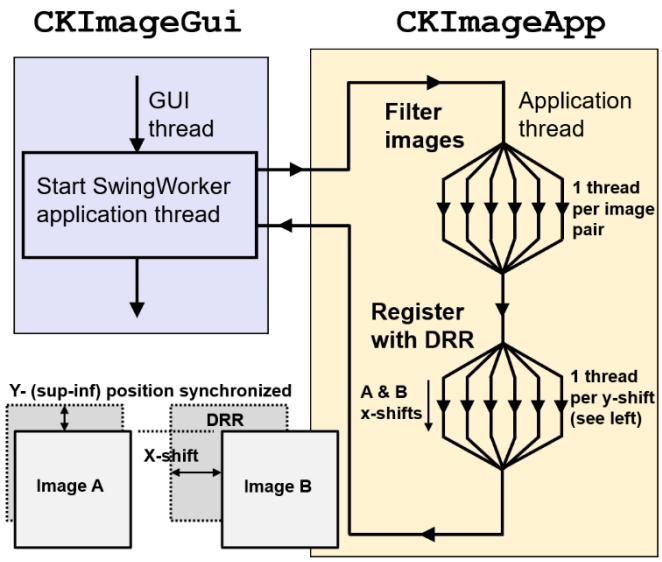

Figure 2. Thread structure of the CKImage software.

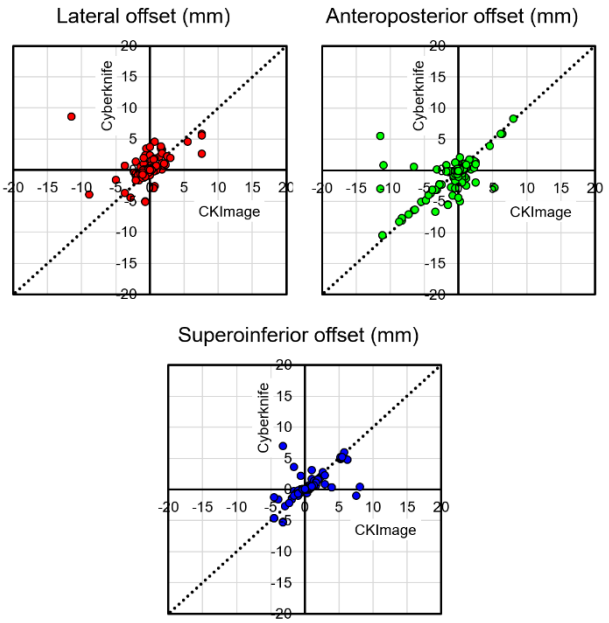

Figure 3. Comparison of positions recorded by CKImage and Cyberknife for the high-contrast test object. The 1:1 diagonal line is to guide the eye.

In this benchmarking study, the method was applied to 177 pairs of images acquired of a dose checker device, which formed a high-contrast test object. The results were compared with the rigid registration method ('6D skull') used by Cyberknife during positioning of the device. The method was also applied retrospectively to 1249 pairs of images acquired from four patients with pancreatic PTVs. As the patients were treated with fiducials, there were fiducials present in the treatment images, but the fiducials were removed from the DRRs by the bone suppression algorithm used, so this was not considered to influence the registration algorithm. The results using CKImage were compared with those produced at the time of treatment using a point-based fiducial registration method.

3 Results

The software takes 1-5 s to register each image in the time sequence using 16 processor threads, depending on the size of the planning target volume and the margin around it. Test results using the high-contrast test object are given in table 1 and the distribution of differences between CKImage and Cyberknife is shown in figure 3.

Table 1. Absolute differences between CKImage and Cyberknife for the high-contrast test object.

	Median (mm)	Min (mm)	Max (mm)
Lateral	0.4	0.0	20.1
Anteroposterior	0.3	0.0	17.0
Superoinferior	0.3	0.0	10.2
3D difference	0.8	0.0	21.8

The agreement for the four clinical patients between fiducial and fiducial-free tracking is shown in table 2 for the three cardinal directions. A histogram of the 3D differences is shown in figure 4.

Table 2. Absolute differences between CKImage (markerless tracking) and Cyberknife (fiducial tracking) for the four pancreatic target volumes.

	Median (mm)	Min (mm)	Max (mm)
Lateral	1.2	0.0	10.1
Anteroposterior	1.7	0.0	9.5
Superoinferior	2.4	0.0	15.3
3D difference	4.1	0.2	16.1

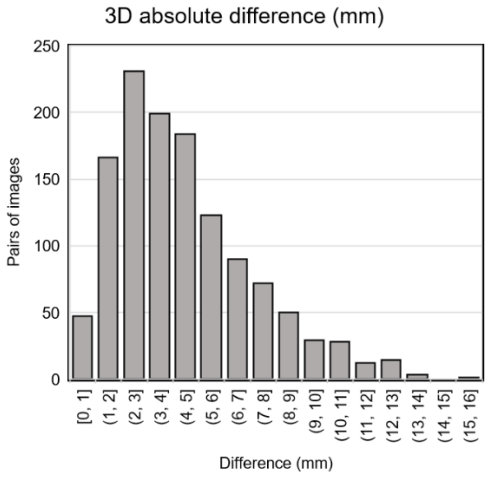

Figure 4. Histogram of absolute 3D differences between markerless (CKImage) and fiducial (Cyberknife) tracking for the four patients with pancreatic targets.

4 Discussion

This study uses image processing and careful image region matching to provide optimal conditions for accurate correlation of the DRRs and the treatment images. The results demonstrate that for a well-defined geometric target and for a small cohort of pancreas targets, it is possible to identify the position of the PTV in patient space from the treatment images relative to the DRRs with a median accuracy of several millimeters. For the well-defined target, the accuracy is better than in the pancreatic targets, where the target volume and surrounding anatomy is considerably less well defined on both the DRRs and treatment images.

This accuracy is promising but not as high as that shown by Nakao et al. [4]. In their study, an image generative network is used to map from 2D images, in the form of DRRs with randomly added setup shifts, to 3D deformation vectors. These vectors, together with vertices from 3D organ models are then input to a graph convolutional network to provide deformed 3D organ shapes. This approach allows multiple vertex points in the organ model, all projecting to the same 2D image point, to have different deformations. This is a much more sophisticated method than that of the present study, but it also uses DRRs to represent kV images, thereby permitting greater accuracy.

The present work compares markerless tracking with fiducial tracking at the time of treatment, but further work is needed to compare with a static method without tracking to ensure that the method is superior to an approach using an internal target volume. Further work is also desirable to define a more customized bounding region for the registration process. Use of rotations is thought to be a useful addition to the process, although rotations are not very prominent in this tumor site.

Deformable image registration may also be valuable for dealing with multiple organs in the pancreatic region. As an intermediate step, it may be useful to perform separate rigid registrations for several organs in the vicinity and then combine these into an overall map of organ displacement. Some measure of the dosimetric impact of the loss in accuracy of the markerless tracking method compared to tracking with fiducials is also desirable. The methods described in this study may also be beneficial for other abdominal tumor sites.

5 Conclusion

This study demonstrates the performance of new software for the tracking of pancreatic targets. The software currently operates retrospectively, but the multithreaded design is expected to give sufficiently high speed that it can be applied in the real time context. This study is limited to some preliminary comparisons, but using a small cohort of pancreas patients shows that the software is able to perform tracking without fiducials. The median accuracy appears to be in the order of 4 mm for pancreas. Some further developments are also proposed.

Abstract Deep learning has demonstrated to be capable of predicting realistic radiotherapy dose distributions. Collecting and curating clinical data is a labour-intensive and time-consuming task, making large, curated datasets scarce for training deep learning dose prediction models. Partly due to the lack of training data, model size has never been fully explored in previous studies. In this study, we investigated how training dataset size and model size impact 3D dose prediction performance for prostate cancer. For a curated dataset consisting of 1250 contoured planning CT-scans, ground truth dose distributions were fully automatically generated for each patient using Erasmus-iCycle, guaranteeing consistent trade-offs. Three HD U-Nets with two, four and six pooling layers were trained from scratch with different sized datasets (50/250/1000 plans) for prediction of dose distributions. Mixed precision was applied to optimize GPU VRAM usage. Prediction accuracy was lowest for the 2-level model, while differences between 4-levels and 6-levels were small. For all model sizes, agreement improved with increasing training dataset size, suggesting that more training patients could further increase prediction accuracy.

1 Introduction

Treatment planning for RT is a fragmented, labor-intensive and time-consuming collaboration between physicians, medical physicist and dosimetrists. There is a growing need for shorter treatment planning times, as cancer incidences and staff shortages are increasing [1], while the RT field is also moving towards (online) adaptive treatment strategies and same-day treatment [2]. Although multi-criterial optimization based automated treatment planning as applied in our center has shown to drastically reduce hands-on treatment planning workload in the clinic while producing high quality plans [3, 4], substantial computational time is required. Deep learning has been proposed to predict the patient-specific 3D dose in the order of seconds [5, 6, 7, 8]. The predicted dose can either be used as a directive for the physician [9] or converted to machine parameters to obtain a deliverable treatment plan [10, 11]. From previous studies it is expected that the dosimetric performance of deep learning dose prediction depends on the size and quality of the dataset used for training [12, 13]. However, no consistent dataset size study has been performed to assess whether larger datasets could improve prediction accuracy. In addition, model size has never been fully explored in previous works.

In this study, we systematically investigated the impact of training dataset size and model size on 3D dose prediction performance for prostate cancer, using a curated dataset of 1250 contoured planning CT-scans. All ground truth (GT) plans used for the analyses were generated with Erasmus-iCycle [14], a system for fully automated multi-criterial plan generation, guaranteeing consistent trade-offs between all treatment objectives. Many studies have demonstrated superiority of Erasmus-iCycle plans compared to manual planning [3, 4, 14, 15, 16, 17].

2 Materials and Methods

2.1 Patient Cohort

Patients with low, intermediate or high-risk prostate cancer without metal hip prostheses were included in this study. The data was combined from two sources: 719 patients were included from the multicenter phase 3 randomized trial on hypofractionation for prostate cancer (HYPRO) [15, 18], which was complemented with 531 recent patients from the Erasmus University Medical Center Rotterdam.
Erasmus-iCycle was used to automatically generate for each patient a 10 MV 23-beam GT IMRT plan, mimicking VMAT dose distributions, using original CT resolutions. The clinically established and applied delineations of the target volumes, rectum, anus, femoral heads, bladder and body were also used in this study. The patient cohort consisted of three groups, based on the risk of involvement of the seminal vesicles. For Group 1 patients, a dose of 78 Gy (PTV high) was prescribed to the prostate. For Group 2, a dose of 78 Gy was prescribed to the prostate and 72.2 Gy (PTV low) to the seminal vesicles. In Group 3 patients, prescribed dose for both prostate and seminal vesicles was 78 Gy.

2.2 Experimental setup for Deep Learning

The CT scan, binary masks of the structure delineations and GT dose distributions were downsampled to a grid size of 256 x 256 x 128, reflecting a patient resolution 1.95 x 1.52 x (1.5-3) mm^3, where the original slice distance was conserved. The data was divided into 1000 training, 100 validation, and 150 test patients using stratified sampling. Stratification was based on the patient Groups (1-3), size of the patient in the isocenter slice, and the volume of the high

dose target. For training, target volumes were combined into one target map where each voxel value was set to the corresponding prescription dose. Generated models had seven input channels: the CT scan, target map, and binary masks of the anus, bladder, rectum, combined femoral heads and patient contour. The Hounsfield units in the CT were clipped to a range of [-1000, 1500] to improve training convergence, following Liu et al.[19]. All model inputs were left unscaled for training.

The dose prediction models for the investigated dataset sizes and model sizes were based on the Hierarchically Densely Connected U-Net (HD U-Net) architecture proposed by Nguyen et al. [20]. We extended the HD U-Net with a mixed precision learning strategy to optimize VRAM usage. Three HD U-Nets with two, four and six pooling layers were separately trained on randomly stratified subsets of the training data, N=50/250/1000 (5/25/100%), resulting in nine trained models. All model training was performed with the Adam optimizer with a learning rate of 10^{-4}, batch size of 1 and mean squared error (MSE) as the loss function. We trained each experiment with four different patience parameters (5, 10, 15 and 20) for the reduce on plateau learning rate scheduler, and early stopping with a threshold of 25 epochs was used to reduce overfitting. The model with the lowest validation loss was used to assess the test data. Training of all models was performed on a cluster with 15 NVIDIA A40 GPU cards with 48 GiB of VRAM.

Predicted dose distributions were interpolated back to their original CT resolutions. All models were evaluated on the same test set without normalization of doses. The performance of the models was evaluated using dose metrics, spatial dose distributions, mean absolute error (MAE) and MSE. To evaluate target dose, we computed $V_{95\%}$ for PTV high and PTV low, and $V_{107\%}$ for PTV high for the predicted dose distributions and GT. For the rectum, we computed V_{75Gy}, V_{60Gy} and Dmean. The bladder was evaluated for V_{65Gy} and Dmean, and anus for Dmean. The near maximum dose, $D_{0.03cc}$, was used to evaluate dose delivered to the femoral heads, and V_{20Gy} was computed for the patient contour to evaluate the prediction quality in the low to intermediate dose regions. Statistical significance of differences between predicted and GT parameters was assessed with two-sided Wilcoxon signed rank tests, using $p<0.05$ for significance.

3 Results

Figure 1 shows predicted and GT dose distributions for an axial slice of a random patient from the test set. Where the 2-level model with 50 training patients only gives an impression of the dose distribution, details start showing up with 4-levels and 250 training patients, with highest correspondence to GT for the 6-level model and 1000 training patients. For the 4-level and 6-level models, the accuracy of the predicted dose distributions clearly increased with more training data, especially regarding the distinct spikes in the intermediate dose regions (20-30 Gy). In figure 2, the population MAE and MSE show the same trend. For all model sizes, a reduction in both metrics was found with increasing training dataset size, indicating that more plans are needed for training to reach convergence. For each training dataset size, the 4- and 6-level models clearly outperformed the 2-level model in both MAE and MSE, while differences between the 4-level and 6-level models were minor for all dataset sizes.

Figure 3 shows box-and-whisker plots for the selected dose metrics. Overall, all models showed good performance for targets and OARs. For PTV high $V_{95\%}$, PTV low $V_{95\%}$, rectum V_{75Gy}, rectum V_{60Gy}, bladder V_{65Gy}, bladder Dmean, anus Dmean and patient V20, increases in agreement between predictions and GT were observed with increasing training dataset size. For fixed dataset sizes, no noticeable differences were observed between model sizes, except for bladder Dmean and V_{20}, where the 2-level models had larger errors. The 6-level model trained on 1000 patients had overall the smallest dose metrics differences between predictions and GT.

4 Discussion

The purpose of this study was to systematically investigate the effect of training dataset size and model size on deep learning 3D dose prediction accuracy for prostate cancer, based on a large curated dataset of contoured planning CT-scans and corresponding highly consistent, automatically generated GT plans.

The 3D dose distributions showed a consistent trend in dosimetric detail when using more data and/or deeper models (Fig. 1). The MAE and MSE (Fig. 2) were clearly highest for the 2-level model, while differences between 4-levels and 6-levels were small. For all model sizes, MSE and MAE went down with increasing training dataset size, suggesting that more patients could further increase prediction accuracy. Differences in the 20-30 Gy areas (spikes in Fig. 1) contributed substantially to the found MSE and MAE differences. A study by Kandalan et al. [21] also showed issues with prediction accuracy in these dose regions. Probably, there is more dosimetric variation between patients for intermediate and low doses.

Contrary, for the evaluated (high dose) plan parameters, there was overall no clear dependency of prediction accuracy on model size, while predictions based on 1000 training patients were slightly more accurate than those for 250 or 50 training patients (Fig. 3).

Given the observations, evaluation of deep learning dose prediction accuracy based only on target and OAR plan parameters appears insufficient for a full assessment.

This study was based on a large dataset with highly consistent, automatically generated GT plans. It remains to be investigated how the conclusions from this work will translate to datasets with clinically/manually generated plans. Due to well-known variability in quality and trade-offs in manual plans, we do expect that convergence will already be reached with smaller training datasets, and differences between model sizes will become smaller.
This study has some limitations. We have only investigated model size in terms of model depth. U-Net based architectures are capable of capturing global information. That capability is influenced by the number of trainable parameters. The number of trainable parameters of a model can be increased in more ways than only in depth. Further research is needed to investigate if model width can compensate for a lack of depth. This study investigated prostate dose prediction. In a next study, we will investigate dataset size and model size for head-and-neck cancer, with more anatomical variability and more complex treatment plans than the prostate site. Currently, data is gathered to create a large size head-and-neck database.

5 Conclusions

Using a large set of fully-automatically generated prostate cancer plans with consistent trade-offs, increasing the training dataset size from 50 to 250 to 1000 patients resulted for (high dose) PTV and OAR plan parameters in relatively small reductions in differences between deep learning predictions and GT. More substantial differences were found for dose spikes in the 20-30 Gy dose range around the PTV. For all model sizes, MAE and MSE decreased with dataset size, possibly indicating that further enhancing the training dataset size could further increase prediction accuracy.

Abstract

Doses deposited outside the treatment field during external photon-beam radiotherapy, known as out-of-field doses, appear to favor the appearance of radiation-induced cancer and hematological toxicities. These low doses are not currently estimated on a routine clinical basis, due to the lack of a suitable solution.
With this proof of concept, we demonstrate the value of deep learning for the development of a tool enabling rapid, routine-compatible out-of-field dose estimation. For this purpose, a 3D U-Net, considering as inputs the in-field dose, as computed by the treatment planning system, and the patient's anatomy, was trained to predict out-of-field dose maps, using a dataset of 3151 pediatric whole-body dose maps estimated with analytical methods as ground truth. Consistent results in line with the literature were obtained (RMSD of 0.28, 0.41 and 0.32 $cGy.Gy^{-1}$ for the training, validation and testing), arguing in favor of the use of neural networks for out-of-field dose estimation.

1 Introduction

In external beam radiotherapy (EBRT) with photons, non-zero doses are inevitably delivered outside the treatment field; often referred to as out-of-field or peripheral dose. The out-of-field doses are mostly low dose values (< 4 Gy), but the question of their potential impact on the probability of radiation-induced adverse events, such second cancers (1) and immunological dysfunctions like radiation-induced lymphopenia (2) is of the utmost importance. In particular, it has recently been shown that even very low doses resulting from computed tomography (CT) scans contribute to the development of radiation-induced cancers (3). In radiotherapy, this topic is currently experiencing renewed interest, particularly as modulated treatments (such as volumetric modulated arc therapy (VMAT) or intensity-modulated radiation therapy (IMRT)) are now routinely used in clinical care and are known to be associated with higher peripheral doses due to longer beam on times and larger irradiated volumes when compared to three-dimensional conformal radiotherapy (3D-CRT) (3,4)

Treatment planning systems (TPS) are used in clinical routine to estimate in-field dose distribution, but have been shown to systematically underestimate out-of-field dose for 3D conformational radiotherapy treatments, for intensity modulated treatments and for CyberKnife devices (Accuray, Sunnyvale, USA) (5–8). Thus, despite clear clinical potential, the out-of-field dose computation is currently not available in clinical practice. Two methods are currently used in the literature for out-of-field dose estimation for research purposes: Monte Carlo simulations and analytical approaches. These methods can provide accurate out-of-field dose estimation (7) but are inappropriate for clinical routine implementation, because of their lack of versatility and their cumbersome application (9).

Artificial intelligence and in particular technologies based on deep learning (DL) have drastically changed clinical practice in radiotherapy in recent years, allowing notably the automation of several time-consuming tasks, including segmentation and treatment planning, or the generation of virtual images (synthetic images), demonstrating their ability to identify complex hierarchical features from spatially structured data (10). Three main components contribute to the out-of-field dose: patient scatter, head scatter and head leakage. Apart from leakage, which is a signature specific to each accelerator and whose signal is minimal in the irradiation field, the other components exhibit a valuable in-field signal for assessing the out-of-field dose. Based on the assumption that the in-field dose map associated with the patient's anatomy contains most of the information needed to calculate the out-of-field dose, our objective was to evaluate the ability of a unique deep learning-based out-of-field dose estimation algorithm to adapt to a wide variety of configurations, bringing an answer to the problems of computation time, information extraction, and versatility, making it compatible with clinical use.

2 Materials and Methods

Three thousand one hundred fifty-one whole-body dose maps, from the French childhood cancer survivor study (FCCSS) cohort were used as ground truth for the development of our neural network. With the goal to develop a deep learning model for out-of-field dose estimation suitable for megavoltage photon irradiations, we only selected patients treated with a photon beam and using linear accelerators with a high voltage (> 1 MV) or ^{60}Co irradiators. Whole-body dose maps were estimated using an analytical method originally developed for epidemiological purposes (11,12). Twenty-five irradiation devices were represented in our dataset and were grouped into 3 categories: standard linacs, cobalt units and betatron units. Our dataset included 38 different pathologies, of which the most represented were nephroblastoma and other nonepithelial renal tumors (695 patients), Hodgkin lymphomas (449 patients) and astrocytomas (235 patients).

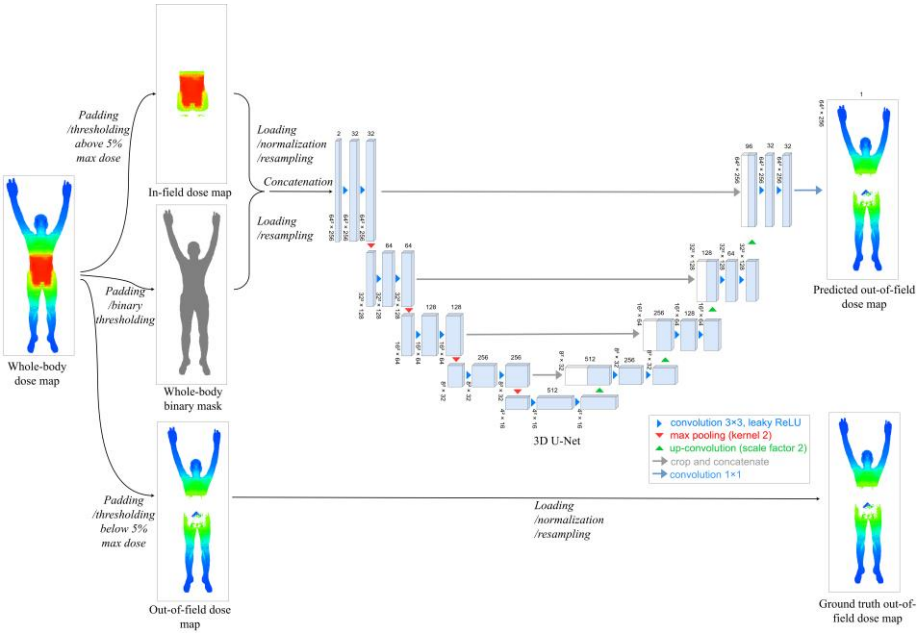

Figure 1 Dose map preprocessing pipeline and comprehensive design of the implemented 3D U-Net. Dose maps are displayed using logarithmic scale

Several preprocessing steps were applied to the analytical dose maps to make them deep-learning compliant. These included: 1) padding into [370, 242, 1131] matrix sizes, 2) resampling of padded files (originally in Statistical Analysis System (SAS) format) to [128, 128, 512] sizes, 3) extraction of in-field and out-of-field dose maps from whole-body dose maps (a 5% isodose threshold was chosen in this goal considering the maximum dose per patient as the reference dose), 4) creation of binary masks from the whole-body dose maps by a thresholding method separating the background from the foreground. An on-the-fly preprocessing pipeline was then applied using Medical Open Network for Artificial Intelligence (MONAI 0.8.0) (13), including in the following order: loading, normalization, resampling, and concatenation. During the normalization step, 3D dose maps intensities were normalized by dividing by 100 Gy, to provide the neural network with values within [0,1]. The on-the-fly resampling step was implemented to test the impact of batch size as a function of available VRAM (video random-access memory). A nearest neighbor interpolation strategy was used for the resampling step. Finally, we transformed the data to fit a multi-dimensional structure denoted as B×2×H×W×D. In this expression, B refers to the batch size used during the training phase of the process. C indicates the number of channels present, while H, W, and D correspond to the height, width, and depth of the matrix, respectively. Figure 1 summarizes the preprocessing pipeline.

A conventional 3D U-Net (14,15), composed of four down-sampling blocks followed by four up-sampling blocks, was implemented (Figure 1). The Mean Square Error (MSE) evaluated only on the foreground voxels outside the 5% isodose, i.e. only in the region considered as the out-of-field dose, was selected as loss function. Learning rate and weight decay were considered in the ranges $[1e-7, 1e-3]$ and $[1e-8, 1e-4]$, respectively, with 1e-4 and 1e-6 providing the optimal results. The Adam optimizer was used to update the network parameters. Instance normalization was preferred. Batch size of 20 corresponding to a resampled size of $64 \times 64 \times 256$ was selected. The 3D U-Net was trained for 600 epochs (~50 hours) on a Nvidia RTX A6000. No early stopping was used. Weight based on best performance on validation loss were saved.

The dataset of 3151 patients was conventionally split into training (N = 2213), validation (N = 505), and test cohorts (N = 433). The test set was divided into 5 sub-cohorts, including two classic linear accelerators (names of accelerator model unavailable) operating at 6 MV and 16 MV, two cobalt 60 units (Alcyon and Mobiletron), and finally a betatron operating at 1.25 MV. All patients treated with betatron devices were voluntarily kept into the test set, because of its very specific design compared with a conventional linear accelerator or a cobalt unit. None of the devices in the test set were included in the training and validation sets. This was made in order to test the generalizability of the trained network on unknown devices.

We finally performed 2 additional experiments. The first aimed at evaluating if the inclusion of betatron-treated patients in the training set could improve performance for a subgroup of 46 patients here considered as a new sub-test set. The second additional experiment aimed to study the

benefits of a custom model, compared with the use of a generalized model. In this aim, we selected 100 of the 128 patients treated with a ^{60}Co-Alcyon, and trained the 3D U-Net from scratch considering only these data. Finally, as a last experiment, we fine-tuned the original model using the 100 ^{60}Co-Alcyon training patients for 2000 epochs and tested the performance of this fine-tuned model on the 28 ^{60}Co-Alcyon patients included in the test set. We used the root mean square deviation (RMSD) (corresponding to the root of the MSE) as performance evaluation metric.

3 Results

Best performances were achieved at epoch 467/600. For visual purposes, Figure 2 shows three examples of out-of-field dose maps generated by our trained network from test sets for patients with good (RMSD of 0.16 cGy.Gy^{-1}), median (RMSD of 0.29 cGy.Gy^{-1}) and poor performance (RMSD of 1.00 cGy.Gy^{-1}). RMSD of 0.28 ± 0.08 and 0.41 ± 0.26 cGy.Gy^{-1} were obtained for the training and validation datasets, respectively. Values of 0.27 ± 0.06, 0.26 ± 0.07, 0.28 ± 0.06, 0.30 ± 0.12 and 0.45 ± 0.25 cGy.Gy^{-1} were achieved for the 6 MV linac, 16 MV linac, ^{60}Co-Alcyon, ^{60}Co-Mobiletron, and betatron devices test sets, respectively, demonstrating overall performance similar to or better than that of the validation set, except for the fifth test set, corresponding to the betatron device. A RMSD threshold value of 0.6 cGy.Gy^{-1} was considered to separate good from poor out-of-field dose reconstructions. 87 out of 505 patients showed weaker performances in the validation set; 85 of whom being treated with a single device: a Sagittaire linear accelerator operating at 25 MV. This value was equal to 24 (out of 433 patients) in the test set, with 21 of the 24 patients identified having been treated with the betatron accelerator.

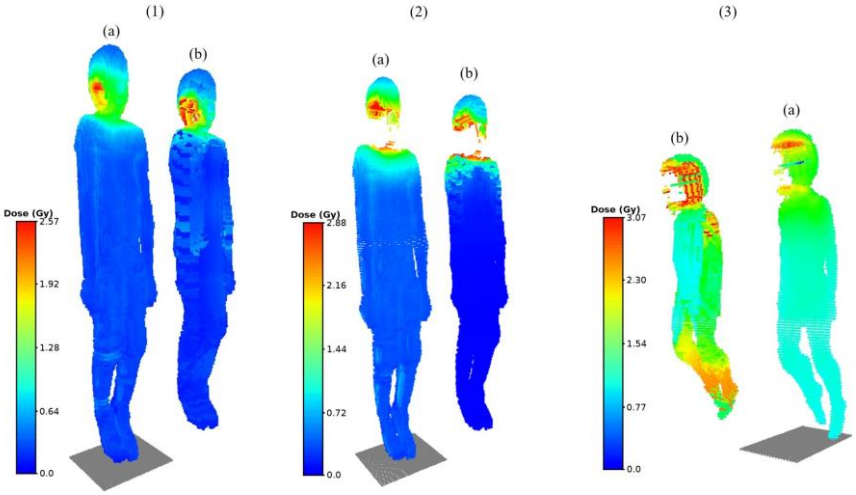

Figure 2 Comparison of out-of-field dose maps predicted by the 3D U-Net (a) and computed by the analytical model, the ground truth (b), for 3 patients. Patient 1 (RMSD=0.16 cGy.Gy^{-1}, into the 5% percentile) corresponds to a 15-year-old girl diagnosed for a primary pathology of retinoblastoma in 1982 and treated with a Neptune 6 MV device. Patient 2 (RMSD=0.29 cGy.Gy^{-1}, in ± 1% of median) is also a 15-year-old girl who was diagnosed and treated in 1982 for an intracranial neoplasm using an Alcyon 60Co device. Patient 3 (RMSD=1.00 cGy.Gy^{-1}, below 95% percentile) is a 5-year-old girl diagnosed in 1982 treated the same year with a 1.25 MV betatron device for an

Retraining the neural network using the original patient training set plus the 46 betatron patients kept aside resulted in a mean RMSD of 0.64 ± 0.41 cGy.Gy^{-1}, to be compared with 0.26 ± 0.11 cGy.Gy^{-1} for the same 46 patients as a benchmark value (no betatron patients included at the training stage). For the second additional experiment, mean RMSDs of 0.16 ± 0.01 cGy.Gy^{-1}, 0.53 ± 0.22 cGy.Gy^{-1} and 0.13 ± 0.05 cGy.Gy^{-1} were obtained for the benchmark configuration, configuration considering training with only the 100 ^{60}Co-Alcyon training set patients, and configuration considering the original model fine-tuned with the 100 ^{60}Co-Alcyon training set patients, respectively.

4 Discussion

The results are rather encouraging, with RMSD values of the same order of magnitude in the test sets (mean value of 0.32 ± 0.15 cGy.Gy^{-1} in the test set) as in the validation set (0.41 ± 0.26 cGy.Gy^{-1}) or the training set (0.28 ± 0.08 cGy.Gy^{-1}), suggesting that the neural network has acquired a strong degree of robustness and generalization. However, we notice that significantly lower results were observed for test set corresponding to the betatron accelerator. In addition, most of the poorest results in the validation set concerned patients treated with the Sagittaire accelerator operating at 25 MV (the highest voltage of the linear accelerators considered in the training set was equal to 20 MV). These results logically highlight the fact that the generalization capabilities of the neural network cannot be extended to out-of-distribution cases including non-conventional or highly atypical linear accelerators, i.e. with different spectral characteristics, shielding properties, or head geometries. Another limitation of our proof of concept is the tendency by the neural network to systematically overestimated doses at locations farthest from the field. This discrepancy appears to stem from our choice of cost function (MSE), which minimizes absolute dose errors. Consequently, the greatest relative deviations are observed in these distant regions, where the lowest dose are expected.

The first additional experiment shows that adding betatron patients to the training set resulted in an unexpected decline in performance (0.26 ± 0.11 cGy.Gy^{-1} for the benchmark compared to 0.63 ± 0.41 cGy.Gy^{-1} when considering betatron patients in the training set). We hypothesize that the number of betatron cases in the training set is too small to allow the neural network to converge towards a solution tailored to this accelerator, and that this accelerator may be too unusual and confuses the network. The results obtained from the second additional experiment demonstrated that the model developed from 100 ^{60}Co-Alcyon patients showed poorer averaged performance on the 28 ^{60}Co-Alcyon test patients than the original model, trained

without any ^{60}Co-Alcyon data, but on more than 2000 patients (0.53 ± 0.22 cGy.Gy^{-1} for the custom model versus 0.16 ± 0.01 cGy.Gy^{-1} for the benchmark). This suggests that the inclusion of a wider variety of patient anatomies and irradiation configurations allows the network to better predict out-of-field dose distributions than focusing on a model that has been trained on data from a single accelerator, but with a smaller number of patients and diversity of treatment conditions. The results of the fine-tuned model nevertheless demonstrate the benefits of specializing the model to a certain extent. Indeed, the fine-tuned model makes it possible to achieve hitherto unequalled performance (0.13 ± 0.05 cGy.Gy^{-1}). This approach appears to be the most promising since it enables both optimizing performance on a particular machine of interest and using the vast diversity of treatment conditions found in the original database.

To address the identified limitations (overestimation of the lowest dose values far from the field and limited application for the most atypical linear accelerators), a strategy involving the incorporation of a relative or local component in the network's cost function, along with the inclusion of additional data in the training dataset, could offer remedies. Furthermore, a separate research team is collaboratively working on developing whole-body dose maps for contemporary linear accelerators and treatments, such as intensity modulation, using Monte Carlo simulation. Retraining the network with these new data will enhance its applicability to modern irradiation conditions. Finally, we carried out experimental measurements (and are still continuing this campaign) on a whole-body anthropomorphic phantom using radiophotoluminescent dosimeters with the aim of experimentally validating the whole-body dose maps generated by deep learning.

5 Conclusion

Based on this proof of concept, we have shown that deep learning is a relevant tool for addressing the limitations of analytical methods or MC simulations for out of field dose estimation. Thanks to its generalization capabilities and short inference times of just a few seconds, this tool should make it possible to move forward for routine clinical application and mass application in retrospective studies. We are convinced that a tool for estimating out-of-field dose in clinical routine would be a powerful aid for optimizing modern radiotherapy treatments.

Accurate Selection of Calculation Grid Size for Radiation Plans with Small Brain Tumors in Intracranial Stereotactic Radiotherapy

T.A-ALAWI, M. AL-GAOUD, E. RASHAIDI, N. SHORBAJI

Department of Radiotherapy, King Abdullah Medical City, Makkah, Saudi Arabia

1 Introduction

Stereotactic Radiosurgery or Radiotherapy SRS/SRT and Stereotactic Body Radiation Therapy SBRT technique facilitates delivery of high doses of radiation to the target volume in one to five fractions with acceptable toxicities to OARs.

Faster treatment time, higher accuracy in the delivery of high total dose to the target with acceptable toxicities to OARs, and patient comfort all contribute to a better clinical outcome [1]. SRS/SRT treatment for brain tumors requires conformity in both high and intermediate dose regions for better sparing normal brain tissue [2].

Intracranially, there are many indications that are currently being treated with SRS including, for example, AVMs, acoustic neuroma, meningiomas, pituitary adenoma, vagal schwannoma / paragangliomas, brain metastasis, anaplastic astrocytoma/ glioblastoma multiforme (GBM), trigeminal neuralgia, cochlea, thalamotomy, and pallidotomy [1]. Volumetric modulated arc therapy (VMAT) is a common treatment method for brain SRS/SRT which leads to a greater improvement in the radiation therapy treatments, where the radiation is delivered by the rotation of the linear accelerator gantry along one or more arcs, with the beam continuously on.

Typically, VMAT brain treatment planning is done with a beam energy from 6MV to 10 MV; these beams are often “hardened” with a flattening filter to produce a flat beam profile. However, there is also the option of a flattening filter free (FFF) beam, i.e. removing the flattening filter [3]. Removal of the flattening filter from a linear accelerator permits a considerable increase in the dose rate delivery during volumetric-modulated arc therapy (VMAT) [4].

Calculation grid size of 2.5mm spacing is sufficient to reduce dose calculation error to less than 1% in VMAT [5]. In radiosurgery, high doses of radiation are delivered safely due to more rigid immobilization and localization techniques, Current localization and positional techniques such as cone beam computed tomography (CBCT) and 6 degree of freedom couches have improved the localization accuracy to 0.2-0.6mm [5].

Thus with the ability to achieve tighter positional accuracy as well as sharper dose gradients, the smallest grid size should then be used in for accurate dose calculation. However, dose calculations using a fine grid size increases computation time significantly and may not be practical [5]

2 Materials and Methods

The study design is a retrospective study using the CT planning image acquired with radiosurgery treatment approach for 16 patients having small brain lesions treated between Jan 2021 to Jul 2023 and prescribed dose is 22.5Gy in five fractions. Eight treatment plans are to be generated for each patient using Varian Eclipse AAA analytical anisotropic algorithm for dose calculation and PO (photon optimizer) for dose optimization. First: four plans with the same MUs (monitor units) and with different grid sizes from 1mm to 4mm will be created. Second: another set of four plans will be planned with normalization at target mean and different grid sizes from 1mm to 4mm. Each plan contains two complete arcs with two different collimator angle sets. 6FFF energy (flattening filter free) beam will utilized for all plans to avail the advantage of high dose rate 1400MU/min, that has the benefit of using limited number of radiation beams to deliver such highly dose per fraction and to minimize the total treatment time.

- Arc1 start angle 181 end 179 with collimator 45 deg.
- Arc2 start angle 179 end 181 with collimator 315 deg

The ability to meet DVH objectives and constraints can be used along with dose conformity, homogeneity, and mean dose to the OARs to assess the plan quality [7].

The conformity index (CI) and homogeneity index (HI) of the resultant treatment plans will be computed using Eq. 1 and 2, respectively:

$$CI = V95\% / VPTV \quad (1)$$

The CI describes the volume within the PTV that receives the prescription dose or higher (V95%) divided by the

volume within the external body contour that receives the prescription dose or higher (VPTV) and provides a metric to determine how close the prescription iso-dose volume is spread within the PTV and normal tissue[7].

HI= D99.5% / D0.5% (2)

The HI describes the uniformity of the dose within the planning target volume and is a ratio of the minimum dose (D99.5%) to the maximum dose (D0.5%) [7].

The Gradient Index defined as the ratio of the 50% isodose (V50) volume to the prescription isodose volume [8]

GI = V50% /V100% (3)

3 Results

In terms of CI, it was clearly observed that for the first four plans where NN (no normalization) is selected, as the GS increases, the CI decrease Fig (1), whereas for the second group where TM (target mean) is selected , CI is not affected by changing the grid size.

However, the homogeneity index is not affected by changing GS for all types of plan normalization selected Fig(2) . On the other side, GI increases significantly with deceasing the GS, Fig (3).

Also there were no significant dosimetric differences in terms of OAR maximum doses as the grid size changes with both normalization types Fig (4, 5).

Finally the target volume PTV covered by 95 % of the prescribed doses is impacted significantly with changing the grid size , as the grid size increases the coverage decreases in the plans with NN is selected but there were no change in the target coverage as we keep plan normalized to target mean even with different GS Fig(6).

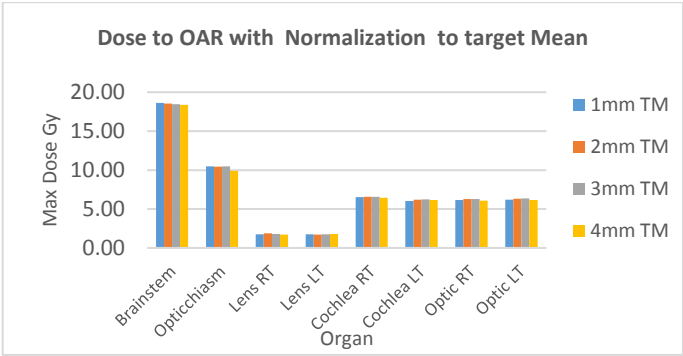

Fig 4 Dose to OAR with normalization to target mean plans

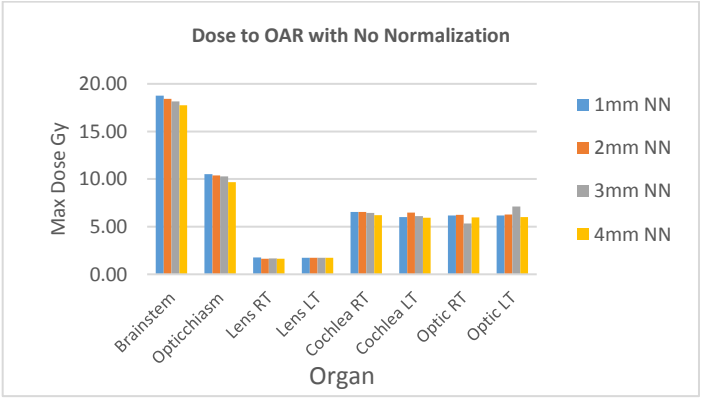

Fig 5 Dose to OAR with no normalization plans

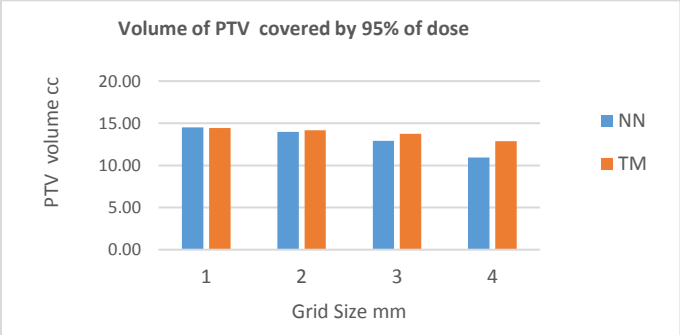

Fig 6 Target volume PTV covered by 95 % of the prescribed doses

4 Discussion

The main purpose of this study is to evaluate the effect of different calculation grid size on the accuracy of calculated dose for small brain lesions in intracranial stereotactic radiosurgery (SRS).

It was confirmed that by changing grid size during planning of small brain lesions, PTV covered by 95 % of the dose increased when the GS was decreased from 4mm to 1mm.

5 Conclusion

Selection of the calculation grid size is significantly influences the quality of the treatment plans in both conformity, gradient indexes and target coverage. For an accurate calculation of the treatment plans, it is recommended that the use of smallest possible grid size GS.

To calibrate or not to calibrate: a decision support approach using microcontroller-based tiny machine learning

Abstract A decision support tool is proposed to determine whether it is reasonable to calibrate a linear accelerator with an ionization chamber according to recent changes in atmospheric pressure. The response of an ionization chamber is indeed sensitive to variations in atmospheric pressure, which can be very unstable in certain regions at some periods of the year. For this purpose, a neural network is trained on a two-year local weather station database classified using tools from statistical process control. The originality of the method relies on the use of machine learning code explicitly implemented for deployment on a microcontroller. More specifically, the training was done using a TensorFlow neural network implemented on a standard desktop computer. The obtained model was then deployed on an IoT Arduino board, by means of the TinyML library. The resulting device is low-cost, low-energy and has an accuracy of 0.834 for classifying atmospheric pressure.

1 Introduction

Dose calibration of a linear accelerator (linac) involves quantifying the link between measured dose in water under reference conditions and the fluence of emitted particles [1,2]. The dose measuring tool used for this purpose is an ionisation chamber whose response is highly dependent on atmospheric pressure. The measurement given by the chamber must therefore be corrected according to the current atmospheric pressure, which is generally read on an analogical barometer that is itself calibrated and regularly checked.

Many factors can lead to a correction in the calibration of the linac, which is checked daily before the first treatment. If the observed deviations exceed the permitted tolerances, recalibration is necessary. This is a long and tedious process, requiring careful experimental set-up and rigorous measurement. Calibration determines the accuracy of the dose that will actually be delivered to future patients, both to the target and to organs at risk and healthy tissue.

In many parts of the world, atmospheric pressure can change abruptly and/or reach exceptionally low or high values. Such unstable conditions are thus not ideal for ionisation chambers [3,4]. As a consequence, it becomes counterproductive to calibrate the accelerator, with the risk of having to start again a few days later when the pressure returns to a standard value in a more stable context.

In this context, we present a decision support tool based on an electronic board containing a pressure sensor and a microcontroller. A specific machine learning model is trained and then deployed inside the microcontroller.

2 Materials and Methods

The whole process has three main stages. The first step consists of data gathering and preparation. As a second step, a machine learning algorithm is trained to help deciding whether or not to calibrate according to the current atmospheric pressure. Finally as a last step, the trained model is modified so that it can be used by a microcontroller with ultra-light operating system.

Data collection and preparation

Atmospheric pressure values from the last two years, measured every three hours, were collected from the local weather station. These values were separated into three-month periods to reflect potential seasonal variations.

Exceptionally high or low pressure values, or values that drifted slowly or abruptly, were detected using statistical process control (SPC) tools [5]. More specifically, individual values chart (IV), moving range charts (MR) and exponentially weighted moving average charts (EWMA) were used to detect unusually low or high values, abruptly changing values and slowly drifting values, respectively [6]. Upper and lower control limits were established using 1.96 standard deviations for each type of chart.

Pressure values were then classified as unacceptable for linac dose calibration as soon as they exceeded the control limits of at least one of the three SPC charts.

Finally, all classified data were separated into 12 successive pressure values. The objective of the machine learning step was then to correctly classify the acceptable/unacceptable status of a given pressure value given the last eleven measures recorded every three hours.

Machine learning process

The proposed approach is fairly straightforward once the data has been collected and prepared as described above.

A simple neural network was implemented on a standard desktop computer using the TensorFlow [7] platform v2.4.1 and Python 3.8 in the Anaconda interface. The network consisted of two consecutive fully connected layers with 48 neurons followed by a ReLU activation function, one dropout layer with a 0.2 rate to prevent overfitting, and one fully connected layer with one output neuron followed by a sigmoid activation function. Dataset was split into 80% train-

ing data, 10% validation data and 10% test data. Three hundred epochs were used during the learning computation, using the Adam optimizer.

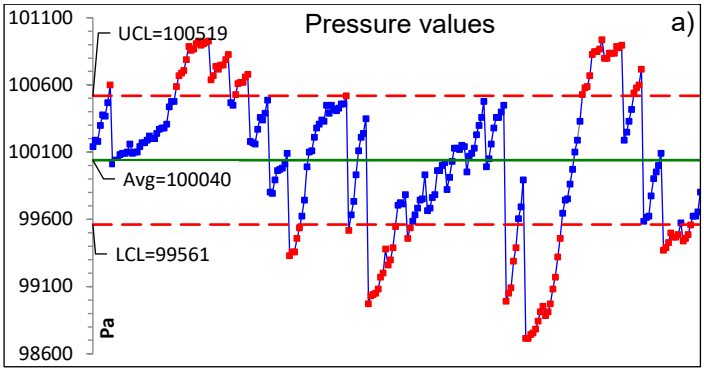
Microcontroller incorporation

Once built, the model was transferred into a Nano 33 BLE Sense board (Arduino, Torino, Italia) with embedded nRF52840 microcontroller (Nordic Semiconductor, Trondheim, Norway) and LPS22HB piezoresistive absolute pressure sensor (STMicroelectronic, USA). The process requires several steps in order to make the model work inside such a device, with only 1MB of CPU flash memory and 256 kB static RAM.
The objective of the first step was to convert the model to the TensorFlow Lite format using the dedicated TFLiteConverter function from TinyML [8]. No quantization was used because of the relatively small size of the model.
The aim of the next step was the effective deployment of the generated *.tflite* model inside the microcontroller. This was made possible by a simple conversion of this file into a hexadecimal *.h* format directly usable by the microcontroller.
As a last step, a C++ program was generated inside the Arduino IDE in order the microcontroller to read and record the pressure value every three hours during 33 hours, and to classify the current value according to the last eleven values and the deployed tiny machine learning model.

3 Results

A total of 5834 atmospheric pressure values were retrospectively collected during 2021 and 2022, from the local weather station, at a frequency of 1 measurement every 3 hours. A representative SPC analysis for the month of May 2022 is shown in Figure 1.
Atmospheric pressure was classified as unacceptable for calibration (Fig1-d) as soon as it exceeded control limits in at least one of the three analysis charts (Fig1-a,b,c).

For the sake of clarity, values are presented for a one month length, but in the study data were tracked during three months periods to account for potential seasonal effects.



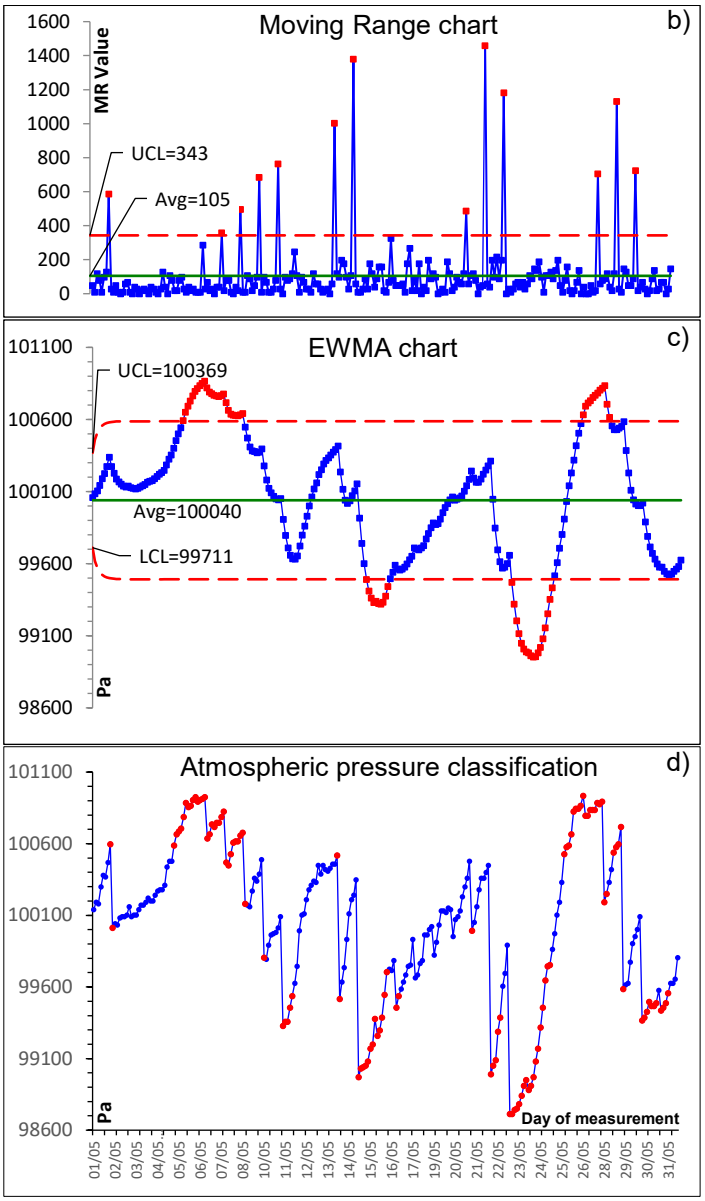


Figure 1: Atmospheric pressure values from the local weather station, recorded during May 2022, and SPC analysis. From top to bottom : a) individual values (for detection of very high or very low pressure values), b) moving range values (for detection of abrupt changes), c) EWMA values (for detection of smooth drifts), and d) final classification. Red dots correspond to pressure values above control limits. Values on the x-axis are all the same and correspond to the date and time of measurement during the month.

This type of individual classification was used to build the actual learning dataset, which consisted of independent series of twelve consecutive atmospheric values. The objective for the model was to predict the classification of the current pressure (acceptable or not for dose calibration) from the last eleven measurements (recorded every three hours, for a total of 33 hours prior to the current value).
Using this principle, a total of 486 independent series of 12 consecutive pressure measurements were generated (see Figure 2 for an example). Three hundred and eighty-eight were used for training, 49 for validation and a further 49 for model testing.

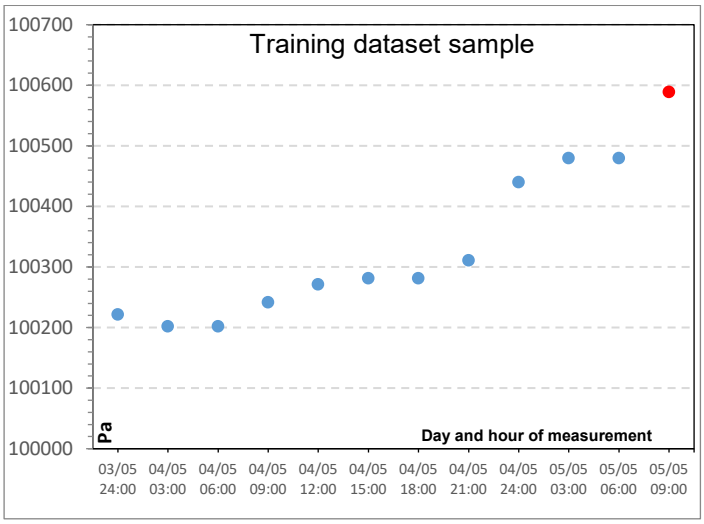

Figure 2: Sample from the training dataset. A sample from the training data, representing 12 consecutive measurements every three hours, over a period of 33 hours. The tested point is the last (05/05 at 09am), classified as unacceptable (red dot) by the SPC analysis. The training, validation and test datasets include 388, 49 and 49 independent series of this type, respectively.

The function loss for training and validation with respect to the 300 epochs is shown on Figure 3. Final accuracy for validation dataset was 0.874. Results for the test dataset were 0.834 for accuracy, 0.783 for recall, 0.841 for precision and 0.811 for f-score.

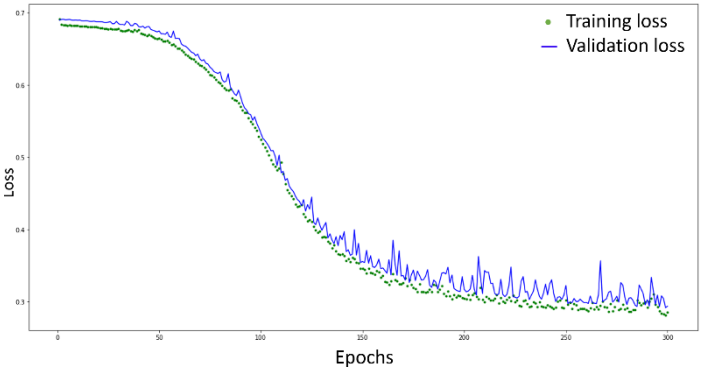

Figure 3. Training and validation loss during neural network optimization.

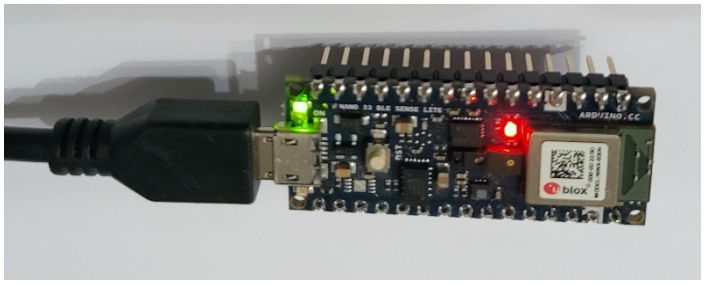

Figure 4. An example of minimalist output. In this configuration, the Arduino board was programmed to put the output LED on red in case of an unacceptable atmospheric pressure, and on green in the case of an acceptable pressure for linac calibration (LED on the left is on/off LED).

An example of possible output is given on Figure 4, where the classification of the current atmospheric pressure is provided by a simple output LED embedded on the board. If the LED is green, the atmospheric pressure is considered by the device to be sufficiently consistent and typical to proceed with calibration of the linac, by measuring the dose with an ionization chamber. Otherwise, the LED lights up red, as shown on the Figure.

4 Discussion

In this work a decision-support tool was presented for deciding whether to calibrate the delivered dose of a linac according to the stability of atmospheric pressure, which can drastically alter the reliability of dose measurement by ionization chamber.

In this exploratory and feasibility study, we have demonstrated the simplicity of the procedure, even if substantial room for improvement remains. In particular, the database can considerably be expanded, since atmospheric pressure measurements have been available since 2010 from the local weather station. Also, pressure measurements were separated into independent samples of 12 consecutive values, leading to only 486 samples. This number could be increased by sampling every 6 hours instead of every 12 hours, while maintaining a number of 12 values in each sample. It is not certain whether the resulting overlap would cancel out the gain in database size. Furthermore, the learning model proposed in this work is a very simple neural network that would benefit from further optimization.

5 Conclusion

The decision-support tool proposed in this study is relatively easy to implement for people with standard python and machine learning knowledge. The presented work provides the user with a low energy and low cost device able to classify the current atmospheric pressure as acceptable or not for linac dose calibration. Trends in atmospheric pressure, measured every three hours over the past 33 hours, are taken into account when making the decision. Accuracy of the machine learning model is 0.834 on test values, a score which could be easily improved by extending the training database and by refining the neural network structure.

2 Department of Radiation Oncology, Wonju Severance Christian Hospital, Yonsei University Wonju College of Medicine

Abstract Traditional methodologies often fail to accommodate anatomical shifts or source movement, compromising treatment efficacy. In addressing the limitations of current brachytherapy, particularly the challenge of precise dose delivery and minimizing radiation exposure to normal tissues, this study experimentally validates the use of an integrated C-arm CT/SPECT system for real-time adaptive, image-guided brachytherapy. Utilizing a DRTECH detector, our prototype demonstrated significant advancements by accurately distinguishing between materials within a PMMA-Agar phantom and tracking Co-60 source movements with high precision. Experimental findings revealed the system's capacity for real-time modifications, with the in-house developed image intensity enhancement algorithm reducing the full width at half maximum of the Co-60 source to 3.80 mm and 2.91 mm along the x/y direction, respectively. This result shows the system's potential to surmount the prevailing challenges in brachytherapy by ensuring precise radiation delivery and enhancing patient safety and treatment outcomes through adaptive imaging and dose monitoring capabilities.

1 Introduction

Brachytherapy, especially for cervical cancer, generally prescribes doses ranging from 300 to 700 cGy across 5 to 10 sessions, raising the risk of side effects like bleeding and tissue necrosis if sensitive organs such as the rectum receive excessive radiation. Shigematsu et al. reported that 36% of 143 patients who underwent cervical cancer treatment experienced adverse effects due to rectal bleeding [1], while Cook et al. reported that 48% of adverse effects occurring after treatment in 348 patients with cervical cancer were related to the rectum [2].

The consistency of device placement and tissue positioning is vital to reduce these risks, yet variability in the attending physician for a single patient, patient movement, and anatomical changes pose challenges to maintaining treatment accuracy. Regular analysis of daily CT images during treatment sessions is crucial to adjust and verify treatment plans based on changes in the patient's condition, aiming to minimize side effects and complications. Prospective studies, like those by Georg et al., affirm the benefits of image-guided adaptive brachytherapy in lowering late side effects [3].

Nonetheless, the global standard procedure in image-guided brachytherapy, requiring patient transport between imaging and treatment rooms, risks device displacement and consequent dose distribution errors, as noted by Andrew et al. [4]. This highlights the urgent need for advanced, in-room 3-D imaging techniques that can obviate the need for patient transfer, offering precise verification of internal applicator positioning.

Despite technological advancements, many centers still continue to use 2D X-ray imaging for brachytherapy due to various internal constraints. Developing affordable, efficient, and room-integrated 3-D imaging solutions is crucial for advancing brachytherapy's effectiveness. Furthermore, real-time 3-D monitoring of the trajectory of radiation source movement and activity is essential during treatment sessions. Also, real-time in vivo patient dose monitoring based on this information is required.

Therefore, we previously proposed an integrated C-arm CT/SPECT imaging system to overcome the current limitation discussed above and realize an online adaptive image-guided brachytherapy (Fig. 1). In this study, we

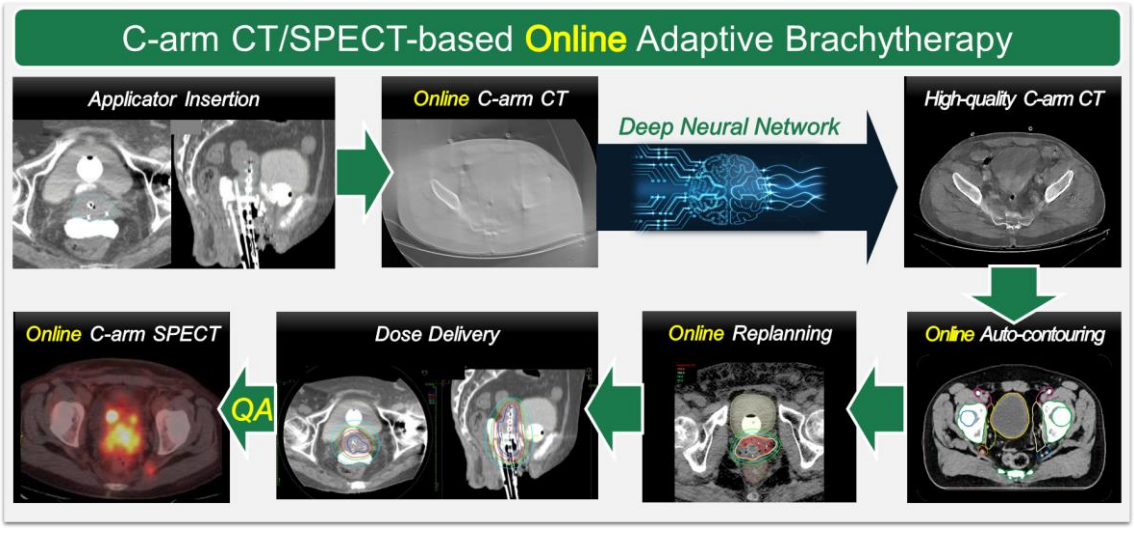

Fig. 1. C-arm CT/SPECT system-implemented clinical workflow for online adaptive brachytherapy.

experimentally validate the proof-of-principle of C-arm CT/SPECT system using commercial digital detector and in-house designed experimental solution.

2 Materials and Methods

A. Construction of a Prototype C-arm CT/SPECT System for Proof-of-Principle

For the acquisition of C-arm CT/SPECT images, an industrial DRTECH detector, EXT1616R, composed of a Csl scintillator and an IGZO TFT with a pixel pitch of 98 µm , was employed in this study. The detector, weighing ~3 kg with an imaging area of 161x161 mm² and external dimensions of 195x190x50 mm², was optimized for capturing both C-arm CT and C-arm SPECT images under various operational conditions. For C-arm SPECT imaging, a parallel-hole tungsten collimator, determined through prior Monte Carlo simulations, featuring 0.5 mm hole thickness, 45 mm length, and 0.2 mm septal thickness, was utilized. Additionally, to facilitate the acquisition of CT or SPECT images in three dimensions according to the rotation of the C-arm device, a rotation stage capable of simultaneously rotating both a PMMA phantom and a Two-ovoid applicator was constructed (Fig. 2). This rotation stage was equipped with an automatic rotation scheduler that allows rotation to a limited angle, considering the dwell time of each 58.12 GBq Co-60 source position according to the brachytherapy plan.

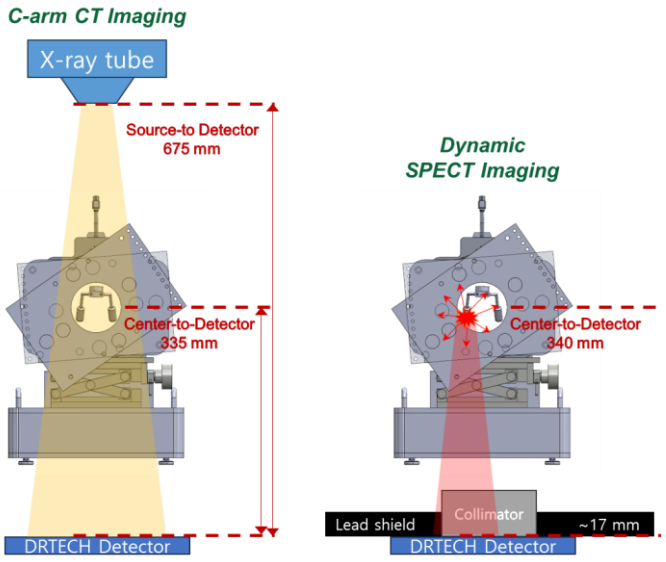

Fig. 2. Experimental setup for C-arm CT/SPECT imaging with an in-house designed phantom and applicator rotation equipment

B. C-arm CT/SPECT Image Acquisition based on Brachytherapy Plan using PMMA Phantom

To rotate a Two-ovoid applicator fixed at the center of a PMMA ($\rho \approx 1.18$ g/cm³) phantom, a phantom composed of an agar material ($\rho \approx 1.01$ g/cm³) in a cylindrical shape with a diameter and length of 10 cm each was fabricated. CT images of the PMMA-Agar phantom with the Two-ovoid applicator inserted were acquired using a TOSHIBA Aquillion CT scanner, and these images were utilized for planning a vaginal-cuff brachytherapy for a virtual target volume. The treatment plan was designed such that a 58.12 GBq Co-60 source would move 2 cm at 5 mm intervals from the endpoint, ensuring 1.83 Gy dose coverage over 90% of the target volume. The dwell times for the source at four positions were approximately 24 seconds, 51 seconds, 67 seconds, and 70 seconds, respectively, and the phantom rotation stage was scheduled to rotate repetitively by 110 degrees for each source position during their respective dwell times. C-arm CT images were acquired by capturing projection images at 1-degree intervals as the phantom rotated, under conditions of 90 kV and 10 mAs, and reconstructing these into a three-dimensional space. C-arm SPECT images were obtained by recording video in real-time at a rate of 1 frame per second while the phantom rotated. To enhance the quality of the acquired SPECT images, an in-house developed image intensity enhancement algorithm was applied.

3 Results and Discussion

When we obtained X-ray images at various phantom rotation angles using a commercially available industrial DRTECH detector, it was confirmed that the geometric structures of the Two-ovoid applicator, PMMA material, agar gel, and air cavity within the phantom were successfully distinguished. Similarly, CBCT images acquired following a 200-degree rotation of an Elekta VersaHD linear accelerator-mounted CBCT device, using the same phantom, also successfully differentiated boundaries between materials with similar densities inside the phantom (Fig. 3). This indicates that an online immediate brachytherapy plan modification is feasible in the treatment room during the patient setup using limited-angle C-arm CT images.

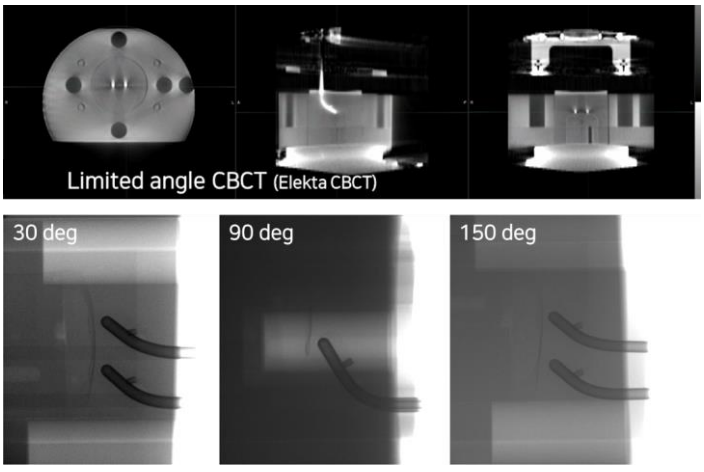

Fig. 3. X-ray Imaging at Various Rotation Angles Using a Commercial Detector (90 kV, 10 mAs)

In this experimental study for C-arm SPECT image acquisition, we verified the capability to track the position of Co-60 sources in real-time with a parallel-hole collimator structure optimized for Ir-192 sources, as predicted by our prior Monte Carlo simulation studies conducted. Analysis of a single frame of SPECT image demonstrated that, upon applying the in-house developed image intensity enhancement algorithm, the full width at half maximum (FWHM) of the peak for Co-60 source were evaluated to be 3.80 mm and 2.91 mm in the x and y directions, respectively (Fig. 4). Comparing this to the FWHM of 2.66 mm for a 275 GBq Ir-192 source assessed without the application of the image intensity enhancement algorithm, as found in our preceding Monte Carlo simulation study, it was confirmed that the movement characteristics of Co-60 sources within patients can be tracked with sufficiently high accuracy in actual clinical settings [5].

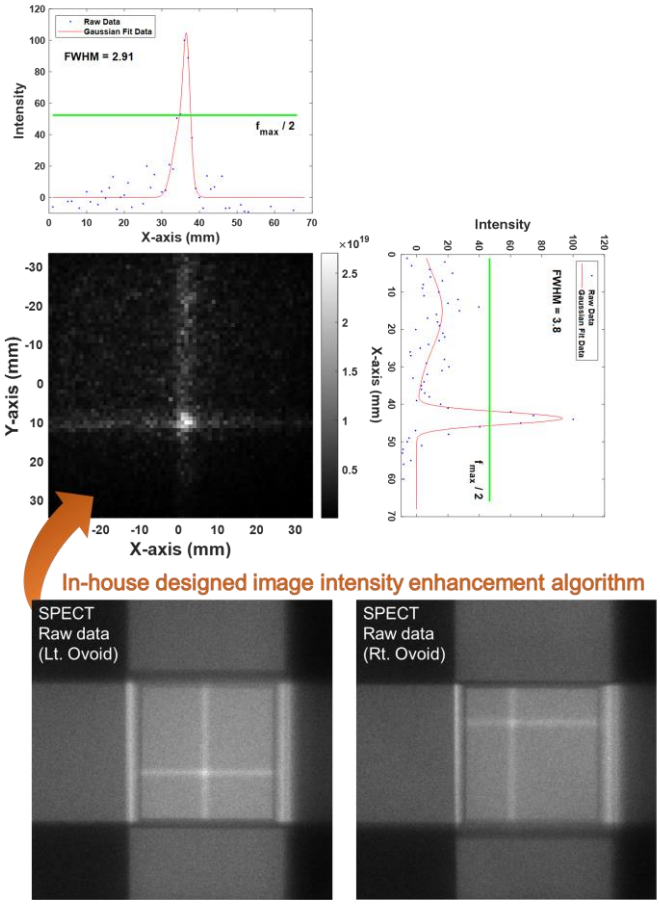

Fig. 4. Result of SPECT Imaging and FWHM Evaluation for Co-60 Source with In-house Designed Image Intensity Enhancement Algorithm

4 Conclusion

In this study, we experimentally verified the feasibility of online adaptive, image-guided brachytherapy using a C-arm CT/SPECT system. Given that the experiments were conducted using commercially available digital detectors, we believe these experimental results showed significant credibility for potential clinical application. The C-arm CT/SPECT device, designed to be more compact than O-arm devices and minimally obstructive to the conventional environment utilizing the C-arm device commonly used in various institutions, offers the advantage of online C-arm CT imaging for verifying a patient's internal condition. Additionally, it enables real-time in vivo patient dose monitoring during brachytherapy with C-arm SPECT imaging. In the future, we plan to further develop and optimize the operational and structural characteristics of the C-arm CT/SPECT device for practical use in clinical settings, leveraging these advantages.

Multiphysics modeling and simulations for Y-90 liver radioembolization

Emilie Roncali[1,2], Carlos A. Ruvalcaba[1], and Gustavo C.A. Costa[1]

[1]Department of Biomedical Engineering, University of California Davis, Davis , USA
[2]Department of Radiology, University of California Davis, Davis , USA

Abstract. Yttrium-90 (^{90}Y) radioembolization is a form of liver cancer therapy where radioactive microspheres are injected into the liver arterial bloodstream via a catheter, delivering localized radiation to the tumor cells. Studies have shown a strong correlation between the administered dose and patient outcomes, highlighting the importance of accurate dosimetry in treatment planning.

However, current standard-of-care dosimetry practices in liver radioembolization rely on generic models that do not accurately consider individual patient anatomy, vasculature, and tumor burden. To address this limitation, we present an approach involving computational fluid dynamics (CFD) and Monte Carlo simulation developed at UC Davis. Patient cone-beam CT (CBCT) images are collected to extract the liver vasculature, which is then used to simulate the blood and microsphere transport through CFD in OpenFOAM. The volumetric distribution of microspheres and ^{90}Y absorbed dose distribution in the liver is then computed with the Geant4-based application GATE. The pre-treatment absorbed dose calculations aim at determining the optimal dose distribution for personalized treatment planning.

This abstract outlines ongoing investigations to develop a personalized dosimetry approach using CFDose improving the model fidelity and validating it against clinical ^{90}Y PET.

1 Introduction

Yttrium-90 (^{90}Y) radioembolization is an internal radiation therapy to treat liver cancer (primary or metastatic), using microspheres 20-60 µm in diameter loaded with ^{90}Y. The ^{90}Y microspheres are injected selectively into the liver arterial bloodstream through a catheter to deliver localized radiation. ^{90}Y represented more than 10,000 interventions in the US in 2022 [1]; multiple studies have shown a clear correlation between the tumor dose and patient outcome, which indicates that dosimetry should be considered in treatment planning. However, standard-of-care dosimetry remains simplistic, based on generic models in which a simple scaling factor is used to compute the absorbed dose distribution from ^{90}Y activity [2]. This model does not account for the patient's unique anatomy, vasculature, and tumor burden. Due to the intricacy between blood flow, microsphere transport in the liver vasculature, and radiation physics, multi-physics computational methods are well-suited to achieve accurate radioembolization dosimetry [3]. This abstract presents our current efforts in combining computational fluid dynamics (CFD) and Monte Carlo simulation to develop personalized dosimetry informed with patient imaging. We collect patient cone-beam CT (CBCT) images to extract the liver vasculature, in which we simulate the blood and microsphere transport using CFD in OpenFOAM [4]. This provides the microsphere volumetric distribution and ^{90}Y activity distribution which in turn is used to compute the absorbed dose with Geant4 Application for Tomographic Emission (GATE) [5]. Our goal is to create a liver digital twin for radioembolization treatment planning, in which the digital twin is used to compute the optimal dose distribution. We called this liver model CFDose [3].

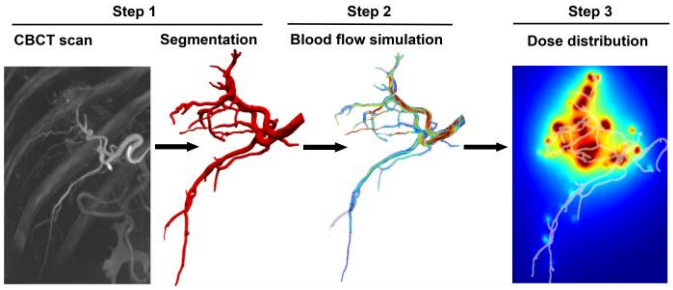

Figure 1. CFDose. 1) Hepatic artery segmentation from CBCT. 2) CFD simulation. 3) Simulated radiation dose distribution.

2 Materials and Methods

2.1 Patient data and image processing

In CFDose, personalization is achieved by using each patient's angiogram to create the vascular mesh to carry out the CFD simulation. The CBCT acquired during treatment planning was segmented with a piece-wise approach based on level sets in 3D Slicer and meshed with gmsh [6]. In the example shown in Figure 1, segmented vessels were as small as 0.45 mm in diameter, and 46 outlets were identified.

2.2 CFD simulation and multiscale model

To improve the precision of the microsphere simulation in small vessels, we modeled three phenomena that strongly direct the local microsphere deposition and were not previously considered in CFDose: blood is modeled as a non-Newtonian fluid, the catheter tip geometry and positioning extracted from patient scans (Figure 2), and discrete particle transport simulating microsphere dynamics. This new model included a 1-way coupling between the microspheres and the blood through discrete phase modeling to account for particle forces experienced by the microspheres during transport [7]. The model adequately captures the microsphere transport dynamically throughout the vasculature. Boundary conditions at the vessel wall are considered non-slip and non-deforming, while resistor-capacitor circuit analogs (known as 2- and 3-element

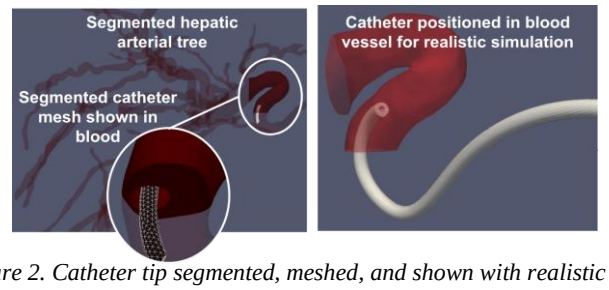

Figure 2. Catheter tip segmented, meshed, and shown with realistic positioning in blood flow.

windkessel-type) are prescribed at the vasculature downstream from the simulation domain which is not resolved in the image-based CFD domain. The resistors were assumed to be equally distributed amongst outlets, for each liver segment.

2.3 Microsphere dose distribution with GATE

^{90}Y is a β- emitter with a maximum energy of 2.28 MeV and a mean energy of 930 keV, corresponding to a maximum and mean electron range of 11 mm and 2.5 mm in water [8].

An isotropic dose point kernel with a 0.25 mm x 0.25 mm x 0.25 mm size was computed in GATE, using the ^{90}Y energy spectrum calculated from the Fermi theory for beta decay (Figure 3).

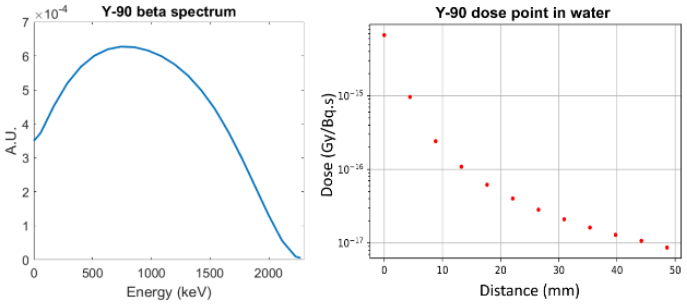

Figure 3. Left: ^{90}Y beta spectrum (mean energy 930 keV). Right: Dose kernel profile showing a rapid decrease of deposition with distance (log scale).

The dose distribution was obtained by convolving the dose kernel with the microsphere distribution obtained from the CFD simulation or using a full Monte Carlo simulation [9].

2.4 Comparison with clinical dosimetry

Scans up to 60 minutes were acquired within 48 hours of treatment to image the ^{90}Y activity with the total-body uEXPLORER scanner (United Imaging Health) for high quantitative accuracy at high resolution in a single bed position, using a protocol we previously validated [9]. The actual dose distribution was computed in the liver using the quantitative ^{90}Y images, the patient CT, providing the closest measurement to ground truth [9]. All PET acquisitions were accompanied by a low-dose CT scan for attenuation correction and anatomical delineation. Partial volume correction was applied using a previously determined recovery coefficient [10].

3 Results

3.1 CFD simulations

CFD simulations including particle transport showed the asymmetry of the flow and distribution between vessels and the importance of considering the vessel tortuosity when developing the flow upstream of the inlet (Figure 4). [11]

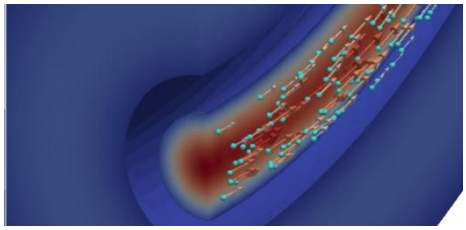

Figure 4. Illustration of skewed microsphere flow toward the vessel wall.

Our most recent work has focused on modeling the catheter geometry and flow within the vessel, to fully account for its perturbation of the blood flow in which the injected microspheres blend.

3.2 Comparison between simulated dose distribution and clinical PET

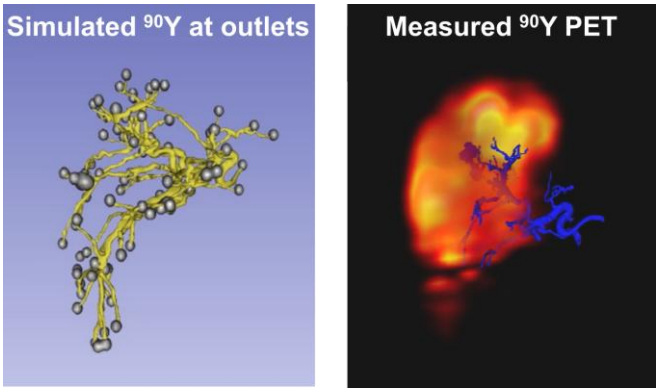

Figure 5. Left: Arterial tree segmented from CECT with predicted microsphere clusters at the outlets. Right: Clinical ^{90}Y PET overlaid with the arterial tree.

We compared the liver dose distribution with a clinical ^{90}Y PET scan acquired 1 h post treatment (Coronal view, Figure 5) and found that the predictive dosimetry was consistent with the activity mostly located in segments 7 and 8, as determined by a board-certified radiologist [3]. Figure 5 shows the 3D vascular mesh with clusters of microspheres simulated at each outlet. The cluster size is indicative of the number of microspheres. This encouraging first comparison indicates the accuracy of CFDose and shows the feasibility of validating CFD-based dosimetry with ^{90}Y PET.

Next steps include voxelwise comparison of the simulated and measured distributions, adding motion correction to the clinical PET data, and developing the liver model.

4 Discussion and conclusion

We present our newest results on the development of CFDose, a computational vascular model of the liver that we plan to integrate into an optimization program to find the best activity and injection spot in ^{90}Y radioembolization. Our next steps include personalization of the boundary conditions, which is an important part of transforming this model into a liver digital twin. While this model utilizes computationally intense CFD simulations, we plan to apply our expertise on generative adversarial networks (GANs) to speed up the computation and rapidly provide an estimated dose distribution.

Abstract This work introduces a deep learning-based approach to enhance image quality in partial-ring PET scanners, which often suffer from significant artifacts due to incomplete angular field of view. Our method utilizes implicit neural representation (INR) learning with coordinate-based multilayer perceptrons (MLPs) featuring sinusoidal activations. These MLPs parameterize partial-ring PET images, training the patient-specific network to predict fully sampled images from partially sampled ones. This approach was validated using twenty digital brain phantoms, Monte Carlo simulated Derenzo phantom, and experimentally acquired hot rod phantom data from the partial-ring PETITION PET scanner. The results show that the INR learning method significantly improves image quality, achieving a PSNR above 30dB and SSIM over 0.95 for all cases. This method presents a promising solution for enhancing PET images from partial-ring scanners.

1 Introduction

Positron Emission Tomography (PET) plays an important role in functional imaging. Traditional PET systems rely on detectors arranged in a ring configuration [1, 2] to capture comprehensive imaging data across all angular views. However, the emergence of partial-ring PET systems has introduced both economical and practical advantages, particularly in specialized applications such as locoregional imaging [3] or online heavy-ion therapy verification [4]. Despite these benefits, partial-ring configurations inherently suffer from incomplete data acquisition, leading to significant image artifacts and reduced image quality.

Previously, model-based techniques have been employed to correct limited-angle PET images. For instance, sinogram completion using interpolation prior to reconstruction is an approach [5]. Another approach is the use of compressed sensing [6], which leverages the sparsity of data in a transform domain. Applying regularization constraints such as total variation [7] further helps in enforcing smoothness, thereby helping in artefact reduction. However, these model-based approaches have limitations, particularly when it comes to parameter optimization for regularization and computation times. To address these limitations, recent advances in deep learning (DL) and medical imaging have opened new pathways. The concept of implicit neural representation (INR) [8] presents a promising approach to obtain high-fidelity images from incomplete data sets [9]. The potential of deep learning, particularly in the context of INR learning, offers an innovative approach to correct and enhance PET images acquired from partial-ring systems. Unlike conventional DL approaches that depend on large labeled datasets, INR's ability to train unsupervised with sparse data makes it ideal for enhancing image quality in partial-ring PET systems. Here, we propose a framework that uses INR learning to effectively correct partial-ring PET images, particularly focusing on the developed partial-ring PETITION (PET for InTensive care units and Innovative protON therapy) scanner's design for proton therapy [10].

2 Materials and Methods

2.1 INR-based PET Image Correction

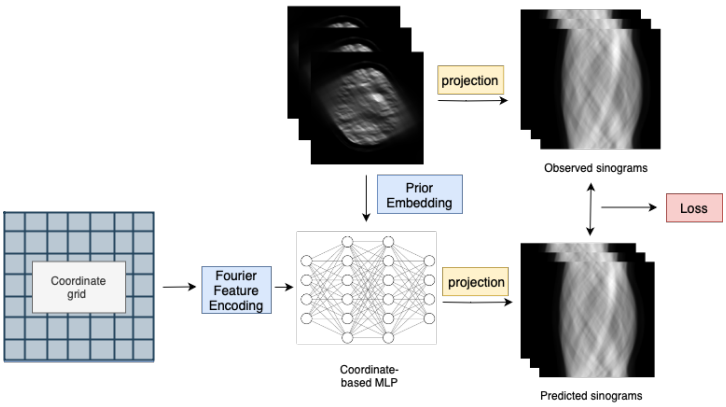

Figure 1: Network architecture for partial-ring PET image correction.

INR learning involves representing images using a neural network. We used a coordinate-based multi-layer perceptron (MLP) [8], $M(\theta)$ that transforms pixel coordinates $\{\mathbf{c}_i\}$ into their corresponding intensities.Our model consists of an MLP with 8 fully connected lay-

ers, 256 neurons each, employing sinusoidal activation functions. For efficient high-frequency signal representation, we used Fourier feature encoding, given by $F(\mathbf{c}_i) = [\cos(2\pi\mathbf{B}\mathbf{c}_i), \sin(2\pi\mathbf{B}\mathbf{c}_i)]^T$. The matrix $\mathbf{B}$, drawn from a Gaussian distribution with $\sigma = 4$ controls the frequency range. Inspired by a previous work that initialises the INR network parameters by pre-initialising the network with a prior image [9], we pre-trained the network with the uncorrected PET image from the limited-angle scan, which is the only accessible PET image of the scanned object in the real clinical scenario.

The PET reconstruction problem is often described as

$$\hat{\mathbf{x}} = \underset{\mathbf{x}}{\operatorname{argmin}} \|\mathbf{A}\mathbf{x} - \mathbf{y}\|_2^2, \tag{1}$$

where $\mathbf{x}$ is the reconstructed image, $\mathbf{y}$ is the measured data, and $\mathbf{A}$ is the forward model encapsulating the imaging physics.

With the INR learning, we parameterised the image $\mathbf{x}$ by the INR network, i.e., $\mathbf{x} = \mathcal{M}(\theta)$. The corresponding training loss function is therefore designed as

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \|\mathbf{A}\mathcal{M}(\hat{\theta}) - \mathbf{y}\|_2^2. \tag{2}$$

Once trained, the recovered image $\hat{\mathbf{x}}$ is inferred by $\hat{\mathbf{x}} = \mathcal{M}(\hat{\theta})$. The network architecture is depicted in Figure 1.

2.2 Datasets

Three distinct datasets employed for evaluation of our network are as follows:

- **MRI-based Brain Phantoms:** Twenty brain phantoms were sourced from BrainWeb [11, 12], and were adjusted to the PETITION scanner's resolution. Grey to white matter ratio was set at $4:1$, mimicking ^{18}F[FDG] PET and a hyperintense lesion was added onto each phantom. The geometry and the angular field of view of the PETITION PET scanner [10] was replicated.

- **Monte Carlo Simulation:** A Derenzo phantom with spheres of diameter 2.0, 2.2, 2.6, 3.2, 4.0 and 5.0 mm was simulated in GATE(v9.0) [13], where each sphere was uniformly filled with ^{18}F. The total simulated activity was 19 MBq with the acquisition time being 1800 seconds.

- **Real-Data Acquisition:** Utilizing a hot-rod phantom with uniform ^{18}F distribution, data was experimentally acquired with the PETITION PET scanner to reflect a realistic scenario of the physical effects.

2.3 Model Training

Model training was performed on a NVIDIA GV100GL GPU using PyTorch with the Adam optimiser. The model's performance was assessed using mean squared error (MSE), peak signal-to-noise ratio (PSNR), structural similarity index measure (SSIM) for different datasets in comparison to the ground-truth image that would have been obtained with a full-ring PET scanner. For the digital brain phantom dataset, we also compared the INR model with the widely used 2D U-Net [14]. Unlike the INR, the U-Net, being a data-dependent model, required division of the data into training, testing, and validation sets. Of the twenty brain phantoms, fifteen were allocated for training, four for testing, and one for validation. For the Derenzo phantom, peak-to-valley (PTV) ratios were computed for line profiles generated through different sphere diameters to assess the quantitative performance of the model. PTV ratio was calculated as the average intensity ratio of the uptake and no uptake region for each sphere.

3 Results

3.1 Digital Brain Phantoms

Figure 2 presents a comparison of various images for a slice of one of the brain phantoms. Quantitative comparison shows that the input partial-ring image lacks clarity (low PSNR and SSIM) and cannot reconstruct the lesion effectively. The U-Net and INR yielded similar SSIM and PSNR values, but INR-based correction outperformed U-Net in lesion reconstruction visually (figure 2) along with the required training times (15 minutes vs. 2 hours for U-Net).

3.2 MC Simulated Derenzo Phantom

Figure 3 displays the INR-corrected Derenzo phantom image, showing visually clear distinction between uptake and no-uptake regions. With prior initialization, INR achieves a PSNR of 31.73dB and an MSE error of 4×10^{-4}. Without prior initialization, it achieves a PSNR of 27.95dB and an MSE error of 1×10^{-3}. INR also exhibits higher SSIM values (0.95 with prior, 0.82 without) compared to the ground truth full-ring image. Quantitative analysis using PTV ratios (Figure 4) further validates the superior performance of INR, particularly when initialized with a prior. PTV ratios for the 2mm spheres are not indicated as this is beyond the resolution capabilities of the PETITION scanner.

3.3 Measured Hot-Rod Phantom

Visual comparison in Figure 5 demonstrates the improved image quality of the INR-reconstructed image

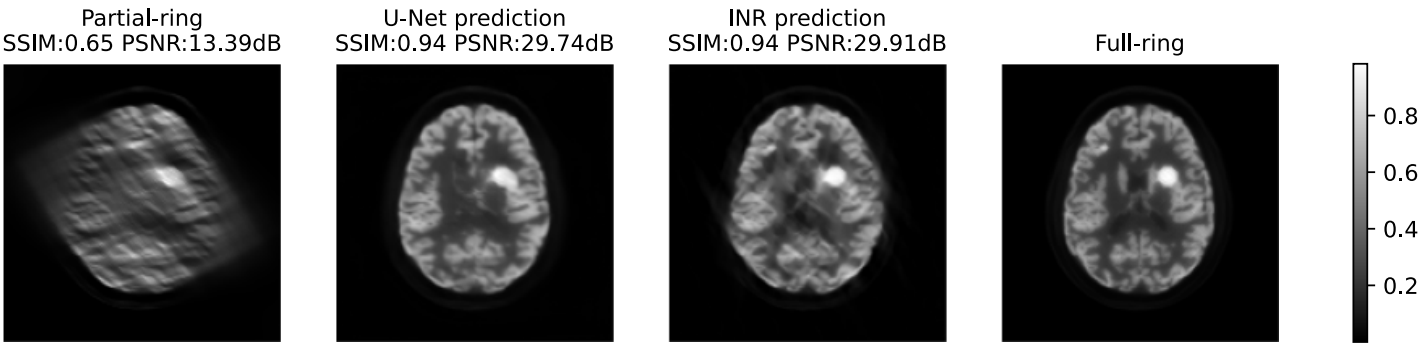

Figure 2: The central slice of a digital brain phantom. From left to right: original partial-ring MLEM reconstruction, corrected image using U-Net, corrected image using the proposed INR, and reference ground-truth image obtained with the full-ring scan.

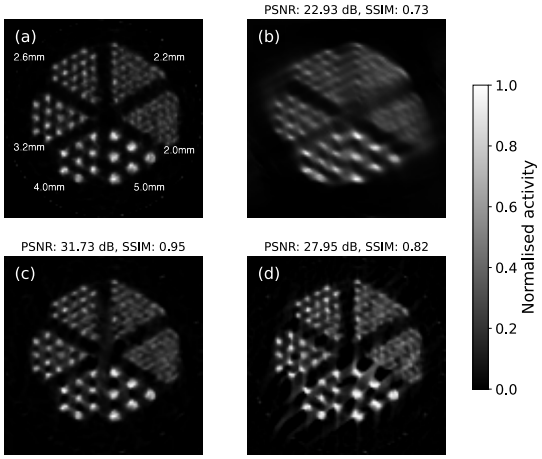

Figure 3: Results of the INR learning in representing the MC simulated Derenzo phantom.(a) Ground truth full-ring image, annotated with sphere diameters.(b) Partial-ring image.(c) Prior initialized INR corrected image and (d) INR corrected image without a prior.

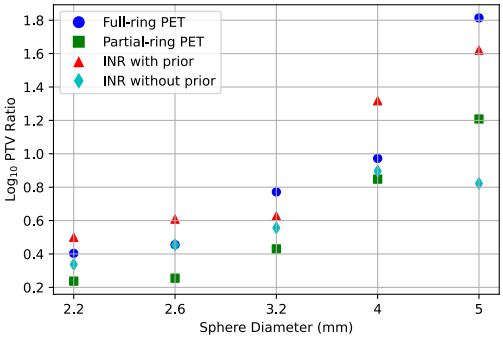

Figure 4: Peak-to-valley(PTV) ratio comparison amongst the four reconstructed Derenzo phantom images shown in Figure 3 for different sphere diameters.

compared to the initial partial-ring reconstruction. INR achieved a PSNR of 35.49 dB and an SSIM of 0.98 compared to the ground-truth full-ring PET image. Line profiles also illustrate INR's ability to recover intensities comparable to the ground truth full-ring image.

4 Discussion

This study presents an INR-based approach for partial-ring PET image correction. Unlike traditional data-driven deep learning methods that often suffer from overfitting issues and require extensive datasets, the proposed INR model does not require any external dataset but only uses the acquired partial-ring image for model training. This patient-specific nature of INR enables optimized imaging for each individual scan.

The efficiency of INR learning is seen by its faster training times compared to the 2D U-Net model. Additionally, the size of the model is dependent on the complexity of the signal rather than the discrete voxel grid size.

Our evaluation across three distinct datasets (analytically simulated brain phantom data, Monte Carlo simulated data, and phantom measurement data) demonstrates its robustness. For the digital brain phantom data, the INR model consistently achieved high PSNR and SSIM values, comparable or superior to U-Net, but with the added advantage of reduced training time. The model's ability to recover signal in artificially-inserted lesions in the brain phantom dataset, as seen in figure 2, illustrates its effectiveness in capturing structural changes and recovering missing signals. Inclusion of scanner effects in the dataset further extends the application of the method to realistic imaging scenarios. The performance improves with prior initialization of the INR model, especially in intensity prediction and separation of individual spheres in the Derenzo phantom. Similar performance was observed in measured data, reinforcing the application to different scenarios.

Furthermore, the proposed network architecture can significantly benefit longitudinal PET studies. For in-

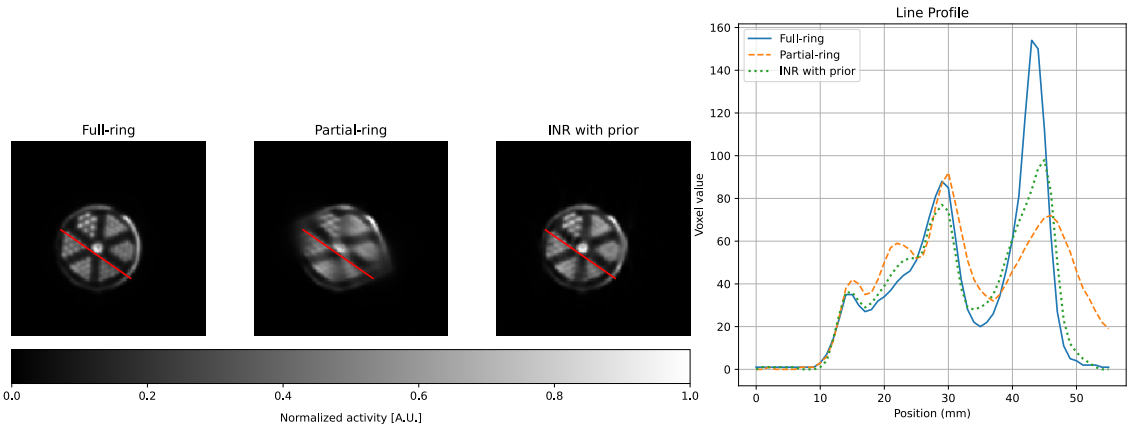

Figure 5: Depiction of full-ring, partial-ring and INR reconstructed images for the experimental hot-rod phantom. Line profile through the red line indicated in the three images is shown in the fourth column.

stance, in fractionated treatments where a new PET scan is required for verification or adaptation, the model trained during the first fraction can be reused for subsequent fractions. This not only saves inference time but also utilizes prior information to fine-tune important features.

Despite its advantages, the model has only been tested for phantom studies, due to the constraints of the PETITION PET scanner. This highlights the need for further validation with measured patient data. Future work will explore the model's performance in patient imaging and its extendibility to higher dimensionalities, such as 3D PET imaging.

5 Conclusion

This study demonstrates an INR-based approach for PET image correction, offering significant advantages in terms of efficiency and image quality. The model has been evaluated for partial-ring PET scanners without requiring a large training dataset. This approach helps in the development of further dedicated limited angle PET scanners or tomographs for varying applications.

Abstract Proton therapy is a cancer treatment method that utilizes proton beams to irradiate cancerous tissue, with a key objective of minimizing the dose to surrounding healthy tissue. Its full potential is limited by range uncertainties stemming from causes such as variations in patient anatomy and CT Hounsfield unit conversion uncertainties. In 2023, the NOVO collaboration introduced the NOVCoDA system, utilizing fast neutron and prompt-gamma rays emitted along the beam's path to detect beam range shifts. However, limitations in NOVCoDA, such as measurement uncertainties, pose challenges to achieving desired millimeter range shift detection precision. In general, conventional methods like MLEM and MAP result in noisy or less informative reconstructed images for proton range verification. In this work, we propose a hybrid approach, using images predicted by an encoder-decoder network (EDN) trained on Monte-Carlo data to guide MAP reconstruction. Tested on a single case, the MAP-EDN algorithm yields an image with nearly 4 times smaller mean squared error than the implemented list-mode MAP. Further exploration is warranted to assess the utility of the MAP-EDN algorithm for range shift identification.

1 Introduction

Proton therapy is a highly attractive radiotherapy treatment for cancer due to sharp dose gradients and greater healthy tissue sparing potential that it offers. However, its full potential is limited by range uncertainties caused by anatomical changes, organ motion, and day-to-day variations; tissue and tumor changes in response to treatment, patient setup or positioning errors; and inevitable uncertainties in the conversion of CT Hounsfield units to relative proton stopping powers. Numerous non-invasive range verification systems have been proposed, relying on imaging the emission probability distribution of secondary particles from proton interactions with tissue. Challenges include achieving millimeter range detection precision amidst limited counts and high statistical noise. Early 2023, the NOVO (NeutrOn and gamma-ray imaging for real-time range VerificatiOn and image guidance in particle therapy) collaboration demonstrated a hybrid multi-particle approach to range assessment-based treatment verification in particle therapy where a 1 mm range shift precision was achieved at relatively low proton intensities (10^7 protons per spot) [1], using list-mode MLEM, but noteably without the consideration of detector resolution effects. A core component of NOVO is the compact detector array known as NOVCoDA, composed of optically segmented, densely stacked organic scintillator bars. Imaging using the NOVCoDA relies on the assumption that the origin of detected particles, fast neutrons (FNs) and prompt-gamma rays (PGs), lie on the surface of a so-called event cone. Reconstructed event cones serve as input to the tomographic reconstruction of the particle emission origins used for range verification. Tomographic reconstruction for systems using event cones, such as Compton Cameras, neutron scattering cameras, and, in our case, the NOVCoDA, are usually based on algorithms like Maximum Likelihood Expectation Maximization (MLEM) and Origin Ensemble (OE), and variations thereof [1–3]. In the case of few detected events, these conventional methods produce extremely noisy images due to high statistical variations [4] and inevitable detector resolution effects like uncertainties in energy, time, and position measurements. Noise effects can be handled by introducing a regularizing function to the reconstruction, based on, for instance, prior information about the unknown emission distribution one seeks to image. In the context of proton beam range verification, the formulation of a suitable regularization function is still in its infancy, and to the best of our knowledge, the available literature on the subject is scarce. In this work we present a novel approach to image reconstruction for proton range verification using an encoder-decoder network (EDN) trained on Monte-Carlo simulated data in combination with a Maximum A-Posteriori (MAP) algorithm, referred to as the EDN-MAP algorithm. Traditional imaging relies on models of the physics and statistical nature of the measured signal and noise, e.g. assuming a Poisson model for the noise. On the other hand, a direct EDN-driven reconstruction solely relies on an EDN model whose weights are learned based on high-quality examples. Such a model operates as a "black box" and has low interpretability of the imaging process. Our proposed hybrid approach combines the traditional MAP and EDN reconstruction (heavily inspired by the use of AI in PET reconstruction [5]), leveraging the EDN-predicted image to guide the iterative MAP update. Specifically focusing on 2D imaging and with a list-mode approach, we compare the effects of EDN-MAP on the calculated range landmark (RL), defined in the next section, to the conventional reconstruction algorithms Simple Backprojection (SBP), MLEM, and MAP. We do not evaluate OE algorithms in this work and consider only imaging of FNs, leaving PGs, and combined FN and PG imaging for future studies.

2 Methods

As a benchmark for the proposed EDN-MAP algorithm, we used the list-mode approach to SBP, MLEM, and MAP. A direct reconstruction algorithm, SBP simply projects event cones onto a discretized image plane positioned on and whose surface normal is perpendicular to the proton beam axis. The intersection of multiple cone surfaces with the plane provides an estimate of the particle emission distribution. The iterative methods MLEM and MAP are based on a Bayesian approach, where the probability distribution of the sought emission distribution, represented by the image vector $\boldsymbol{\lambda}$, given the data vector $\boldsymbol{y}$ is expressed using Bayes' rule

$$p(\boldsymbol{\lambda}|\boldsymbol{y}) = \frac{p(\boldsymbol{y}|\boldsymbol{\lambda})p(\boldsymbol{\lambda})}{p(\boldsymbol{y})}. \quad (1)$$

MAP aims to find the solution that maximizes the a-posteriori probability distribution $p(\boldsymbol{\lambda}|\boldsymbol{y})$, while MLEM searches for the solution that maximizes the likelihood $p(\boldsymbol{y}|\boldsymbol{\lambda})$. The objective function in MAP is

$$\max_{\boldsymbol{\lambda}} \log p(\boldsymbol{\lambda}|\boldsymbol{y}) = \max_{\boldsymbol{\lambda}} \log p(\boldsymbol{y}|\boldsymbol{\lambda}) + \log p(\boldsymbol{\lambda}). \quad (2)$$

Given that the list-mode data is modeled as independent Poisson random variables, the point-wise update equation (derived for binned data in [6]) for the MAP estimate is

$$\lambda_j^{new} = \frac{\lambda_j^{old}}{s_j + \beta \frac{\partial V(\boldsymbol{\lambda})}{\partial \lambda_j}\Big|_{\boldsymbol{\lambda}^{old}}} \sum_i \frac{a_{ij}}{\sum_b a_{ib}\lambda_b^{old}}. \quad (3)$$

where λ_j^{old} is the old value of pixel j, s_j is the pixel sensitivity (set to $s_j = 1, \forall j$ for simplicity), a_{ij} is the system matrix element indicating the probability that the ith event of the list was emitted from pixel j. System matrix elements were computed using an approach similar to the marching algorithm presented in [7]. A common means of describing $p(\boldsymbol{\lambda})$ is with a Gibbs prior

$$p(\boldsymbol{\lambda}) \propto e^{-\beta V(\boldsymbol{\lambda})} = e^{-\beta \sum_j \sum_k (w_{jk}\phi(\lambda_j - \lambda_k))} \quad (4)$$

where the potential function $V(\boldsymbol{\lambda})$ describes desired properties of the unknown image, $\phi(u)$ is a non-negative function and symmetric about 0, and the weight w_{jk} is a measure of the strength of the relationship between pixels j and k: $w_{jk} = 1$ for orthogonal nearest neighbors, $1/\sqrt{2}$ for diagonal neighbors and 0 otherwise. As the parameter $\beta \to 0$, (3) tends to the MLEM update function. In this work we have chosen the potential function examined in [8]

$$V(\boldsymbol{\lambda}) = \sum_j \sum_k w_{jk} \log\left(1 + \left(\frac{\lambda_j - \lambda_k}{\mu}\right)^2\right) \quad (5)$$

whose partial derivative with respect to λ_j, needed in (3), is

$$\frac{\partial V(\boldsymbol{\lambda})}{\partial \lambda_j} = \sum_k w_{jk} \frac{2(\lambda_j - \lambda_k)}{\mu^2 + (\lambda_j - \lambda_k)^2}. \quad (6)$$

This potential function discourages the separation of uniform regions, penalizing high-frequency noise, while avoiding excessive penalties for larger separations that are likely to occur at the boundary between two distinct regions of the image, such as the edge of the FN emission distribution. The parameter μ adjusts how much the prior is influenced by the difference between nearby pixel values. In the EDN-MAP algorithm, we use an EDN-predicted image $\boldsymbol{\lambda}^*$ to guide MAP reconstruction by replacing λ_k in (6) with λ_k^*.

Encoder-Decoder Network

The EDN was created using the machine learning framework PyTorch (v. 2.0.1) [9]. The architecture of the EDN considered in this work comprises 3 convolutional layers in the encoder, a linear (fully connected) layer before and after the latent space that is of dimension 20, and 3 transpose convolutional layers in the decoder. The convolutional layers utilize 4x4 kernels with (2x2) pixel strides. Training data was generated using GATE (v.9.0) simulations [10] of a Gaussian profiled ($\sigma_y = \sigma_z = 2$ mm) proton beam fired at a $40 \times 40 \times 40$ cm^3 water phantom. The proton beam energy was set to 85 MeV and contained 10^9 protons (corresponding to a high-intensity treatment beam spot). Produced within the phantom by primary proton interactions, FNs were detected by a $30 \times 20 \times 20$ cm^3 detector volume with a material composition similar to that of plastic scintillators (with carbon-to-hydrogen atom ratio 10:11 and density 1.099 g/cm^3). A total of 11 range shifts were simulated by adding and removing material in steps of 1 mm from the phantom of the dimension parallel to the beam. Following simulations, FN hits in the detector volume were processed in ROOT v.6.28/06 [11], involving the introduction of detector resolution to the hit data (using resolutions of an organic glass scintillator (OGS) - a candidate scintillator for the NOVCoDA: 10% energy resolution, 10 mm depth-of-interaction resolution, and 500 ps time resolution [12]), the pairing of two consecutive detector hits caused by the same neutron - i.e., double coincident events (DCE) - and construction of FN event cones. For each processed range shift simulation, bootstrapping was used to randomly sample (with replacement) n event cones to represent lower treatment beam intensities ($N = 10^6, 10^7, 10^8$). The number of bootstrap samples was determined using the observed DCE efficiency $\eta = 1.7 \cdot 10^{-4}$ per primary proton and desired beam intensity N

$$n = \eta N. \quad (7)$$

Using different random seeds, 100 bootstraps were performed for each range shift and the three proton intensity. The SBP and ground truth (GT) image of the FN emission distribution was generated for all bootstraps, yielding $11 \times 3 \times 100$ = 3300 sets of SBP-GT image pairs. The images measured (400×400) pixels, with pixel width and height equaling 1 mm, and were normalized such that pixel intensities were in the range of [0, 1]. A single SBP-GT image pair was

isolated for each range shift and proton intensity, saved for later used in evaluation of the EDN-MAP algorithm. The remaining dataset was split into 70:30 training and validation subsets. In the training step, the SBP image serves as the input and the GT as the target image. The optimization of model weights involved minimizing the mean squared error (MSE) loss between the model's output and the associated GT. This optimization process utilized the 'Adam' optimizer [13] with an arbitrarily selected learning rate of 0.001. A batch size of 10 was selected without specific criteria, and the network underwent training for 10 epochs. Training concluded when the validation loss showed signs of stagnation. Training and validation of the model took roughly 1 hour to complete and was conducted on a MacBook Pro (2017) running macOS Monterey (version 12.5.1) with a 3.1 GHz Intel Core i5 processor, 8 GB of memory, and 256 GB of storage. The machine was equipped with an Intel Iris Plus Graphics 650 graphics card.

Evaluation

To compare the performance of the EDN-MAP and conventional image reconstruction algorithms, we use the MSE as a measure of agreement to GT image and the standard deviation (SD) to quantify noise levels of the image in question.

$$MSE = \frac{1}{J}\sum_{j=0}^{J-1}(\lambda_j^{recon} - \lambda_j^{GT})^2 \tag{8}$$

where J represents the number of pixels, λ_j^{recon} is the reconstructed image, and λ_j^{GT} is the GT image. The SD of the image, whose average pixel value is $\bar{\lambda}$, was calculated by

$$SD_{\boldsymbol{\lambda}} = \sqrt{\frac{1}{J}\sum_{j=0}^{J-1}(\lambda_j - \bar{\lambda})^2} \tag{9}$$

We introduce a range landmark (RL) parameter to assess algorithms performance on range prediction performance, defining RL as the weighted average of the normalized 1D emission distributions, obtained by collapsing the image onto the axis parallel to the beam axis,

$$RL = \frac{\sum_m (h_m bin_m)}{\sum_m h_m} \tag{10}$$

where h_m is the weight and bin_m is the position (in mm) of the mth bin. The standard deviation of the estimated RL

$$SD_{RL} = \sqrt{\frac{\sum_m h_m (bin_m - RL)^2}{\sum_m h_m}} \tag{11}$$

The relative RL error, using $\Delta RL = |RL - RL^{GT}|$ was computed as

$$\delta = \frac{\Delta RL}{RL^{GT}} \times 100\% \tag{12}$$

Evaluation metrics were computed for images cropped at 100 mm depth into the phantom.

3 Results

The EDN-MAP algorithm's performance was evaluated against SBP, MLEM, and MAP reconstructions for a single range shift case: a 0 mm range-shifted proton beam of 10^8 primaries (corresponding to $1.7 \cdot 10^4$ imageable FN event cones). Hyperparameters were determined through a series of trials and subsequent adjustments based on performance outcomes. In (3), β was set to 0, 0.2, and 0.1 for MLEM, MAP, and EDN-MAP reconstruction, respectively, and μ in (6) was set to 1. The iterative methods were stopped after an arbitrary number of 20 iterations. For the GT and the reconstructed images in Fig. 1, the corresponding evaluation metrics are reported in Tab. 1 and 1D emission distribution are shown in Fig. 2. Among the methods evaluated, EDN-MAP emerged as the top performer, generating an image that closely resembled the GT with the lowest MSE, nearly 4 times lower than the MAP image, and relative RL error. In contrast, conventional methods exhibited anticipated interpretability challenges, such as severe blurriness (SBP), noise amplification (MLEM), or a combination of both issues (MAP). Note that the reconstructed 1D distributions' tail make their respective RL value larger than the GT's.

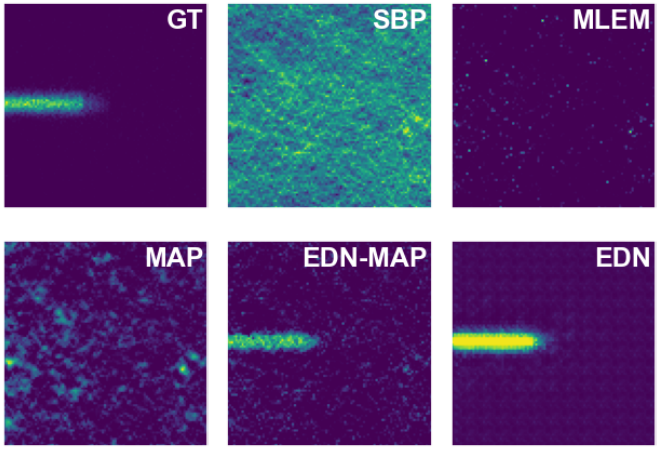

Figure 1: Ground truth (GT) and reconstructed images for 10^8 primary protons with 0 mm range shift. Images cropped are at 100 mm into the phantom.

4 Discussion

Despite promising results, acknowledging challenges and limitations is crucial. The MAP update function in (3) is not guaranteed to converge in general and depends on the choice of potential function $V(\boldsymbol{\lambda})$ and the value of β, previously pointed out in [6]. Additionally, limited training data and EDN model complexity and hyperparameters (e.g., depth, loss function, optimizer, learning rate) may impact performance. Future studies will explore different network archi-

Table 1: Evaluation metrics of various algorithms compared to ground truth (GT).

Alg.	MSE	SD_{λ}	RL [mm]	SD_{RL} [mm]	ΔRL [mm]	δ [%]
GT	0.0	0.99	23.26	2.52	0.0	0.0
SBP	2611.16	1.02	50.81	2.92	27.54	118.41
MLEM	28.23	5.20	42.89	5.64	19.63	84.37
MAP	1.37	0.69	42.43	4.85	19.17	82.39
EDN-MAP	0.35	1.02	36.75	3.92	13.49	57.99
EDN	0.68	1.58	34.27	3.47	11.01	47.34

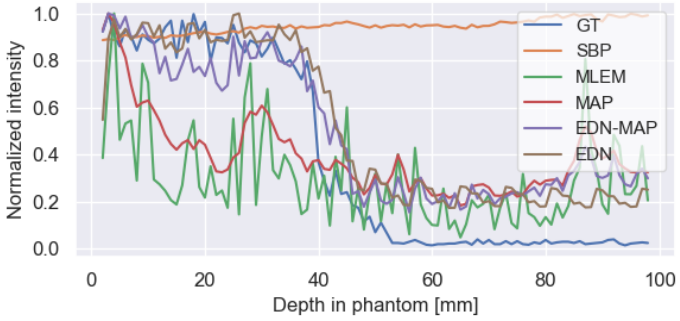

Figure 2: 1D projection of the reconstructed and ground truth (GT) FN production distribution, for 10^8 primary protons with 0 mm range shift.

tectures, hyperparameter optimization, and the generation of realistic training data, considering phantom heterogeneities and various clinical proton beam energies. Moreover, there will be a focus on investigating whether range shifts can be successfully identified and at what precision levels this can be achieved.

5 Conclusion

The EDN-MAP produces an improved image as indicated by the MSE metric calculated for this single case. However, more efforts are needed to produce more conclusive evidence for the usefulness of the proposed method. The current work is the preliminary stage of an extensive project, and additional efforts are required to comprehensively evaluate the efficacy of the method for range shift identification in both homogeneous and even more importantly, heterogeneous phantoms.

Head and Neck Deformable Registration Using Self-Attention with Positional Encoding

Elizabeth McKenzie[1], Taman Upadhaya[1], Hengjie Liu[2], and Ke Sheng[3]

[1]Department of Radiation Oncology, Cedars-Sinai Medical Center, Los Angeles CA, USA
[2]Department of Radiation Oncology, University of California Los Angeles, Los Angeles CA, USA
[3]Department of Radiation Oncology, University of California San Francisco, San Francisco CA, USA

Abstract This study proposes a completely attention-based deformable image registration (DIR) model which we call AmorWarp. An attention-based model allows one to incorporate long-range dependencies in registration techniques. Large motion is not well handled in DIR, and we endeavor to harness attention's unique abilities to improve DIR in the setting of large head-and-neck motion. Our resulting model demonstrates improved robustness for both inter- and intra-patient DIR relative to an established CNN model and a B-spline technique. In the setting of large motion, our method reduced the average 95% Hausdorff distance across 17 contours from 17.12mm (pre-registration) to 6.88mm for intra-patient registrations, and from 15.52mm to 7.92mm for inter-patient registrations. Our method reduced the average target registration error across 4 landmarks from 9.80mm to 3.37mm. Our attention-based model performed similarly to more established methods, and we hope that this proof of concept initiates further DIR applications of this powerful technique.

1 Introduction

Deformable image registration (DIR) remains a challenging problem in medical imaging. Despite its importance in tracking disease progression, combining imaging modalities, and adapting radiation therapy to changes in patient anatomy, there are still many opportunities for improvement, especially in the presence of large motion[1]. Network-based DIR, primarily using convolutional neural networks (CNNs)[2-10], has shown several advantages in registering images with small deformation but is limited by a local approach to image processing and struggles with large deformations.

To address these limitations, we propose the use of self-attention networks, a technique initially developed for natural language processing but recently shows promise in image processing[11]. Self-attention networks, unlike CNNs, consider the entire image to determine responses at specific points, facilitating long-range data connections[12]. We leverage this strength to build a network to take cues from the entire 3D volume, thus potentially providing more accurate registration in scenarios with significant anatomical movement, such as in head and neck radiation therapy.

However, self-attention networks are computationally expensive, especially for large 3D images. To overcome this, we use computationally efficient axial attention, which breaks down images into 1D components and computes attention sequentially, reducing computational complexity[12].

We extend this idea to build a fully self-attentional DIR model for 3D images, predicting deformation vector fields (DVF) for a pair of images. This model was tested on head and neck CT scans, and its performance was compared with a traditional CNN-based DIR model[3,] and a B-spline DIR[13-14] approach. The results demonstrate the potential of self-attention networks to accurately handle large motion and complex deformations in medical image registration.

2 Materials and Methods

We collected head and neck CT images from The Cancer Imaging Archive[15] to create a training dataset of 409 volumes, with testing and validation datasets of 44 and 53 volumes, respectively. Additionally, we collected paired CT's from 14 patients for intra-patient registration testing. All volumes were rigidly registered to a template, downsized to 128x128x128 (4mm isotropic voxels), clipped to an intensity range of [-1024, 3000], and then normalized to [-1,+1].

Our network, which we call *AmorWarp*, takes a pair of 3D images (source and target) as input and outputs a predicted DVF, which is then used to deform the source image. To combine the two input volumes, we first pass each image through two convolution layers, concatenate, and perform max pooling. This results in a 64x32x32x32 tensor. After the images are combined, they enter the U-shaped portion of the network. The number of features going down the encoder branch was 256, 512, 1024, and 2048 for each level, respectively. The decoder branch reversed these feature numbers. Each level of the U-net was constructed using a self-attention block with positional encoding and a residual identity path, followed by a non-linearity. Each level of the U-net was connected via skip connections with concatenation and convolutions of kernel size 1. The attention block was both preceded and followed by 1x1x1 kernel 3D convolution. Each axial attention component was constructed by reshaping the input into a 1D tensor along the selected dimension. For example, the axial depth tensor had the shape [*batch size* x *height* x *width*, *features*, *depth*]. By factoring a 3D tensor into sequential 1D operations along the height, width, and depth, we efficiently trained a network with a global receptive field for attention. The axial attention formulism with positional encoding is given by:

$$y_o = \sum_{p \in \mathcal{N}_{1xm}(o)} softmax_p\left(q_o^T k_p + q_o^T r_{p-o}^q + k_p^T r_{p-o}^k\right)\left(v_p + r_{p-o}^v\right)$$

where m is the span of the entire input at that layer, and r_{p-o}^q, r_{p-o}^k, and r_{p-o}^v are the relative learned positional

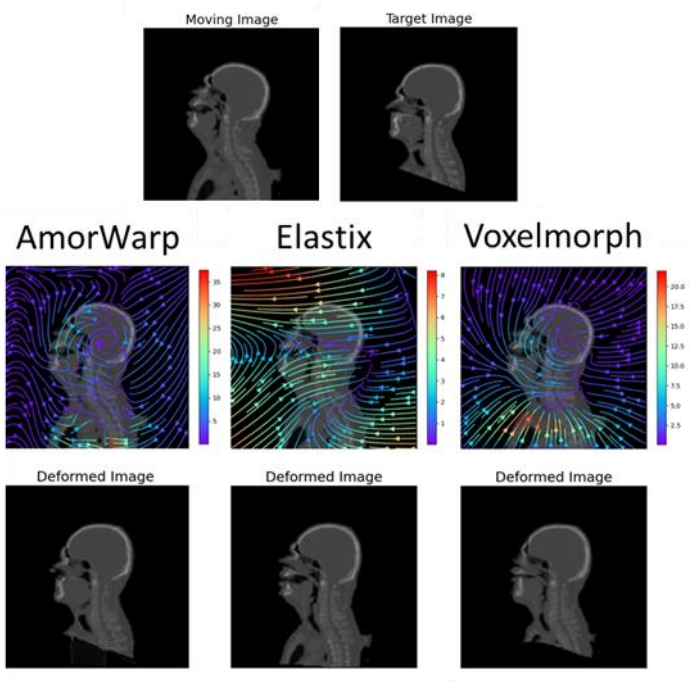

Figure 1 Comparison among registration methods: Amorwarp (axial attention), Elastix (B-spline), and Voxelmorph (CNN). The deformation vector fields are overlaid on the moving image [middle row]. The resulting deformed moving images [bottom row] show our methods ability to match the target image even in the presence of large neck flexion.

encodings for the queries (q), keys (k), and values (v), respectively. Note that the subscript is $p - o$ for the positional encodings, indicating that these positions are relative relationships between the input and output locations. The result is a map of attention that looks to the entire input for guidance, incorporating information about all the input values and their positions. The above formulation was first proposed by Wang et al[12], and we have adapted it for 3D inputs and outputs in DIR.

Our loss function contained 3 terms: a mean square error fidelity term between the deformed source image and target image, a bending energy term to promote a smoothly varying DVF, and a deep feature VGG loss term[16-17] to improve detail matching between the deformed and target images. Additionally, we trained the network with and without an average dice term derived from 17 previously auto-segmented contours[18] (note that the contours were not provided as input).

The network was trained using stochastic gradient descent, 10 warm-up epochs, and an initial learning rate of 0.0257 with a cosine learning rate schedule. The model was trained for 280 epochs, with random pairs of source and target images sampled from the 409 samples for a total of 167,281 potential pairs.

We analyzed the network's performance for both inter and intra-patient deformable image registration. We compared the accuracies of the registrations using 95% Hausdorff distance of 17 automatically created head and neck contours, as well as the target registration error (TRE) of 4 manually placed landmarks (nose, front teeth, chin, and

Figure 2 Saliency map showing where the network is attending. Without input contours, the network has learned to pay attention to anatomically relevant portions of the image when predicting the deformation vector field.

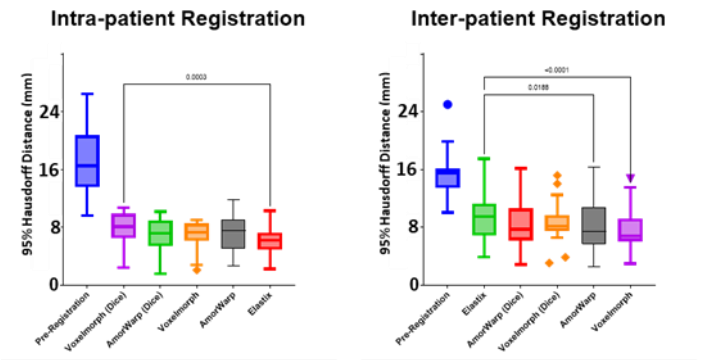
epiglottis). These results were compared among our axial attention-based network, a CNN-based network (Voxelmorph[3]), and a B-spline non-network registration application (Elastix[13-14]).

3 Results

Qualitatively, our network matched the head and neck CT volumes well even in the presence of gross anatomical distortion (e.g., opening and closing the mouth). Inspecting the DVF's showed that it learned discontinuities around the motion of connected components, demonstrating the model's ability to associate disparate parts of the image. The B-spline and CNN methods showed relatively unanatomical smooth DVF's, and a corresponding lower aptitude in regions of large deformation, such as going from a chin-up position to a chin down [Fig. 1].

In attention-based networks, the saliency maps are more interpretable since they reveal what the network has learned to "pay attention to."[11] When examining the saliency maps, we discovered that our network learned to pay attention to relevant portions of the anatomy without any contouring input. For example, it learned to attend to the mandible, shoulders, and skull [Fig. 2]. Of note, the shoulders and skull were not contours included in the average dice loss term, and thus emerged strictly from the training.

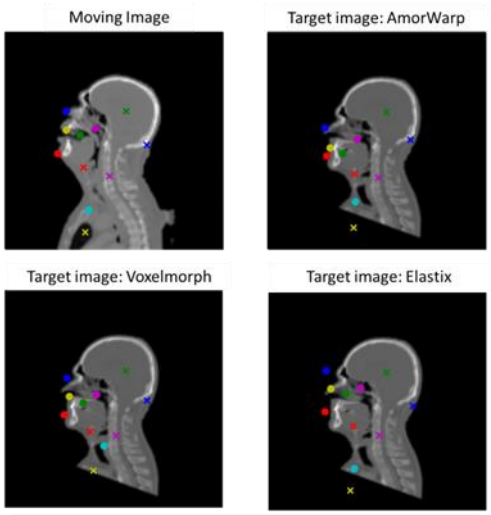
Quantitatively, we compared contour matching using 95% Hausdorff distance averaged across 17 head and neck contours (brainstem, cord, chiasm, right and left orbits, right and left submandibular glands, right and left optic nerves, right and left parotids, right and left cochleae, mandible, larynx, pharynx, and esophagus) [Fig. 3]. For the inter-patient comparisons, the best performers were the CNN and our attention-based techniques, which were both significantly better than the B-spline technique. For the intra-patient comparisons, the best was the B-spline technique, followed by our attention-based technique. Interestingly, we found that including an average dice loss



Type	Mean (mm)	Stdev (mm)
Pre-Registration	17.12	4.96
Voxelmorph (Dice)	7.76	2.48
AmorWarp (Dice)	6.92	2.4
Voxelmorph	6.92	2
AmorWarp	6.88	2.48
Elastix	6.12	2.04

Type	Mean (mm)	Stdev (mm)
Pre-Registration	15.52	3.36
Elastix	9.36	3.68
AmorWarp (Dice)	8.64	3.72
Voxelmorph (Dice)	8.64	3.12
AmorWarp	8.36	3.92
Voxelmorph	7.92	3.2

Figure 3 Evaluation of registration accuracy using 95% Hausdorff distance across 17 automatically generated head and neck contours. The left column gives the accuracy when registering two images of the same patient (intra-patient registration). The right column is for registrations between images from two separate patients (inter-patient). Pre-Registration indicates the amount of contour matching prior to deformable registration. Voxelmorph is the CNN-based deformable registration, Elastix is the B-spline-based iterative deformable registration, and AmorWarp is our proposed axial attention approach. Networks trained with a contour dice loss are indicated with a (Dice) suffix. Each boxplot is summarized in a table below the figure. Our proposed method is second-best for both intra- and inter- patient registration, demonstrating robustness in both large and small deformations.



Type	Mean (mm)	Stdev (mm)
Elastix	9.80	2.80
Pre-Registration	7.66	1.63
Voxelmorph (Dice)	5.44	2.04
Voxelmorph	4.03	1.29
AmorWarp	**3.56**	**1.67**
AmorWarp (Dice)	**3.37**	**1.62**

Figure 4 Evaluation of intra-patient registration accuracy using target registration error (TRE) for a selection of manually created landmarks. The top of the figure shows an example comparing the deformable image registrations (DIR) for the proposed (AmorWarp), CNN-based (Voxelmorph), and B-spline-based (Elastix) methods. The registration has been applied to the moving image's landmarks, and each method's deformed points are superimposed on the target image. The average and standard deviations of the TRE across the 14 test patients is shown in the bottom table. Our proposed registration method was superior to both the CNN and B-spline based techniques.

term led to poorer performance for both the CNN and attention-based networks.

In addition to contour matching, we also investigated intra-patient landmark matching which gives a finer analysis of how well the individual voxels are deformed. Our analysis revealed that the axial attention-based network outperformed both the CNN and B-spline method. Figure 4 visualizes this performance, demonstrating how our method more accurately places anatomical landmarks such as the nose, teeth, and epiglottis.

4 Discussion

Our novel 3D DIR model relies on a self-attention backbone to compute the DVF as a representation of the relationship between two inputs. The major advantage of self-attention is its ability to model long range dependencies in the input. Since our input is the combination of moving and target images, understanding long range relationships within this amalgamation is crucial for appropriate deformation prediction. Additionally, attention provides a unique way to aggregate information from the input. Instead of learning a series of static filters, attention dynamically computes filters based on what it sees in the input[12]. This is due to its elegant system of keys and queries. This system is extended to an additional spatial advantage. Whereas convolution kernels spatially represent relationships through relative value placement in their kernels and layer down-sampling, attention with positional encoding learns dynamic representations of relative positional encoding across the entire input and output[12]. This allows for greater flexibility for the network to learn long-range spatial relationships prominent in the head and neck anatomy.

We harnessed these advantages to create the first fully attention-based DIR network. We showed that it performs comparatively or better than a selection of current DIR solutions. Notably, it performed well in *both* an inter- and intra-patient registration setting despite their somewhat conflicting goals for a single algorithm to manage. These results suggest an increased robustness in our network to both large and small distortions. We contend that this is because our network better learns matching points at large distances in its input, which is a unique feature of attention-based networks.

While our network exhibited strong results in inter- and intra- patient DIR, we recognize that this is an early implementation of a promising technique. Many design choices of this network could be further optimized for better results. Our proposed method was compared to more established techniques which have been extensively optimized. With further research into attention-based DIR, the exciting advantages of this technique can lead to a new paradigm in medical 3D deformable image registration.

5 Conclusion

A novel self-attention based deformable image registration model was developed for 3D medical imaging. We leveraged axial factorization to overcome the computational complexity of attention networks and to allow us to apply them to fully 3D input. This work opens the door for further applications of attention techniques in medical DIR.

The Prognostic Value of Foundational Radiomics and Clinical Features in Locally Advanced Non-Small Cell Lung Cancer in NRG Oncology Trial RTOG 0617

Taman Upadhaya, Elizabeth M. McKenzie, Indrin J. Chetty and Katelyn M. Atkins

Department of Radiation Oncology, Cedars-Sinai Medical Center, Los Angeles, USA

Abstract

This study investigated the feasibility of the foundational radiomics technique on the downstream task of predicting overall survival outcomes in patients with locally advanced non-small cell lung cancer (NSCLC). In an analysis of 449 patients from NRG Oncology/Radiation Therapy Oncology Group (ROTG) 0617, univariate cox regression identified 241 foundational radiomic and 19 clinical features as significant (p-value≤0.05) independent predictors of survival. Subsequently, the performance of popular predictive models, such as Least Absolute Shrinkage and Selection Operator (LASSO) in conjunction with a generalized linear model (GLM), Random Forest (RF), and Support Vector Machine (SVM) were evaluated using 5-repeat 10-fold cross-validation (n=278) and in an unseen independent test set (n=140), yielding an AUC of 0.67 (95% confidence interval [CI], 0.64-0.70) and 0.64 (95% CI, 0.54-0.73) based on foundational radiomics model solely employing SVM and 0.66 (95% CI, 0.73-0.68) and 0.67 (95% CI, 0.58-0.76) based on the clinical features model solely employing LASSO/GLM, respectively. When the foundational radiomics features were combined the clinical features, the AUC using a RF model increased to 0.74 (95% CI, 0.72-0.77) for the validation datasets and 0.67 (95% CI, 0.58-0.76) for the unseen independent dataset. This suggests that radiomics signatures provide complimentary information to clinical features for prediction of survival outcomes in patients with locally advanced NSCLC.

1. Introduction

A foundational model is an artificial intelligence (AI) model that uses a self-supervised learning technique to build the deep learning model on a vast amount of unlabeled data that can be applied to a wide range of downstream use cases. Recently, foundational models have demonstrated significantly enhanced performance in language and vision, driving successes in applications of ChatGPT, BERT, and CLIP in natural language processing (NLP), and SimCLR, YOLO, DINO, SAM and DALLE in computer vision [1, 2]. Furthermore, leveraging a foundational model for downstream tasks helps address the challenge of both limited and labeled data for modeling. This is particularly true in the domain of medical image analysis as colleting a substantial amount of data for modeling can be challenging. Thus, a foundational model capable of learning from diverse datasets through self-supervised learning, independent of specific outcomes, and capable of predicting various downstream tasks is highly desirable. To date, the only known foundational model study for 3D medical imaging was published by Pai *et el.,* [3] which was trained using a comprehensive dataset of 11,467 radiographic cancers on computed tomography (CT) imaging for various clinical relevance tasks. While there are many studies related to hand crafted radiomics features (intensity, texture, morphological) and deep radiomics (based on deep learning) the research for foundation radiomics (based on a foundational model) for prediction of oncologic outcomes is largely unexplored [4, 5].

In this work we exploit a pretrained foundational model from Pai *et el.,* for the downstream task of predicting 2-year overall survival in patients with locally advanced NSCLC. Our approach utilizes the foundational model as a feature extractor with various minor and major modification. In addition, we evaluated the complementary value of foundational radiomics features with clinical features using popular machine learning (ML) classifier namely generalized linear model with LASSO penalty, Random Forest (RF) and Support Vector Machine (SVM) for their performance.

2. Materials and Methods

2.1. Clinical cohort data

The NRG Oncology/Radiation Therapy Oncology Group (ROTG) 0617 data set from the National Clinical Trials Network (NCTN) was utilized. [6]. All relevant CT images, RT plans and clinical features such as Zubrod performance status, tumor histology, age, race, gender, smoking history, pneumonitis, esophagitis, chemotherapy, cetuximab, and RT dose groups (60 vs. 74 Gy) were utilized as per the NCTN dataset [7]. Additionally, dose statistics from heart, left anterior descending coronary artery [8], planning tumor volume (PTV), clinical tumor volume CTV), and ipsilateral lung structures were included in the analysis. Survival time and vital status were used to estimate 2-year overall survival (OS).

2.2. Foundational radiomics extraction

We employed a pretrained foundational model developed by Pai *et el.,* which was pre-trained on 11,467 diverse annotated cancers identified on computed tomography (CT) imaging. This foundational model is the modified version of the original SimCLR framework to effectively represent the nature of medical images [9]. It adopts ResNet50 architecture as encoder with the contrastive loss function in a self-supervised manner to learn to identify positive pairs of 3D patches surrounding the lesion and negative pairs, randomly sampled 3D patches from the rest of the scan [3, 10]. Once the model is trained, it can be used on various

downstream tasks, such as demonstrated in the original study. Furthermore, for our specific task, even though we used the same pretrained model, we modified the image transformation step by removing the seed-based crop to lesion-based crop to accommodate cancers of various sizes and multiple lesions within the region of interest. We then used these regions of interest from the CT images to extract 4098 features for our downstream task of predicting 2-year OS, which was termed features foundational radiomics.

2.3 Feature selection and machine learning

Univariate cox regression and correlation were applied to identify significant and independent predictors of 2-year OS. Subsequently, popular predictive models, such as LASSO, RF, and SVM were trained. Pre-processing for removing zero-variance features and centering (mean of zero and standard deviation of one) was applied before feeding features to the algorithms. Class imbalance was handled using the Synthetic Minority Over-sampling Technique (SMOTE) and tuning of the parameters for SVM, RF and GLM/LASSO were done using 5-repeat 10-fold cross-validation. All independent predictors were rank based on the importance score from LASSO, RF and SVM and then stepwise forward feature selection based on the previous ranking is used to select the subset of features minimizing the validation error. The final model for testing was chosen based on the highest area under the curve (AUC). For technical details, we direct readers to our prior publications [11, 12]. Three distinct experimental setups were carried out: (i) in the first approach, all RTOG 0617 patients (n=449) were included (for both high and low dose treatment arms), and after preprocessing split into training-testing cohorts (n=278 training, n=140 testing); (ii) the second approach was limited to patients from high dose arm (n=184 training, n=46 testing); and (iii) the third approach involved was limited to patients from low dose arm (n=150 patients training, n=38 testing).

3. Results

The univariate Cox analysis identified 822 foundational radiomics features (hazard ratios ranging from 0.14 to 3.35, and corresponding p-values ≤0.05) and 26 clinical features (hazard ratios ranging from 0.56 to 6.26 and p-values ≤0.05), as significant. Among them, 241 foundational radiomics features, along with 19 clinical features, were identified as independent predictors of survival.

Figure 1 illustrates the comprehensive performance results derived from our experiments. In the initial set of experiments, which incorporated all patients regardless of radiation dose, the model leveraging solely 12 foundational radiomics features achieved an AUC of 0.67 (95% confidence interval [CI], 0.64-0.70) in cross-validation and 0.64 (95% CI, 0.54-0.73) in unseen independent testing

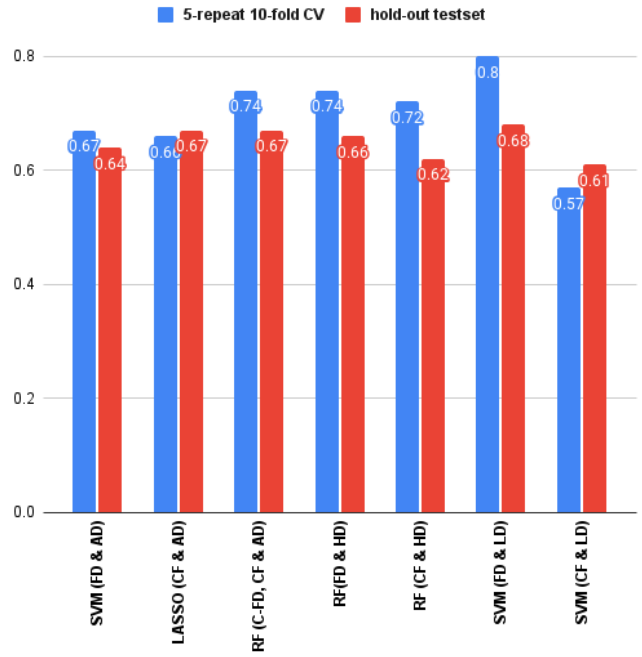

Figure 1. Performance of foundational radiomics feature (FD) based model, clinical feature (CF) based model and their combination (C-FD and CF) using all patients irrespective of dose (AD), as well as separately within high dose (HD) arm and low dose (LD) arm as assessed by 5-repeat 10-fold cross validation and in unseen independent test set.

using the SVM algorithm. In contrast, the model relying solely on 6 clinical features achieved an AUC of 0.66 (95% CI, 0.73-0.68) in cross-validation and 0.67 (95% CI, 0.58-0.76) in unseen independent testing using the LASSO algorithm. The combination of 7 foundational radiomics features and 4 clinical features (grade 3 esophagitis, PTV volume, ipsilateral lung mean dose, v5 heart and v5 lung percentage) produced the highest AUC of 0.74 (12 features) (95% CI, 0.72-0.77) in cross-validation and 0.67 (95% CI, 0.58-0.76) in unseen independent testing RF algorithm.

Similarly, in the subsequent set of experiments involving patients from the high dose arm only, the model based solely on 5 foundational radiomics features achieved the highest AUC of 0.74 (95% CI, 0.70-0.767) in cross-validation and 0.66 (95% CI, 0.50-0.83) in unseen independent testing using the RF algorithm. Conversely, the model relying solely on 6 clinical features (age, PTV log volume, chemotherapy, Left Anterior Descending Coronary Artery (LAD) mean dose, v5 lung and V95 PTV percentage) achieved an AUC of 0.72 (95% CI, 0.69-0.75) in cross-validation and 0.62 (95% CI, 0.45-0.78) in unseen independent testing, once again using the RF algorithm. However, the integration of foundational radiomics and clinical features did not enhance the AUC performance.

In the final experiment which incorporated patients from the low dose arm only, the model relying solely on 12 foundational radiomics achieved the highest AUC of 0.80 (95% CI, 0.77-0.83) in cross-validation and 0.68 (95% CI, 0.50-0.85) in unseen independent testing using the SVM algorithm. Meanwhile, the model relying solely on 9 clinical features (PTV log volume, ipsilateral lung mean dose, grade5 toxicity, LAD mean dose, heart mean dose, heart median dose, V5 and V20 lung percentage, V60 esophagus) achieved the lowest performance, with an AUC of 0.57 (95% CI, 0.53-0.61) in cross-validation and 0.61 (95% CI, 0.42-0.79) in unseen independent testing, once again using the SVM algorithm. Similar to above, the combination of foundational radiomics and clinical features did not enhance the AUC performance.

4. Discussion

In this study, we demonstrated that prediction models for OS can be built using foundational radiomics with ML techniques. In our first experiments involving all patients irrespective of dose received, the model incorporating both foundational radiomics and clinical features outperformed the model replying solely on foundational radiomics features or clinical features. Overall, all methods led to models with modest AUC (around or above 0.66). As we shifted our approach from dose-agnostic to those receiving high vs low dose treatments separately, we observed noticeable variations in model performance, worth of further study. For the experiment involving only patients from the high-dose arm, the foundational radiomics-based model solely achieved a performance of 0.74 in cross-validation and 0.66 in the unseen test set, outperforming the clinical feature-based model. Similarly in the experiment involving only patients from the low dose arm, the foundational radiomics-based model reached a performance of 0.80 in cross-validation and 0.68 in unseen independent test set, again outperforming the clinical features-based model. In both analyses by dose arm, the combination of foundational radiomics and clinical features did not improve the model performance.

To our best knowledge, this study is the first to investigate the prognostic and complementary value of foundational radiomics with clinical features using various popular machine learning algorithms. To date, only one study has been reported using foundational radiomics for prognostication by Pai et al., however they only included one linear classifier. Our study achieved similar performance to the previous study using foundational radiomics, though our approach uniquely explored the additional benefits of combining these foundational radiomics features with clinical features.

Our study has notable limitations. In the model development, we did not perform fine-tuning on our data set that could potentially improve the performance. However, it is important to note as these foundational models get bigger- hosting, building, and training a foundational is an incredibly expensive endeavor—often costing millions of dollars. Therefore, investigating downstream tasks of models such as these would be crucial. Our analysis also did not include handcrafted radiomics features. We are actively working on expanding our work to fine tune the foundational model, include handcrafted radiomics features and additional anatomical structures such as the heart and lung, which could provide further insights into tissue characteristics, as our ML framework is easily amenable to incorporation of additional data [13].

5. Conclusion

In conclusion, a self-supervised foundational model based on radiomics signatures showed promising prediction of 2-year OS for patients with locally advanced NSCLC from RTOG 0617. The combination of foundational radiomics with conventional clinical features provided even better prediction, suggesting the complimentary value of foundational radiomics in outcomes modeling.

Abstract In this work we contrast feature values acquired from different treatment groups for patients receiving MR-guided radiotherapy as part of treatment. A total of 69 patients with localised prostate cancer were included in this study. We explored the impact of different fractionation schemes and androgen deprivation therapy on radiomic feature values acquired from on-treatment T2W-images. Using conventional radiomic approaches, by assessing robustness against contour variation and correlation to volume, we identified 41 features out of 95 to be redundant across treatment groups. An in-house longitudinal methodology for determining representative feature trajectories was used to identify 8 features that were then used for further analysis in assessing relations between feature values within the dominant lesion and entire prostate.

1 Introduction

With the rise in MR guided radiotherapy (MRgRT) there is an increasing amount of rich longitudinal MR imaging data from patient on treatment. There is now an unmet need for models that can fully utilise this rich longitudinal MR data to provide useful clinical insight in to a patient's response to radiotherapy. Radiomic features provide quantitative metrics to derive information relating to the texture, shape and spatial heterogeneity of different tissues which could be used in the development of potential novel image-based biomarkers.

For patients with prostate cancer, radiotherapy is moving to stereotactic ablative radiotherapy (SABR) as standard of care. This is enabled by advances in image-guided radiotherapy (including MRgRT) enabling precision treatments and thus enhanced treatment individualisation For MRgRT, tracking changes in the dominate intraprostatic legion (DIPL) in the prostate becomes possible. Radiomics may allow changes to the DIPL to become discernible, informing treatment escalation if needed. These changes may inform if longer 20 fraction treatments are beneficial in some men over the shorter SABR regimes.

In this work, we investigated the influence of different treatment pathways on radiomic feature values for patients receiving MRgRT for prostate cancer. Our primary aims were to:

- discern if there were any significant differences in the distribution of feature values between each treatment group.
- investigate the trajectory of radiomic features for each ROI during the course of treatment.

We achieved this by utilising pre-existing feature reduction techniques and using our in-house methodology for handling longitudinal changes in radiomic features.

2 Materials and Methods

2.1 Patient Data

In total, 69 patients (median age of 72.5 years and range of 57-77 years) were included in this study. All patients had a diagnosis of localised prostate cancer (Cambridge Prognostic Group 2-4) and received radical MRgRT delivered on a 1.5T MR Linac. Treatment group 1 received androgen deprivation therapy (ADT) and 60 Gy in 20 fractions over 4 weeks of prostate radiotherapy, group 2 received prostate SABR (36.25 Gy in 5 fractions on alternative days over 2 weeks) and ADT and group 3 received SABR alone without ADT.

A 3D T2W-image was collected at each fraction for SABR patients and at fractions 1, 5, 10, 15, 20 for patients receiving 20 fractions. Each image was acquired with an echo time of 278 ms, repetition time 1535 ms, voxel spacing 0.83 x 0.83 mm and slice thickness 2 mm.

The entire prostate and the DIPL was contoured on the first fraction image of each patient by at least one of three clinicians; two clinical oncologists specialising in urology (Observer A and B) and a radiologist (Observer C). A full breakdown of the number of patients in each treatment group and the number of contours provided by each observer is shown in Table 1. The feature values from Observer A were used to conduct all analysis - feature values from Observer B and C were used for the sole purpose of determining robustness against contour variation, as discussed in Section 2.3.2.

Treatment Group	Obs A	Obs B	Obs C	Total
20 Frac + ADT	25	10	4	25
SABR + ADT	23	10	5	24
SABR + no ADT	20	13	5	20

Table 1: Number of patients included in each treatment group with both the whole and DIPL contoured. Patients with SABR received 36.25 Gy in 5 fractions, whilst patients receiving 20 fractions were treated with 60 Gy. Patients with ADT at least 3 months prior to the first fraction of radiotherapy. Obs refers to the clinician that provided the contour of the DIPL mask.

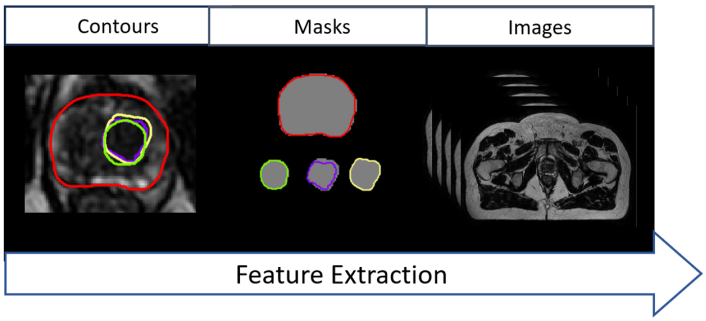

Figure 1: General radiomics feature extraction pipeline. An observer delineates the DIPL contours are generated. The masks from those contours are then used to extract radiomic features from each of the 5 T2W-images per patient acquired during treatment.

2.2 Feature Extraction

Prior to feature extraction, images were rigidly registered and to the first fraction image. Histogram-matching was also per-formed to standardise each image intensity distribution to the first fraction image for each patient. PyRadiomics (v3.1.0) was then used to extract 95 features from each available image with a fixed bin size of 25 and no voxel resampling. Following extraction, feature values were rescaled to be within [0,1] in order to improve comparability.

2.3 Feature Robustness

Multiple studies have shown the importance of feature reduction techniques in radiomics analysis. Identifying potentially useful clinical features involves removing any redundant features. Due to the high dimensionality of radiomics features, a number of feature reduction techniques are needed to determine the most robust and representative features.

2.3.1 Volume Correlation

Traveso et al. have shown that certain radiomic feature values have a strong dependence on the volume of the mask used to extract features from [1]. Feature values at Fraction 1 were correlated to volume values using Spearman rank correlation, ρ.

If $|\rho| \geq 0.6$, features were deemed to be strongly correlated to volume. Features that were identified as strongly correlated to volume in 2 out of 3 treatment groups were removed.

2.3.2 Inter-Observer Variability

The intra-class coefficient, ICC, provides a measure of agreement between different observers. Many studies have shown the importance of test-retest analysis for radiomic feature values since we aim to ensure robustness against variations introduced by different observers [2].

In this work, the ICC was used to measure the consistency of feature values calculated from a subset of patients contoured by all 3 observers. Features with an ICC < 0.75 were removed from further analysis.

2.3.3 Representative Feature Trajectories

Following the feature reduction steps above, we aimed to identify features that were the most representative when accounting for the full trajectory over treatment. Rather than look at single timepoint values or the difference between two timepoints (i.e. delta-radiomics values from fraction 1 to 5), we compared how different radiomic feature values evolved over the course of treatment.

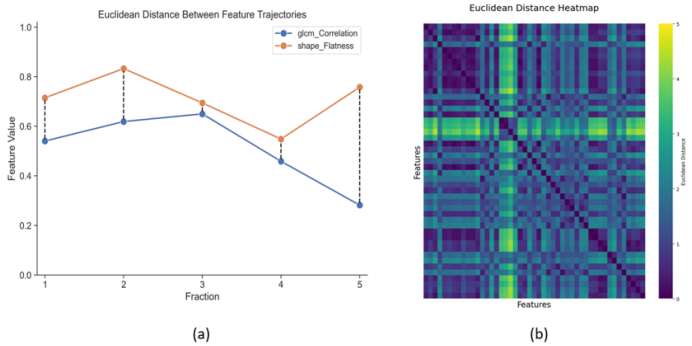

Figure 2: How feature trajectories are used to group together similar features. In (a) the Euclidean distance is used to measure the spatial separation between feature values at each timepoint. These values can then be visualised, like in (b), to see trends across feature sets. These values are then used in our hierarchical clustering algorithm.

For each patient, the Euclidean distance between feature-pair trajectories was computed. These distance values were then used to group features in to similar trajectories based on hierarchical clustering. Clusters of more than 8 features were futher broken down in to sub-clusters and clusters with less than 3 features were discarded as they deemed unstable.

Within these clusters, we performed a Pearson correlation and identified the trajectory with the highest mean correlation to all others. This feature was then passed through to the ranking stage.

The most representative features were then identified from the top 10% of features most commonly ranked across the

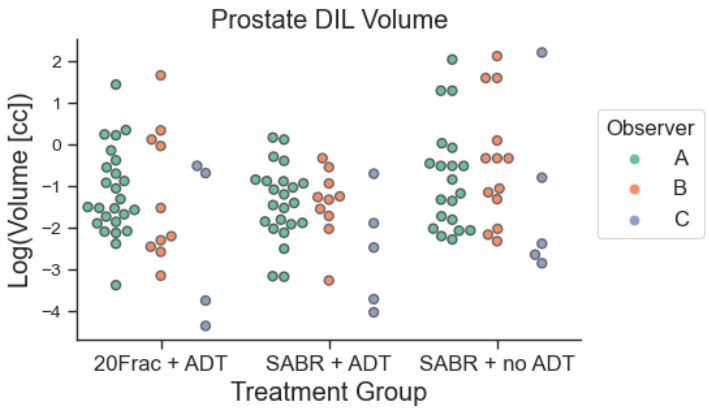

Figure 3: Swarm plot of the log(volume) of each DIPL mask for treatment groups. Patients without ADT appear to have larger volumes. Also shows the degree of consistency between different observers in relation to the contoured volumes.

patient group. Features found to be robust in 2 out of 3 treatment groups were used for further anaylsis.

2.4 Prostate vs DIPL

After identifying the most representative feature trajectories, we used the chosen features to investigate the relationship between feature values calculated from the DIPL and entire prostate mask. At the first and last fraction of treatment, we used the Pearson correlation coefficient to quantify the linear relationship between features calculated on the DIPL and the prostate. We hypothesise that due to the near-uniform treatment dose to the prostate during RT, that features within the prostate and DIPL would become increasingly correlated.

3 Results

3.1 Volume Analysis

The volume of the DIPL contours was compared across treatment groups and observers. Fig 3 shows how the distribution of the DIPL volume masks differ. For the SABR + no ADT group, the mean DIPL volume was 1.42 cm^3 with a standard deviation of 2.41 cm^3. When comparing to patients who did receive SABR + ADT, the mean volume is 0.31 cm^3 with a standard deviation of 0.28 cm^3. For the 20 fractions group that was found to be 0.63 cm^3 and 1.05 cm^3

3.2 Feature Robustness

A total of 13 patients were used to determine ICC values for each feature. Of the 93 features analysed, 30 features were found to be not robust against IOV, leaving 63 features. Upon calculating the correlation to volume, 20 features were deemed strongly correlated. Of those 20, 9 were also sensitive to IOV - totalling 41 redundant features.

The remaining 52 features were then used to determine the most representative feature trajectories over

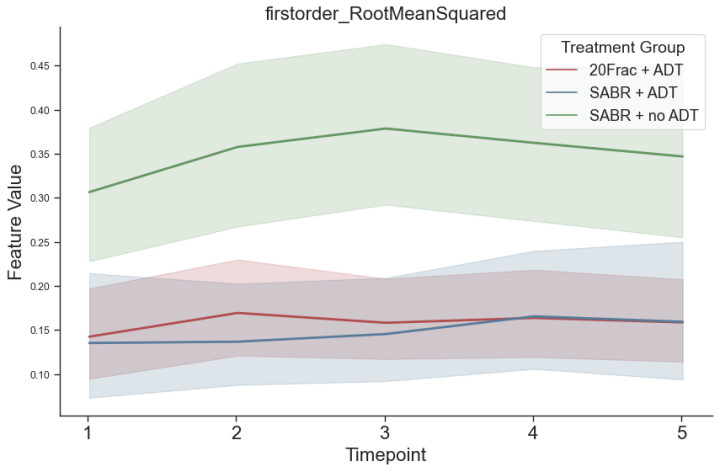

Figure 4: Signal plot of $firstorder-RootMeanSquared$ for each treatment group. Identified as robust in each treatment group. Solid represents the mean and shaded areas denote 95% CI. Clearly shown is the separation between the SABR + no ADT group.

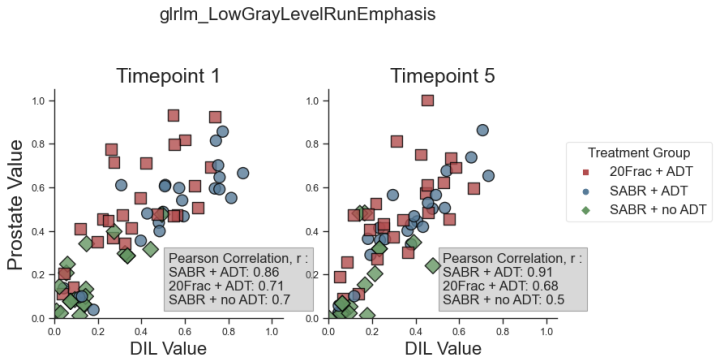

Figure 5: Distribution of feature values calculated at each timepoint. Pearson correlation was used to quantify the linear relationship between the values from the prostate and DIPL.

the 5 timepoints of treatment. Following the clustering process, we identified 4 features selected by each of the treatment groups: $firstorder-RootMeanSquared$, $glcm-JointEntropy$, $glrlm-LowGrayLevelEmphasis$ and $gldm-GrayLevelVariance$. A further 4 features were common in 2 out of 3 feature groups and were carried on to the next stage of the analysis.

3.3 Prostate vs DIPL

In the 20 Fraction + ADT only 2 out of the 8 features showed an increase in the Pearson correlation coefficient. Conversely 6 of 8 features increased in correlation in the SABR + ADT group and 4 features in the SABR + no ADT group showed an increase in Pearson correlation coefficient. Figure 5 shows an example of the feature distributions at the first and last fractions of treatment.

4 Discussion

We were able to identify features robust against observer variations and volume correlation for feature values calcu-

lated between different radiotherapy treatment schemes for prostate cancer. Despite this though, there are stark differences in the distribution of features as shown by Figs 5 and 4. There is a clear distinction between feature values from the SABR + no ADT group and the other two treatment groups. ADT is known to shrink and homogenise signal within the prostate and so this may be the driving force between the relative differences [3].

Another area where the impact of ADT is visible is the volume of the DIPL contours. The mean DIPL contour was over 1 cm^3 larger than contours from the other 2 treatment groups too. Further analysis is required to discern if the pronounced differences is influenced by volume. Another factor when considering the volume of the masks, is the difficulty in generating contours of the dominant lesion, given their small size. This may also be a factor in making them more susceptible to noise.

When comparing feature distributions between the two groups that received ADT, as in Fig 4, we found that there was no clear distinction between patients receiving 5 and 20 fractions of radiotherapy, despite the treatment duration lasting 20 days longer for 20 fraction patients.

Here we have provided a framework for longitudinal analysis of radiomic features acquired from on-treatment images. Future work could involve correlating clinical endpoints and to robust features in order to help further treatment personalisation for patients.

5 Conclusion

To conclude, we showed the strong impact that ADT has on feature values and contrasted the differences in distributions across patients receiving different courses of treatment for prostate cancer. We have also demonstrated a method to identify robust radiomic features across treatment groups and find representative feature trajectories from routine images acquired as part of MRgRT.

Abstract In radiation therapy treatment planning, finding optimal machine configurations, to get maximal coverage of the tumor and minimize damage to critical and healthy organs, is an important optimization problem. Proton Therapy is a new technology enabling high-precision treatment of the tumor close to critical organs. However, treatment planning for proton therapy comes with computational challenges arising from the large number of decision variables and the sensitivity of the treatment to the movements of the patient. In this research, we experiment with different optimization models for proton therapy and evaluate their performance. To tackle large-scale problems, we developed sparsifying and size reduction techniques, including cropping CTs, and prolonging voxels in the interior of organs. In addition, we develop an efficient successive relaxation method for the mixed integer formulation that provides an optimal plan, achieving prescribed DVH constraints. Numerical results show a high level of comformality to DVH goals.

1 Introduction

Creating and delivering an optimal treatment plan, where the target volume receives the prescribed dosage while minimizing exposure to other tissues represents the ultimate goal in radiation therapy. Achieving perfect equilibrium in this regard, however, proves to be an unattainable goal. Instead, the process necessitates making various trade-offs and developing optimization models that deliver clinically sound treatment plans. Numerous factors come into play that influence the degree to which a patient's treatment can be optimized [1]. This research delves into the complexities of optimizing a proton therapy (PT) plan, with a specific focus on challenges related to building and solving large-scale optimization models arising in PT treatment planning.
The characteristics of PT enhance the potential for achieving a treatment with minimal negative impact, primarily due to the precise concentration of dose in the characteristic Bragg peak. This is particularly relevant to the capability of administering elevated radiation doses in close proximity to normal tissue structures, which would typically be dose-limiting in conventional X-ray treatments. Additionally, the finite range of protons contributes to a much reduced integral dose to the surrounding healthy tissues [2].
A primary hurdle in the planning and optimization of radiation treatment lies in integrating prescribed dose-volume goals to ensure adequate coverage of the target and proper sparing of healthy structures. Conventional optimization models incorporating dose-volume histogram (DVH) constraints are computationally challenging. Recently, the planning process in clinical settings has largely become computerized, but the efficiency in meeting specific dose-volume requirements still heavily relies on the planner's experience. Consequently, a typical treatment planning process is resource intensive, as it necessitates numerous iterative and manual interventions from the planner [3].
For PT, efficiently building and solving conventional treatment planning optimization models seemed to be impossible in practice, because of the high number of variables to be optimized and the higher sensitivity of PT to uncertainties and motions. To be more precise, in PT optimization models, numerous beamlets are defined for each spot with specific energy levels for each field. On the other hand, using a fine grid for fully discretized problems, calculating the dose for all voxels, building the optimization model, and solving it efficiently is referred to as one of the major challenges for PT [4]. To mitigate this issue, some authors try to reduce the size of the problem by increasing grid spacing [5] or iteratively resampling from pencil beams [6]. However, such approaches impact the quality of the plan.
In this research, we employ three techniques to reduce both the number of voxels and increase efficiency of optimization:

- Cropping CTs to remove irrelevant voxels.
- Sparsifying dose-influence matrix, which is calculated by MatRad.
- Enlarging voxel size in the interior of organs at risk.

Accordingly, we use three optimization approaches to evaluate their performance for PT. In addition, a successive relaxation algorithm is developed to find an optimal plan, satisfying prescribed DVH constraints.

2 Materials and Methods

Our approach has three major parts: 1) preparing and processing data; 2) building optimization models to find optimal treatment plans; 3) methods to solve the optimization problems. Our methodology is explained in the following sections.

2.1 Data Preparation

Let V denote the set of voxels, and O the set of Organ-at-risk (OARs). The set of voxels in the target volume is denoted by

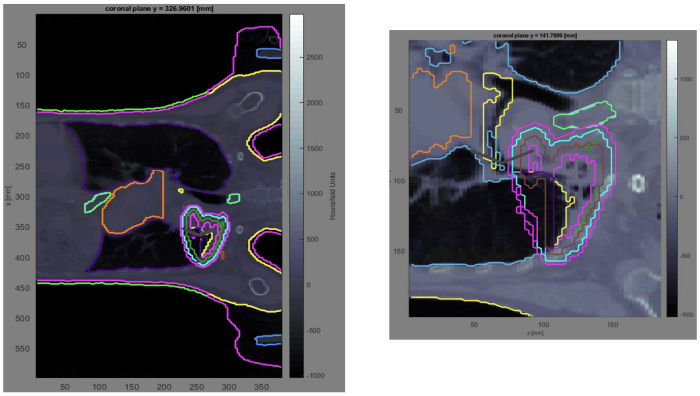

Figure 1: A sample of cropping CT for a Lung cancer case.

V_T, and the set of voxels in OAR o by V_o. Let B denote the set of beamlets. To build the optimization model, one needs to calculate the dose d_{ij} received at voxel i from the unit intensity of beam j. We use MatRad [7] for this calculation. We store the calculated dose d_{ij} in matrix $D \in \mathbb{R}^{|V|\times|B|}$, which is known as the dose-influence matrix. In treatment planning, we are interested in finding the optimal intensity of beamlets, x_j for all $j \in B$. For each beamlet, we can calculate the accumulated dose by $\mathscr{D}_i = \sum_{j\in B} d_{ij}x_j$.
MatRad and other APIs use dose calculation algorithms to calculate the dose-influence matrix in a reasonable time. Although this matrix is usually sparse, the large size of this matrix and the large number of nonzero elements make the solution of the optimization problems impossible. We use three techniques to reduce the size of this matrix.

2.1.1 CT Scans Truncation

Some parts of CT scans are not useful for treatment planning, as that part of the body is not affected by any beams. Thus, we crop parts of CT scans that a clinical expert marked as unnecessary parts. For example, Figure 1 shows how many voxels are removed by cropping a CT scan of a Lung patient.

2.1.2 Sparsification

The dose-influence matrix usually has many extremely small numbers, that create severe numerical problems. Thus, those elements in the dose-influence matrix that are less than a constant times the maximum of the corresponding column are made zero. This way the matrix gets sparser and better conditioned for plan optimization.

2.1.3 Inner Voxel Prolongation

To reduce the number of voxels, one can increase the size of voxels. However, this will affect the quality of the plan. To have a high-quality plan, we use a fine grid with appropriate voxel size. For voxels in the interior of the organs, we double the voxel size by combining adjacent voxels. In this way, the voxels on or near the boundary of organs are small and enable precise calculation for that area. On the other hand, the total number of voxels will significantly decrease as the number of interior voxels by up to 87.5%. We avoid prolongation for voxels in the target volume to have a high-quality plan.

2.2 Optimization Approaches

The general idea of treatment optimization is minimizing the deviation of dose on target from the prescribed bound, while the dose received in OARs is bounded by prescribed DVH constraints. We present three optimization approaches.

2.2.1 Linear Optimization

In the linear optimization (LO) approach, we have prescribed upper bound $T_{\max}$ and lower bound $T_{\min}$ for the dose received by the target volume. Each OAR has an upper bound MD_o.

$$\begin{aligned}
\min\ & \sum_{i\in V_T} s_i + \sum_{i\in V_T} s'_i \\
\text{s.t.}\ & \sum_{j\in B} d_{ij}x_j - s_i \le T_{\max} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j + s'_i \ge T_{\min} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j \le MD_o \text{ for all } i \in V_o \text{ and } o \in O \\
& x, s, s' \ge 0.
\end{aligned}$$

As the objective function and the constraints are linear, we have a linear optimization (LO) model. It can be solved efficiently by commercial optimization solvers, such as Gurobi.

2.2.2 Mixed-integer Optimization

The major disadvantage of the LO approach is that the quality of the plan is not good, since we use a bound on all voxels in the OAR. In clinical practice, physicians usually prescribe a dose limit to a volumetric fraction of the OARs, i.e., limit a point on the DVH curve. More precisely, for OAR o, we have (UD_o, UV_o), which means that UV_0 fraction of voxels in OAR o can NOT receive a dose higher than UD_o. To incorporate such DVH constraints, we need a mixed-integer optimization (MIO) model. Let M be the highest dose a voxel can get, and n_o is the total number of voxels in OAR o.

$$\begin{aligned}
\min\ & \sum_{i\in V_T} s_i + \sum_{i\in V_T} s'_i \\
\text{s.t.}\ & \sum_{j\in B} d_{ij}x_j - s_i \le T_{\max} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j + s'_i \ge T_{\min} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j \le UD_o + (M - UD_o)y_i \text{ for all } i \in V_o,\ o \in O \\
& \sum_{i\in V_o} y_i \le UV_o n_o \text{ for all } o \in O \\
& x, s, s' \ge 0.
\end{aligned}$$

Although the MIO formulation provides an ideal plan, there is no efficient way to solve it, as it is a large-scale mixed-integer optimization problem.

2.2.3 Second-order Cone Optimization

To bridge the LO and MIO approaches, a moment-based approach was proposed in [8]. Consider the DVH curve as a function. Let $\mathscr{D}$ be the resulting DVH curve and $\bar{\mathscr{D}}$ be the prescribed one. Let $\mu_k(f)$ be the kth moment of function f. In the moment-based approaches, the moments of the resulting DVH are bounded by the moments of the prescribed DVH.

$$\begin{aligned}
\min\ & \sum_{i\in V_T} s_i + \sum_{i\in V_T} s'_i \\
\text{s.t.}\ & \sum_{j\in B} d_{ij}x_j - s_i \le T_{\max} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j + s'_i \ge T_{\min} \text{ for all } i \in V_T \\
& \mu_1(d_j) \le \mu_1(\bar{d}_j) \text{ for all } i \in V_o \text{ and } o \in O \\
& \mu_2(d_j) \le \mu_2(\bar{d}_j) \text{ for all } i \in V_o \text{ and } o \in O \\
& x, s, s' \ge 0.
\end{aligned}$$

It is shown in [8] that the above model is a second-order cone optimization (SOCO) model and commercial solvers, e.g., Gurobi, can solve it efficiently.

2.3 Successive Relaxation Method

As mentioned, there are efficient solvers for LO and SOCO, but still solving MIO model is challenging. Here we develop the Successive Relaxation Method (SRM) to solve MIO model as follows. Let $m_o = [UV_o n_o]$ for all $o \in O$.

Step 1. Solve the initial linear problem as

$$\begin{aligned}
\min\ & \sum_{i\in V_T} s_i + \sum_{i\in V_T} s'_i && (1)\\
\text{s.t.}\ & \sum_{j\in B} d_{ij}x_j - s_i \le T_{\max} \text{ for all } i \in V_T && (2)\\
& \sum_{j\in B} d_{ij}x_j + s'_i \ge T_{\min} \text{ for all } i \in V_T && (3)\\
& \sum_{j\in B} d_{ij}x_j \le UD_o \text{ for all } i \in V_o \text{ and } o \in O && (4)\\
& x, s, s' \ge 0. && (5)
\end{aligned}$$

Calculate the dual variables, also called shadow prices, of constraints (4) as sp_{io} for all $i \in V_o$ and $o \in O$.

Step 2. OV_o : the list of m_o voxels with the largest shadow prices for $o \in O$, and $LV_o = V_o - OV_o$.

	Before Sparsifying	After Sparsifying
# of Nonzeros	13,475,201	6,824,686
Min Nonzeros	1.6428e-20	4.01105e-05
Max Nonzeros	4.0110e-03	4.0110e-03

Table 1: Effect of sparsification on the dimension of the data from a Lung patient.

Step 3. Solve the following linear optimization problem as

$$\begin{aligned}
\min\ & \sum_{i\in V_T} s_i + \sum_{i\in V_T} s'_i \\
\text{s.t.}\ & \sum_{j\in B} d_{ij}x_j - s_i \le T_{\max} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j + s'_i \ge T_{\min} \text{ for all } i \in V_T \\
& \sum_{j\in B} d_{ij}x_j \le UD_o \text{ for all } i \in LV_o \text{ and } o \in O \\
& \sum_{j\in B} d_{ij}x_j \le M \text{ for all } i \in OV_o \text{ and } o \in O \\
& x, s, s' \ge 0.
\end{aligned} \qquad (6)$$

Update sp_{io} for all $i \in V_o$, OV_o, and LV_o for $o \in O$.

Step 4. If OV_o is changed, go to **Step 3.**
Otherwise, terminate the algorithm.

We proved the convergence of this algorithm for the MIO approach of proton treatment planning. Numerical results demonstrate its high practical proficiency.

3 Results

We implement our approach in MATLAB. We use data from 7 patients. Five of them are Lung cancer patients and the other two are Brain cancer patients. Gurobi's barrier methods are used to solve the LO and SOCO models. For solving MIO models, we use the proposed SRM. Both the MIO and SOCO models are solved in minutes. Figure 2 illustrates that they provide high-quality plans.

4 Discussion

Table 1 shows that the dose-influence matrix calculated by MatRad contains many tiny elements, as small as 10^{-20}. These tiny elements significantly increase solution time and cause numerical challenges in the optimization process. Our sparsification technique resolve these issue, and Table 1 shows the effect of sparsifying dose-influence matrix on the size of the problem. Computational results show that smart sparsification also allows high-quality plans.

Table 2 shows that by cropping unnecessary parts of CTs, we can reduce the number of rows and columns by half which leads to smaller data and faster optimization. We tried to build LO and SOCO models without sparsification and CT truncation, but the state-of-the-art solvers reached out-of-memory errors even on a computer with 132 GB of memory.

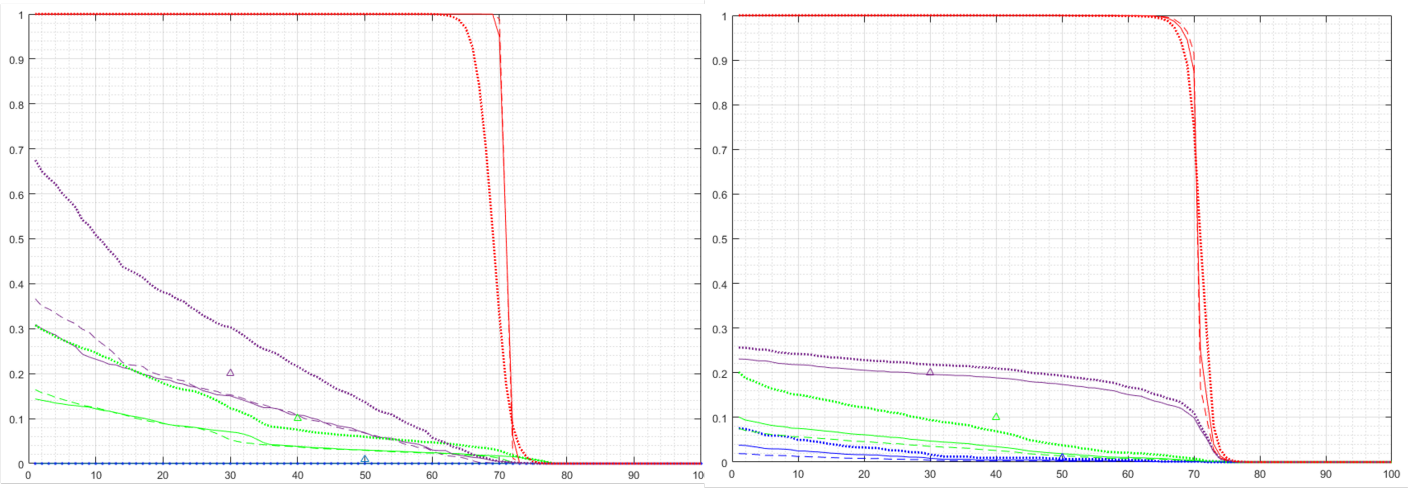

Figure 2: DVH curves of plans for two lung patients. Dotted lines: LO, Solid lines: SOCO, Dashed lines: MIO. Red: Target, Purple: Esophagus, Green: Lungs, Blue: Heart. Triangles indicate prescribed DVH constraints.

	Rows	Columns	Nonzeros
Before truncation	382,247	478,548	89,213,704
After truncation	166,835	222,403	16,717,861
Reduction	56.3541%	53.5254%	81.2608%

Table 2: Effect of cropping CTs on the dimension of the SOCO model for a Lung patient.

	Variables	Constraints	Solution time (s)
Uniform voxel size	414,088	389,395	28,872.22
Different voxel sizes	90,416	65,723	246.36
Reduction	78.16%	83.12%	99.14%

Table 3: Effect of prolonging the size of interior voxels on the dimension of the SOCO model for a Lung patient. For both cases, matrices are sparsified and CTs are cropped.

By sparsification and CT truncation, we solve the LO and SOCO models in a few hours.
To further reduce optimization model size, we increase the size of interior voxels. As Table 3 demonstrates, this significantly reduces problem size, and SOCO solution time reduces to minutes, however MIO models are still solved in hours. To solve the MIO models efficiently, we develop a successive relation technique that solves MIO models in less than one hour. Figure 2 shows that both the MIO and SOCO approaches provide high-quality plans, although plans by the LO approach are not satisfying.

5 Conclusion

In this paper, we proposed proton therapy treatment planning approaches that provide optimal plans satisfying the DVH constraints with a few minutes of optimization time. This process is completely automated and no need for extra intervention from clinical staff. To speed up the process of optimizing a treatment plan, we reduced problem size by cropping CT scans, sparsifying the dose-influence matrix, and enlarging the size of interior voxels. All these preprocessing operations are done in a smart way to ensure a high-quality plan. We present three optimization approaches. Based on the results, the second-order cone and the mixed-integer models provide similarly conformal plans. To solve the mixed-integer model, we develop a successive relaxation method that provides a high-quality plan with respect to DVH goals within minutes.

Abstract A fast-accurate dose calculation algorithm can benefit planning and QA in proton therapy with pencil beam scanning. Recently, a study proposed a neural network (NN)-based dose calculation method for proton spots to accelerate calculation speed. However, there is a lack of a method to apply the NN method in calculating spot dose with complex configurations, such as specific energy, range shifter, isocenter, and scanning location. The study presented a detailed method to calculate the spot dose of clinical plans. In the phase of NN training, a total of 119244 pairs of MC spots dose and CT array were generated. The results showed significant accuracy of the NN. Testing spots' gamma passing rates (GPRs, 3mm/2%) were 98.76 %. The global GPR of 2 untrained patient doses was 97.76 %, and the mean time cost was 0.5s. We successfully established a frame for using NN to calculate complex plan doses.

1 Introduction

Both accuracy and speed are significant in dose calculations for planning and QA in proton therapy with pencil beam scanning (PBS) [1]. However, in clinics, accurate dose algorithms such as Monte Carlo (MC) are always time-consuming [2], which is not suggested in planning. In contrast, analytical algorithms such as the pencil beam algorithm (PBA) [3] have an outstanding speed performance that is widely applied in the calculations of dose influence matrix (d_{ij}) [4] in planning. However, PBA can quickly increase dose errors in heterogeneous tissues, leading to dose variations between optimization dose and final dose QA, and it will decrease the quality of plans.

Recent studies have proposed a neural network (NN) — based dose calculation method for proton spots to accelerate calculation speed [5,6], and the accuracy is higher than PBA. However, the studies were only focused on calculating doses with specific energy but without a method of computing doses in clinical scenes, such as with range shifters or specific gantry angles and emission angles.

Therefore, the study proposed a nova model named spots dose neural network (SDNN); the model input data involves energy and CT images and involves the name of range shifters. The SDNN dose calculation model is towards a clinically implemented proton dose calculation with PBS.

2 Materials and Methods

In establishing the dose calculation model, we generated 119244 data pairs for training and evaluating the model by random MC dose calculations.

2.1 Clinical Data

A clinical dataset was collected that contains 40 clinically implemented cases with PBS, which has CT images (slice size of 512 × 512, with pixel spacing of 1mm × 1mm, and slice thickness ranging from 2mm to 3mm), dose, plan, and contour files.

The 38 cases for generating random MC dose to train the model and the left 2 cases (a case with range shifter, another without) were used to validate the model's accuracy in calculating the global dose based on RTPLAN.

2.2 Random Monte Carlo Dose Generations

To implement NN in the calculated spot dose, we sampled full CT images into 16 × 256 × 256 size CT bars (pixel spacing of 3mm × 3mm × 3mm), with a random gantry angle and spot position, but we only reserved the sampled CT bars that passed the Body area of the patient.

A well-configured TOPAS-based MC frame [7] for PBS was used to calculate the MC dose on CT bars. The MC frame was based on the source plane model; thus, we located the source plane at the first slice of the CT bar with random energies. Moreover, we also computed the dose with a range shifter, which was close to the source plane in the MC dose computation.

In the phase of MC dose generation, a total of 119244 pairs of dose and CT bars were generated, with specific energies and range shifters—111296 pairs for training, 3974 pairs for validating and 3974 pairs for testing.

2.3 The Neural Network Structure

The backbone of the SDNN is an ′encoder-transformer-decoder' structure; the encoder converts 2D CT slice into 1D features; in contrast, the decoder refines the transformer

output 1D array into a 2D-slice array, slice by slice, then forms the 3D dose. The transformer structure takes CT features, energy, and range shifter switch (if the MC dose is calculated with the range shifter, the switch equals 1; it equals 0) and outputs 1D dose features. The overview of the SDNN is in Figure 1. The MSE loss function and Adam optimizer were used to optimize the weights of SDNN.

2.4 The Method of Evaluation

The gamma passing rates (GPRs, 3mm/2%) were used to evaluate the NN's accuracy in the untrained testing dataset and two patient plans. In the phase of computing plan dose by NN, we sampled CT bars according to the plan Dicom files, such as isocenter, gantry angle, spot position, and range shifter. When all the spot doses were calculated on CT bars by NN, a re-sample operation was made to align all spot doses to the dose coordination, resulting in the planned dose.

3 Results

The mean GPRs between the NN calculated, and MC doses in 3974 testing data were 98.76±1.54 %; The GPR for the plan dose without range shifter was 98.85%, for the plan dose with range shifter (water equivalent thickness equal 40 mm) was 96.67%, which shown a significant accuracy in a PBS plan dose calculation, however, the NN achieved an outstanding speed, that outcome a plan dose within 0.5s on an RTX 3090 GPU, in contrast, the TOPAS MC will cost beyond 5 hours to compute a plan dose with the comparable accuracy. The NN method shows a decisive advantage in accurate dose calculation.

4 Discussion

The study proposed a method with NN to compute spot dose in complex clinical scenes, such as with range shifters in specific gantry angles and spot positions. The feasibility study showed the application of the NN method in clinical proton dose calculation. In future studies, we should collect more clinical plan doses to evaluate the accuracy of our NN dose calculation method. Moreover, we should consider more clinical details, such as the couch angle, which was not considered in our study. Another possible attempt to boost the accuracy of NN is using clinical spot dose as training data; in contrast, the spot dose in our study is all generated by random MC dose calculated on random CT bars with random energies, whether clinical spot dose can benefit NN's accuracy should be considered in future. In the last, although we have simplified NN's structure, such as only using a single convolution/deconvolution in encoder/decoder to accelerate the calculation speed, there is still the possibility of simplifying the computation flow of the NN, such as token-selection tech [8] which only reserve the token that effective to the NN's output, to reduce the cost of computation.

5 Conclusion

The study proposed a nova neural network structure that can compute proton spot dose with/without range shifters. Our NN method of spot dose calculation is accurate in both random spot and clinical plan doses. The feasibility study shows that our NN method of proton dose calculation has the potential for clinical implementation.

Abstract We present JulianA.jl, an open source Julia package tailored to the needs of proton radiotherapy. JulianA accelerates proton radiotherapy research in multiple ways. First, it enriches the proton radiotherapy community with the full power of the Julia ecosystem for scientific computing. This allows researchers to use efficient implementations of the latest algorithms to improve treatment success and efficiency. Second, JulianA provides a flexible and modular toolkit of common functionality that relieves researchers from reinventing the wheel. Third, it includes a powerful fully automatic spot weight optimisation algorithm for proton radiotherapy. Fourth, its code is easily readable, usable and extensible even by domain experts with limited programming skills and easy to use even for students with a limited time budget. We demonstrate how a treatment plan of clinical relevance can be generated in only 19 min with just 38 lines of code, fully automatically and without providing objective weights or training data. Finally, we demonstrate JulianA's general utility for proton radiotherapy research with an application in deep learning.

1 Introduction

Software plays an increasingly important role in radiotherapy. From selecting the most beneficial treatment modality [1] to autosegmentation [2, 3] and autoplanning [4] - software already is shaping and advancing the state of the art in radiotherapy and the workflows in clinics. The surge of machine learning and artificial intelligence in radiotherapy [5] will further emphasise the importance of easily available, efficient and well-tested algorithms.

The complexity of radiotherapy workflows requires the combination of multiple specialised systems, sometimes even a mix of in-house and commercial software. Data transfer between these systems is often performed manually in a cumbersome and error-prone process, slowing down research in algorithms and imposing problems with regard to reproducibility. All major vendors offer a scripting API to their treatment planning systems (TPS), which removes the need for some manual steps for operations within the same planning system. However, data transfer to other systems still remains a manual process. The scripts are typically tailored to a specific TPS, sometimes even a specific version. This strong dependence forces clinicians and researchers to reimplement their scripts from scratch after changing a vendor, or even worse, prohibits changing the vendor altogether. This imposes a barrier to code reuse and wastes resources that could be spent on patient care or further clinical research. Finally, the scripting APIs only allow a superficial access to the planning systems, but not to the underlying algorithms. Researcher are limited to using the entire proprietary pipelines, but cannot examine or improve them one piece at a time. This hinders the proliferation of novel algorithms and the reproducibility of results across manufacturers.

Open source TPS efficiently address the problems of limited code reuse and modularity in two ways. First, the unrestricted access to source code fosters code reuse and supports researchers when developing novel algorithms. Second, open source TPS allow to combine functionality in ways that were not foreseen by the original authors. The two most popular open source TPS are matRad [6] and CERR [7]. Both have enabled a plethora of papers, are written in MATLAB and aim to provide TPS functionality to researchers. However, MATLAB, once an obvious choice for scientists without computer science background, is not the pinnacle of scientific computing for domain experts anymore. Specifically, the language is comparatively slow unless the problem can be formulated as matrix operations, which is not always the case in proton radiotherapy (e. g. calculating radiological path lengths, depth-dose curve lookups).

We present JulianA.jl, a novel open source package written in the Julia programming language [8]. It is tailored for applications in proton radiotherapy clinics and research environments and offers highest flexibility. The name JulianA is a portmanteau of the Julia programming language and FIonA, the name of our in-house TPS. JulianA's architecture and design prioritise ease of use, flexibility, extensibility and modularity. JulianA employs a script-first approach: It aims to provides a robust and modern software stack that enables researchers and clinicians to build their own tools. However, it does not contain a graphical user interface (GUI). Rather, it provides clean interfaces to TPS, which allows building TPS-agnostic workflows and implementing algorithms without vendor lock in. On top, it contains an automatic treatment planning algorithm for proton radiotherapy that does not rely on patient-specific objective weights or training data, enabling researchers to create high-quality

treatment plans within minutes [9]. The algorithm was only tested for intensity-modulated proton therapy, but in principle it could be applied to any other radiotherapy modality that relies on an influence matrix for optimisation, such as intensity-modulated radiotherapy. While the autoplanning algorithm has already been published, this work presents the underlying framework as a software package. The following sections explain our reasoning for the choice of the Julia language, outline an overview of the functionality and provide an example code including results to demonstrate the utility of JulianA in a research setting. Finally, we conclude with a presentation of first applications of the package in our research institute.

2 Materials and Methods

2.1 Design and Goals

The target audience of JulianA.jl are medical physicists, dosimetrists as well as bachelor, master and PhD students. This audience often has limited software development skills and limited time for tasks that involve substantial coding. Therefore, any software targeted towards them should be as simple to use as possible. The users should be empowered to quickly try out new ideas, exchange every building block of a workflow and automate any task they might need as a part of their research or clinical workflow. Therefore, JulianA was developed with three main characteristics in mind. First, it is written in a clear and readable way, following principles of modern software design such as SOLID [10], DRY (don't repeat yourself) [11] and KISS (keep it short and simple), to remain future-proof and easy to learn. This also lowers maintenance work and allows quicker addition of features. Second, JulianA is written in a modular way, which fosters code reuse and therefore promises synergies within and hopefully across research facilities. Further, modularity allows to build complex workflows without having to rewrite any code. Third, JulianA is vendor agnostic, yet allows interfacing with any treatment planning system. This property is especially important because it lays the foundation of code reuse across facilities, accelerating the adoption of new algorithms and kindling healthy competition among commercial vendors.

JulianA was implemented in the Julia programming language because it is easy to use and leads to fast code. These properties recently greatly increased Julia's popularity for computational sciences. The increased popularity in turn gave rise to a vast ecosystem of packages in the language. More and more developers of algorithms decide to use Julia for their proof-of-principle codes, which puts Julia at the forefront of computational advances. Additionally, Julia can be interfaced to Python and C code (two-way interfaces), which broadens the wealth of available packages even more. Julia comes with an advanced package management system that not only improves reproducibility, but also facilitates installation and deployment. Finally, Julia makes it easy for domain experts such as medical physicists to implement GPU code without diving into the depths of low-level programming languages. Further advantages of Julia can be found in literature [8, 12].

JulianA.jl is not another open source TPS. This niche is already occupied by excellent codes such as matRad and CERR. Experiences with our in-house TPS FIonA have shown however, that a substantial amount of work is needed to implement, maintain and extend graphical user interfaces (GUIs). In order to streamline quick and flexible development of novel algorithms and powerful workflows, we have employed a a scripting-first philosophy and deliberately abstained from including a GUI. Instead, JulianA.jl provides a stable and flexible foundation on top of which other tools (potentially with a GUI) can be built.

2.2 Features

JulianA caters to both the needs of users who need to automate parts of their workflows and users who need to write their own algorithms. For the former, it provides easy-to use high-level functions. For the latter, it provides a plethora of low-level operations such as calculating binary masks from contours, calculating in-slice distances from a structure, calculating water-equivalent depth and more. This architecture provides a quick entry path into the framework, but still allows users to build their own algorithms based on the low-level building blocks. At the same time, the high-level API serves as an example how to use the underlying low-level building blocks.

JulianA.jl supports many basic building blocks in proton radiotherapy. It can read and write DICOM CTs, structure sets and RT dose distributions. By default, all the metadata is removed to facilitate research, but meta-data can easily be retained or added if required.

JulianA.jl facilitates working with structures by calculating in-slice and full 3D distances to contours. The availability of the distance to the structure allows computing binary masks, which simplify any operations like inside-outside tests, calculating dose-volume histograms, mean and maximum doses to structures, structure expansion and shrinkage and boolean operations such as union and difference. Both the distances and binary masks are part of the structure's representation and can be easily accessed as attributes, which greatly facilitates the implementation of all algorithms that rely on structures.

JulianA.jl contains code to calculate the radiological path for photons and protons and dose distributions and influence matrices for proton radiotherapy. Further, it is possible to interface JulianA.jl with any TPS that allows scripting. The current version supports our in-house TPS FIonA, but we are currently investigating an integration to Eclipse and RayStation.

JulianA.jl also provides reporting and plotting functions. The former enables researchers to compare target coverage and compliance with organ-at-risk (OAR) constraints as tables with just two function calls and export as full LaTeXreports.

The latter creates publication-grade dose distribution and dose-volume histogram plots.
All this functionality has allowed us to quickly develop a novel autoplanning algorithm for proton spot weight optimisation, which is also included in JulianA.jl [9].

2.3 TPS Interface

JulianA can be interfaced with any TPS by specialising the following three functions

```
place_spots(
    tps,
    ct,
    field_definitions,
    # Structures that defines the iso-centers.
    field_structures,
)
calculate_Dij_matrix(
    tps,
    ct,
    plan,
    optimisation_points,
)
calculate_dose(
    tps,
    resolution,
    ct,
    plan,
),
```

where `tps` is a subtype of `Juliana.AbstractTps`. We have implemented them for our in-house TPS FIonA. Running the same JulianA.jl code in another institute with a different TPS can be realised by changing the type of the `tps` struct. No other changes are needed.

3 Results

3.1 Example code

The following code demonstrates how little code is needed to run a fully automatic spot weight optimisation using JulianA.jl:

```
# Load data.
ct, structures =
    Juliana.load_dicom_directory(data_dir)
constraints = Juliana.parse_oar_constraints_file(
    "$(data_dir)/constraints.csv",
    target_dose,
    structures,
)
prescriptions = Juliana.Prescriptions(
    [
        ("PTV_05_5412", 54.12f0),
        ("PTV_05_5940", 59.40f0),
        ("PTV_05_6996", 69.96f0),
    ],
    constraints,
)
tps = Juliana.FionaStandalone.FionaStandaloneTps(
    fiona_standalone_bin_path, fiona_jar_path,
    output_dir,
)
fields, center_structures =
    load_fields("$(data_dir)/beam_arrangement.csv",
    structures)

# Place spots.
plan = Juliana.FionaStandalone.place_spots(
    tps,
    ct,
    fields,
    center_structures,
)
 # Optimise.
optimal_weights, _, _ =
    Juliana.optimise_head_and_neck(ct, structures,
    prescriptions, plan, tps, tps.work_dir)
plan_optimised =
    Juliana.FionaStandalone.update_spot_weights(plan,
    optimal_weights)
# Calculate a dose distribution.
dose = Juliana.FionaStandalone.calculate_dose(
    tps,
    0.35f0, # dose grid resolution
    ct,
    plan_optimised,
)
```

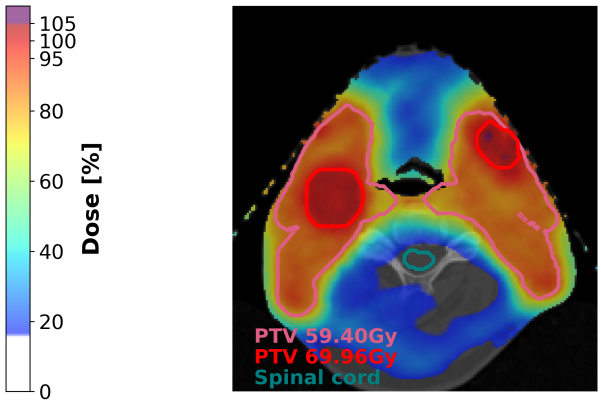

Figure 1: Pencil beam scanning proton dose distribution of a nasal cavity tumor generated and plotted using JulianA.jl. Color wash isodose levels of the prescribed dose are displayed on the left-hand side of the figure.

This code runs in approx. 19 min on an NVIDIA DGX A100 GPU, optimising 6 fields that contain a total of 152′989 spots. The resulting dose distribution is depicted in Fig. 1.

3.2 Applications

The validation study of the JulianA autoplanning algorithm [9] is currently under peer-review. Another study that

examines its capabilities for head-and-neck planning is in the writing stage. Based on the preliminary results, we are exploring the utility of JulianA.jl as a quality assurance tool and for patient selection at our institute. Finally, the JulianA.jl package has accelerated the validation of a deep learning model [13] (currently undergoing peer review) considerably. JulianA relieved the deep learning expert from learning how to use a TPS and manual treatment planning for each patient. In fact, JulianA.jl enabled us to perform clinical quality treatment planning for 12 patients within a single day and is able to scale to even larger datasets.

4 Discussion and Conclusion

We have presented the JulianA.jl package for proton radiotherapy. The package is easy to use and extend and allows researchers without special training to generate clinics-grade treatment plans. We have demonstrated that the package is useful to accelerate research on artifical intelligence in proton radiotherapy and intend to use it as a base package for more research endeavours at our institute. There are plans to extend our TPS interface to automatically upload JulianA.jl treatment plans back to our production TPS and add support for additional commercial TPS. Finally, we hope that our contribution encourages other researchers to write their code in a TPS-agnostic fashion and share it with the community.

[1]Department of Clinical Physics, Proton Therapy Center, Prague, Czech Republic
[2]Department of IBA, Proton Therapy Center, Prague, Czech Republic

Abstract
In Proton Therapy Center in Prague we treat patients since 12.12.2012 with pencil beam scanning technique. We treated more than 10 000 patients so far. For quality control of treatment planning we have developed an independent dose calculation check. Our automated workflow is based on Monte Carlo simulations and enables verification of dose computational algorithms of local treatment planning system RayStation 12A (RaySearch, Sweden).

1 Introduction

Explicit modelling of particle transport makes the Monte Carlo method the method with the highest calculation accuracy. Dose distribution is calculated in real inhomogeneous patient environment, therefore MC provides complementary information to QA measurement in water. Linear energy transfer distribution in patient can be simulated alongside.
Our project is built on open-source software GATE - a Monte Carlo simulation toolkit for medical physics applications (http://www.opengatecollaboration.org). High precision and accuracy of this powerful method is paid by large computation costs. We reduce the computation time through parallel computing with HTCondor (https://htcondor.org) – an open-source high-throughput computing software. Currently we compute on 324 CPU cores.
The workflow is fully automated. The user sends DICOM files from PACS to dedicated server where the pre-processing, the simulation and the post-processing are done automatically. The output files are sent back to PACS and are ready to be imported to TPS or OmniPro I'mRT software (www.iba-dosimetry.com) for further analysis.
The independent dose verification system was validated against the TPS and shows very good agreement. Currently we are in the phase of integrating the system into clinical workflow.

2 Materials and Methods

For a realistic radiotherapy simulation in patient, information stored in DICOM files (RT Plan, RT Structure Set, CT Scans, RT Dose) must be read and processed to specific input files for GATE simulation. DICOM files exported from TPS are not directly readable by GATE, so we have developed various scripts in Python (version 2.7 and 3.8) to process input and output data.
The automated workflow can be divided into three stages: pre-processing, simulation and post-processing.

Pre-processing
1) The patient´s dataset (RTP, RTSS, RTD and CT) is exported from TPS to PACS
2) The entire dataset is sent from PACS to dedicated server.
3) The server automatically checks for the presence of the required DICOM files every 10 minutes and starts to run a sequence of python scripts. The patient directory has a defined structure, the DICOM files and the patient non-specific files are copied to appropriate locations.
4) The first script parses CT directory and RTStructureSet to create voxelized 3D patient phantom. The image is cropped with respect to body contour and PTV and it is resized with respect to slice resolution. Mhd and raw files are generated.
5) The second script parses RTPlan and CT image, it loads main.mac template and it creates main.mac file for each treatment field individually. (Main.mac file contains the main instructions and parameters for running a simulation.)
6) The third script parses RTPlan and creates beam.mac file for each treatment field. Each field is described by gantry angle and collection of spots. Each single spot is defined by its position, weight and energy.
7) The fourth script parses RTPlan, it loads actors.mac template and it creates actors.mac file for each treatment field. Dose actor, LET actor, simulation statistic actor and calculation grid are defined.
8) All the files are prepared for MC simulation. The job is split for parallel processing with HTCondor. The computational task is submitted to 324 cores.

Simulation
Monte Carlo simulations are run in open source software Gate (version 9.2). Gate is a GEANT4 based simulation platform for nuclear medicine. The treatment nozzle is not simulated. For the pencil beam scanning technique only few elements are present in the nozzle and they do not actively participate in the shaping of the beam. Optical properties of each pencil beam in relationship with energy are defined in the source description file. The source

description file is specific for each treatment room and is based on measurements of spots and PDDs for the beam model. The file is a collection of polynomial equations for optical properties (spot size, divergence, emittance), energy properties (energy and energy spread) and MU calibration.
To reduce the computation time parallel computing is utilized. For this purpose HT Condor software is used and the simulation is performed by 324 computational cores. For high simulation efficiency, each core is assigned a number of histories according to its performance. The simulation on each machine finishes at a similar time.
Calculation grid is set to 2mm and physic parameters are set to achieve both clinical level of dose accuracy (simulation statistical uncertainty below 2%) and simulation efficiency.

Post-processing
The post-processing is automatically initiated once all the simulations are completed.
The dose scored by the Monte Carlo method is converted to absolute. From RTP, the total number of Monitor Units (MU) per beam and the number of MU per energy layer can be obtained. The relationship between the number of protons per MU for a given energy is known, therefore the number of protons per given energy layer and per beam can be calculated. From the simulation statistics a total number of simulated protons is obtained and used to determine conversion factor. The absolute dose is calculated.
Dose averaged linear energy transfer is calculated alongside. Dose and LET distributions are converted to DICOM dose planes and they are sent automatically to PACS. They can be imported to TPS or to OmniPro I‘mRT software for comparison with real plan and for further analysis.

3 Results

The automated system was validated on series of patients of various locations (head and neck, prostate, mamma). The evaluation was performed in TPS and in OmniPro I’mRT software. For gamma analysis criteria of 3% and 3mm were used with a threshold of 95% pixels passing. All plans met this criterion. For TPS, dose differences, profiles, dose volume histograms and values for clinical goals were evaluated.

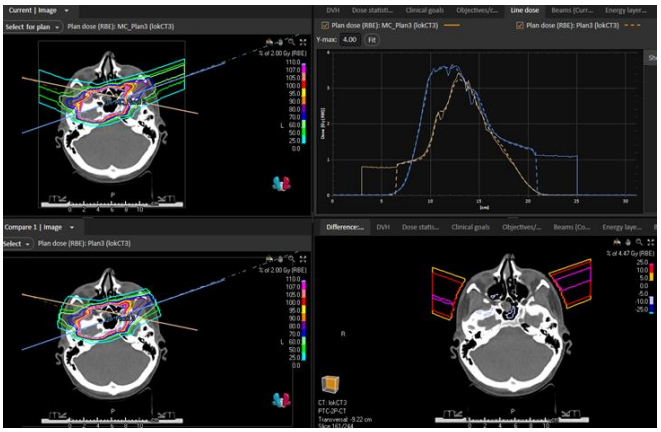

Figure 1: Dose distribution (MC x TPS), profiles, dose difference

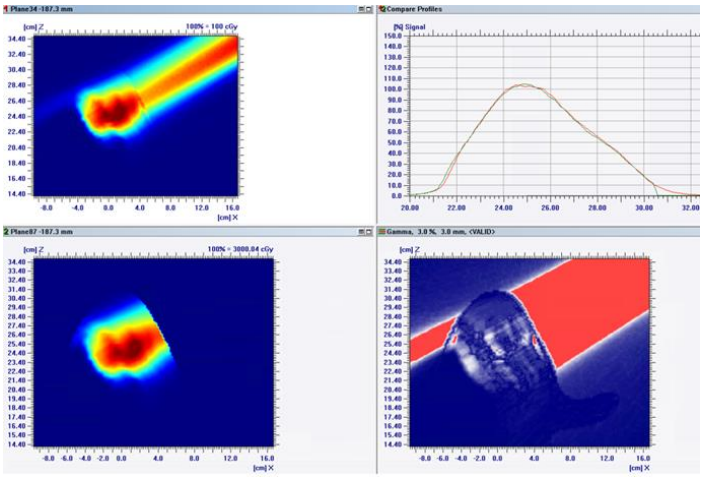

Figure 2: Dose distributions (MC-red x TPS-green), profiles and gamma analysis (3%,3mm)

4 Discussion

An in-house MC method for independent calculation and verification of proton treatment plans was presented. Explicit modelling of particle transport in MC allows more accurate dose calculations in regions with heterogeneities and can be used to benchmark TPS. Our approach calculates dose distributions and dose weighted LET in a patient based on information stored in DICOM files.
The automated system requires minimum interaction, the user just exports DICOM datasets to a specific server. The pre-processing, simulation and post-processing are performed automatically. The resulting Monte Carlo distributions appear in PACS and can be imported for further analysis into TPS or specific software for gamma analysis.

5 Conclusion

The developed MC system was validated and can be used for independent verification of proton treatment planning.
Currently we are in the phase of integrating the system into clinical workflow and prepare protocols.
Our approach can be adapted to other treatment planning systems, in fact this workflow can be implemented at any proton therapy center that uses spot scanning.

RadiSeq: A whole-genome DNA sequencing simulation pipeline to investigate radiation-induced carcinogenesis

Felix Mathew[1,2] and John Kildea[1,2]

[1]Medical Physics Unit, McGill University, Montreal, Canada
[2]Research Institute, McGill University Health Centre, Montreal, Canada

Abstract DNA sequencing holds significant promise for probing the biophysical mechanisms underlying radiation carcinogenesis. However, experimental implementation is hampered by cost and time constraints. To address this, we present a computational pipeline for simulating radiation exposure and subsequent whole-genome DNA sequencing of human cells. Utilizing the TOPAS-nBIO Monte Carlo framework, we constructed a single-cell geometric nuclear DNA model for radiation-exposure simulations. Subsequently, we developed "RadiSeq", an application in C++, to enable bulk-cell and single-cell whole-genome DNA sequencing simulations of radiation-exposed cell models. RadiSeq exhibits acceptable performance, with early validation results showing promise. Upon validation completion, we believe that RadiSeq will be a useful tool for further investigations into the mechanisms of radiation carcinogenesis.

1 Introduction

Iatrogenic cancer risk is often a concern, especially during high-energy radiotherapy [1,2]. Radiation-induced carcinogenesis has long been an area of interest within the scientific community [3,4]. Nevertheless, our understanding of the intricate biophysical mechanisms underpinning radiation-induced carcinogenesis remains incomplete. One promising avenue for advancing our understanding of radiation's genomic impact is through the utilization of DNA sequencing technologies. With the decreasing cost of DNA sequencing, there has been substantial progress in employing this tool to investigate further the radiation-induced mutational processes. Notably, the milestone discovery of a radiation signature in tumors associated with radiation exposure by Behjati et al. in 2016 [5] underscored the effectiveness of bulk-cell whole genome sequencing in identifying radiation-induced mutational profiles.

In our own research program, we have assessed the efficacy of the single-cell whole genome sequencing (ScWGS) technique [6] in discerning radiation-induced genomic alterations within human cells subjected to varying in-vitro radiation doses. Preliminary results from our investigation reveal the potential of ScWGS as a tool for directly assessing the genomic landscape of radiation in exposed cells, offering insights into the early stages preceding mutational cell transformation. Despite its promising applications, it is noteworthy that ScWGS still remains a resource-intensive undertaking, both in terms of expense and time, thereby limiting its widespread adoption for mutational investigations. Addressing these challenges will be imperative for advancing the utility of single-cell sequencing in radiation-induced mutational studies.

Therefore, we developed a comprehensive computational simulation pipeline designed to model ScWGS of radiation-exposed cells, providing a cost-effective alternative to experimental sequencing procedures. Our approach involved the development of a dedicated stand-alone tool named "RadiSeq," designed to simulate both single-cell and bulk-cell whole genome DNA sequencing processes from first principles. Through this tool, we have established a functional pipeline to replicate key experimental procedures: (i) simulating the radiation exposure of cells, (ii) emulating the sequencing library preparation of irradiated cells, and (iii) replicating the whole-genome sequencing of these libraries. This simulation framework closely mirrors the experimental protocol, demonstrating reasonable agreement between simulated and actual procedures.

2 Materials and Methods

Our simulation pipeline for whole-genome DNA sequencing of radiation-exposed cells is executed in two steps : (i) Monte Carlo simulation of cell irradiation and (ii) library preparation and sequencing simulations of the irradiated cells. In this section, each of these aspects is described.

2.1 CELL IRRADIATION SIMULATION

We developed an in-house single-cell geometric nuclear DNA model [7] using the TOPAS-nBio toolkit [8] for Monte Carlo simulations, as shown in Figure 1. This open-source model [9] allows for the stochastic exposure of varying radiation doses, with flexibility in the choice of radiation quality. Within the model, nucleotides, the fundamental structural units of the genome, are constructed using simple spherical volumes. The nucleus, for simulation purposes, is simplified into a cubic grid. Importantly, the number of nucleotide base pairs and the DNA density within the model are maintained to be consistent with that of a human nucleus.

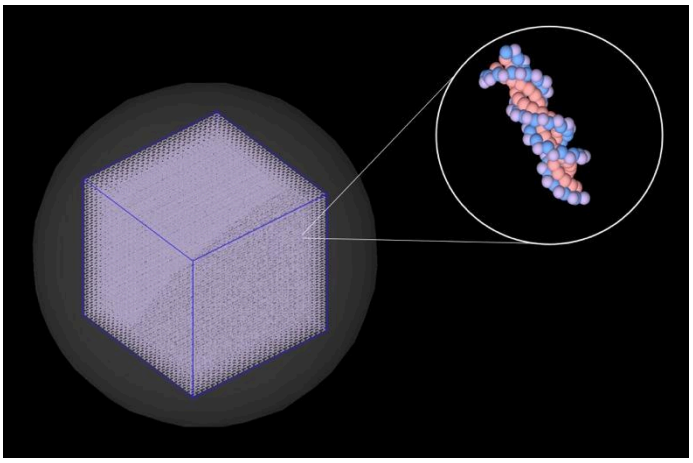

Figure 1: Our geometric nuclear DNA model developed in TOPAS-nBio[7].

In the track structure simulation of secondary particle interactions with our developed model, the underlying physics was managed by the G4EmDNAPhysics_hybrid2and4 physics constructor. Also, the chemistry governing the indirect action to track secondary chemical species was handled by the TsEmDNAChemistry chemistry constructor. Our cell model facilitates the scoring of dose depositions within different geometric volumes throughout the radiation exposure simulation. Furthermore, the model is capable of generating a genomic map detailing all incurred damages, presented as output in the standard DNA damage (SDD) data file format [10]. This approach ensures a detailed and structured representation of the simulated radiation-induced effects on the genome.

2.2 SEQUENCING IRRADIATED CELLS

In the realm of simulating genomic sequencing data from various sequencers, a plethora of computational tools exist [11]. However, when confronted with the task of simulating ScWGS of radiation-exposed cells using our model, none of these tools emerged as a suitable candidate. These artificial read-generating tools are mostly built for application with small, single-stranded reference genomes and are ill-suited for use with our double-stranded, radiation-damaged whole-genome human cell model. Moreover, several of these tools lack adequate testing and validation, necessitating the development of a dedicated tool capable of simulating both sequencing library preparation and the subsequent sequencing process.

To address this gap, we developed RadiSeq in C++, drawing inspiration from the open-source ART simulating toolkit [12]. RadiSeq allows users to simulate bulk-cell or single-cell DNA sequencing of any cell or group of cells, accommodating cell models capable of generating SDD data file outputs. Users have the flexibility to specify parameters such as the Illumina sequencer model (Illumina Inc., San Diego, CA, USA), sequencing coverage, number of cells to be sequenced, and sequencing protocol, among other fine-tuning parameters through a single input file. The software is optimized for handling extensive data files using memory mapping techniques, and its multi-threading capability enables parallelized computation. Incorporating a user-friendly interface, RadiSeq efficiently simulates library preparation and sequencing of irradiated cells from first principles.

Post-sequencing simulation, RadiSeq produces two outputs: (1) FASTQ files containing reads—data derived from small genomic segments analyzed during sequencing—and (2) a run summary file detailing simulation parameters and essential information for result reproduction. Currently undergoing validation with experimentally obtained data, FASTQ files produced by RadiSeq can be processed in a manner similar to those obtained through experimental means. Mutational analysis using diverse bioinformatics tools is expected to yield comparable results, validating the efficacy of RadiSeq in emulating real-world sequencing scenarios.

3 Results

Figure 2 illustrates the processing performance of RadiSeq, comparing the optimized version utilizing memory mapping and multi-threading against the earlier unoptimized iteration of the software. The plot demonstrates that with optimization, RadiSeq can efficiently generate millions of reads within a short time frame, allowing for the simulation of real experimental scenarios in a matter of hours, depending upon the number of CPU cores available for the simulation.

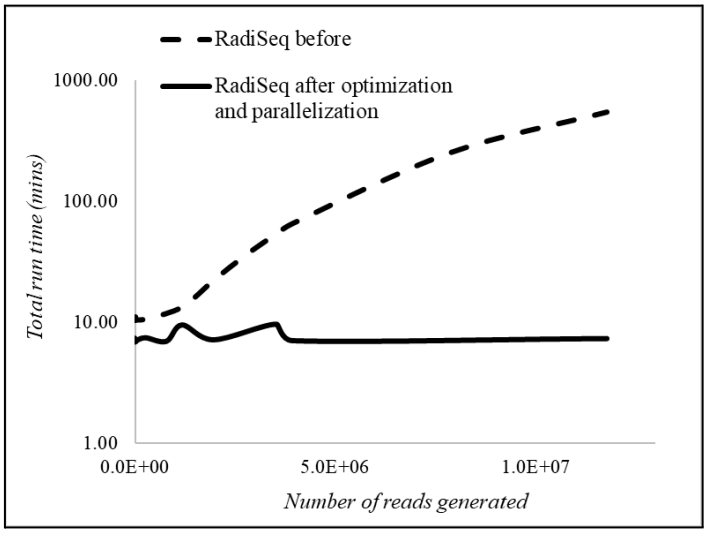

Figure 2: Comparison of RadiSeq performance before and after optimization and multi-threaded parallelization.

In Figure 3, we present preliminary test results from our validation of RadiSeq. The graph compares the distribution of reads across the genome—specifically, the percentage of the genome covered by varying numbers of reads—for both experimentally obtained data and data simulated by RadiSeq. Notably, a reasonable agreement is evident, suggesting the reliability and validity of RadiSeq in faithfully reproducing read distribution patterns observed in actual experimental scenarios.

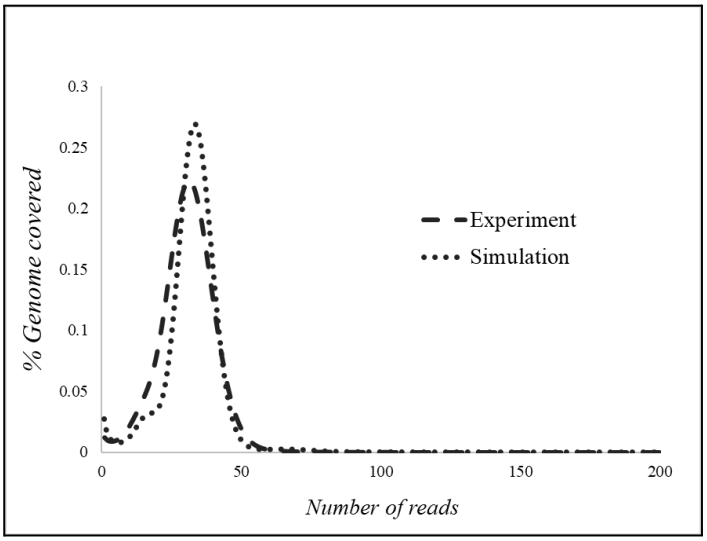

Figure 3: Read coverage obtained from a sequencing experiment and from a sequencing simulation using RadiSeq.

4 Discussion

Our geometric nuclear DNA model, constructed in TOPAS-nBio, is not an exact replication of a human cell; it relies on numerous assumptions and oversimplifications of cellular complexities. This inherent simplification introduces uncertainties and variations in the simulated sequenced data, potentially accounting for observed differences in the comparison of simulation and experimental results. However, it's crucial to note that RadiSeq demonstrates compatibility with any cell model capable of producing an SDD output file from an irradiation simulation. Consequently, researchers have the flexibility to integrate more intricate cell models [13,14] into this pipeline.

Although the preliminary data from RadiSeq's validation are promising, more investigation must be done to verify the accuracy of this tool across multiple metrics. This work is currently ongoing and once RadiSeq is fully validated, we plan to release it under an open-source license.

A notable limitation of our work lies in the omission of considerations for cell repair and cell death following radiation damage. Presently, the cell genome is sequenced with all radiation-induced genomic alterations, akin to performing sequencing immediately after radiation exposure. An enhanced pipeline would encompass the possibility of damage repair after radiation exposure, recognizing that repair processes often rectify simple damages and occasionally result in misrepair, ultimately leading to mutations. While there are tools available for modelling DNA repair subsequent to radiation damage [15,16], these mechanistic models currently suppress the spatial information of damages post-repair, posing challenges in accurately modelling the cell genome. Consequently, within the current framework, our proposed pipeline with RadiSeq is unable to accommodate cell repair.

5 Conclusion

Sequencing analysis holds promising potential in aiding the investigation of radiation carcinogenesis. However, the accessibility of this technology is hindered by its expense and its time-consuming nature. Therefore, we have built RadiSeq to simulate bulk-cell and single-cell DNA sequencing of radiation-exposed human cell models. With this software in place, we have now established a working pipeline that can be used to computationally simulate cell irradiations and irradiated cell sequencing for the purpose of investigating the underlying mechanisms of radiation carcinogenesis at the genomic level. RadiSeq's performance is very promising and the early results from the validation studies of the software suggest that the pipeline is reasonably comparable to the experimental procedure. With RadiSeq, we will be able to identify the optimum experimental irradiation and sequencing conditions prior to commencing experimental work. This will allow us to perform sequencing experiments of irradiated cells cheaper and faster and more efficiently learn about radiation interactions with the genome.

Detectability of Iodine Contrast Agent with Ultra-low Concentration by Photon-counting CT: A Simulation Study

Xiaoyu Hu[1], Yuncheng Zhong[1], Kai Yang[2], and Xun Jia[1]

[1]Department of Radiation Oncology and Molecular Radiation Sciences, Johns Hopkins University, Baltimore, MD, USA
[2]Division of Diagnostic Imaging Physics, Department of Radiology, Massachusetts General Hospital, Boston, MA, USA

Abstract To investigate the contrast-to-noise (CNR) of the iodine contrast agent with low concentrations in CT images acquired with photon-counting detector (PCD), we developed a simulation pipeline to model a multi-channel PCD CT and an energy-integrating detector (EID) CT. A 2D digital phantom was generated with iodine solution inserts of 0.25 to 10 mgI/mL concentrations as the object, and 1/2/3-channel PCD and EID CTs were simulated to compute the CNR of these iodine solutions under a 120 kV x-ray tube voltage with various CT dose levels. Numerical results show that PCD CT outperforms EID CT in terms of CNR in general. Furthermore, the multi-channel PCD-CT provides extra degrees of freedom in the energy dimension for finding the optimal channel, by which an improved CNR can be obtained. When the $\text{CTDI}_{\text{free air}}$ is 3.3 mGy, the PCD CNR averaged over all iodine inserts were 1.26 to 2.13 times greater than the CNR from EID CT. When the $\text{CTDI}_{\text{free air}}$ is 98.7 mGy, the CNR from 1-channel PCD is close to that of EID, but the 2/3-channel PCD CT is able to obtain about 17% higher CNR.

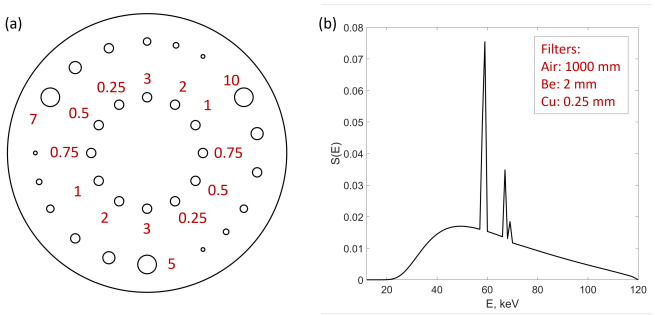

Figure 1: (a) X-ray spectrum at 120 kVp. (b) The digital phantom. The red number indicates the concentration of iodine solutions in the unit of mgI/mL.

1 Introduction

The advent of photon counting technology in computed tomography (CT) has ushered in a new era in medical imaging [1–3]. Unlike traditional energy-integrating detectors (EID), photon counting detectors (PCD) measure the number of incoming photons at discrete energy levels, enabling superior energy discrimination and improved signal-to-noise ratios. This innovative technology holds great promise for providing detailed anatomical information while minimizing patients' radiation exposure dose.

In this context, the application of contrast enhanced CT scans gains even greater significance, offering unprecedented opportunities for precise diagnostic imaging and targeted therapy [4]. Contrast agents help increase targeted abnormal regions and backgrounds, as well as provide functional information, for more effective and sensitive diagnosis. In therapy, the use of contrast agents enhances the delineation of target volumes, facilitating the development of personalized and targeted treatment plans. it also allows monitoring disease responses to treatment over time. Yet, clinical challenges associated with contrast agents, such as potential allergic reactions, nephrotoxicity, and contraindications still persist [5]. It is imperative to enhance the sensitivity of imaging technologies to allow the reduction of contrast agent concentration while maintaining its clinical effectiveness.

The motivation of this study is to investigate thedetectibility of iodine contrast agent in the CT images acquired with PCD. We performed extensive numerical simulations to find the lowest concentration of iodine that can be detected by PCD. The significance of this work is that we show that under a given condition, PCD outperforms EID in detecting the iodine solutions with ultra-low concentrations (< 3 mgI/mL). We focused on iodine contrast due to the wide clinical application, but we expect the method is generalizable to other agents.

2 Method

2.1 Simulation pipeline

We designed a two-dimensional digital phantom for this work as shown in Figure 1(a). The base of the phantom is a pure water cylinder with a 30 cm diameter. Three sets of inserts with different diameters ($0.4 \sim 2$ cm) were filled with 5, 7, 10 mgI/mL iodine solutions, and the 12 equal-sized (1 cm diameter) inserts were uniformly distributed in the inner ring, and iodine solutions with lower concentrations were filled.

The setup of the PCD-CT system was based on a Siemens Force scanner with the source-to-isocenter distance of 59.5 cm [6], and the source-to-detector distance of 108.5 cm. The CdTe PCD had 1500 pixels with a 0.4 mm pixel size and 1 mm thickness. A 120 kVp x-ray spectrum $S(E)$ with a 0.25 mm Copper and 2 mm Beryllium filtration was considered (Figure 1(b)). Additionally, a bow tie filter was added to create a more uniform x-ray beam delivered to the detector.

For a CT system, the signal acquired can be expressed as

$$M(u) = c \int W(E)S(E)\frac{1}{D^2(u)}B(E,u)R(E) \exp\left[-\int_L \mu(E,x)\mathrm{d}l\right]\mathrm{d}E. \quad (1)$$

where u is the detector pixel position, $W(E)$ is the weight of detected photons, $D(u)$ is the distance from the source to a detector pixel in meter, and the term $D^{-2}(u)$ is the inverse square law since the source fluence $S(E)$ was defined at 1 m. $R(E)$ is detector response function. L is the path connecting the source to pixel u, and $\mu(E,\mathbf{x})$ is the x-ray attenuation image of the phantom at energy E and $\mathbf{x}$ is the spatial coordinate. This integral was evaluated using the ray tracing algorithm. The term $B(u,E) = \exp[-\mu_{Al}(E)L_{Al}(u)]$ is the attenuation of the bow tie filter, where L_{Al} is the equivalent aluminum length of the bow tie filter and μ_{Al} is aluminum's total linear attenuation coefficient. Finally, the overall scaling factor c was introduced to control the CT dose level.

The log transformed projection data was then computed as

$$g(u) = -\log\left(\frac{\mathscr{P}[M(u)]+N_e}{M_0(u)}\right), \quad (2)$$

where $\mathscr{P}[\cdot]$ is the Poisson random number generator, N_e is the added electronic noise. $M_0(u)$ is the air norm computed using Eq. (1) without the phantom attenuation term.

For the PCD-CT cases, $W(E) = 1$, and $N_e = 0$. For the ith energy channel defined by lower and upper thresholds T_i and T_{i+1}, the response function was unity within this energy range, and zero otherwise.

We also compared with EID-CT. In this case, $W(E) = E$ and N_e is a Gaussian random number generator with mean 0 and standard deviation σ.

Once the projection data were calculated, we reconstructed CT images using the standard filtered backprojection (FBP) approach with a Shepp-Logen filter. CNR of each iodine contrast insert was measured with the background for each insert defined as the annular surrounding region with the same area.

2.2 Parameter selection

There are two major parameters affecting CNR. The first one is c related to the total photon number per pixel from the x-ray source, *i.e.* the total dose. We estimated the $\mathrm{CTDI}_{free\ air}$ at the isocenter, equivalent to CT Dose Index measured at isocenter in free air corresponding to different c values to ensure the study focuses on a range of doses covering clinically relevant situations.

As for the standard deviation of the electronic noise σ, we selected a square region at the center of the reconstructed CT images and determined the noise level in the CT images by calculating the standard deviation of that region. σ was adjusted to approximately match the image noise level at each dose level to what we observed in typical clinic CT images.

c	10	50	100	200	300
$\mathrm{CTDI}_{\text{free air}}$ [mGy]	3.3	16.5	32.9	65.8	98.7
Noise (PCD) [HU]	62	27	19	14	11
Noise (EID) [HU]	146	37	23	15	12

Table 1: $\mathrm{CTDI}_{\text{free air}}$ and the associated image noise levels.

2.3 Evaluation

In PCD-CT, the lowest energy threshold T_1 was set to 26 keV for all cases, which is the typical setup to eliminate electronic noise. In this study, we modeled the situation of 1 to 3 energy channels. The 1 channel situation utilized photons above T_1 in the the entire spectrum. For 2 channel, the threshold T_2 was used to separate the two channels. Similarly, in 3 channel, two thresholds T_2 and T_3 were used with $T_3 > T_2$. In each situation, we enumerated all possible energy thresholds in the list of energy thresholds from 28 to 120 keV with a 2 keV interval.

We focused on the study to investigate the variation of CNR in PCD-CT as we adjusted the energy thresholds, and compared it with that of EID-CT. In each PCD-CT case, we report the highest CNR among energy channels. When there are more than one energy channel, while it is possible to decompose the PCD-CT images to determine the iodine image, we focused on the PCD-CT images, as material decomposition is expected to increase noise level, likely reducing CNR.

3 Results

3.1 1-channel PCD-CT

The main difference between 1-channel PCD-CT and EID-CT is the energy weighting form and the electronic noise. Since the first threshold T_1 was used to eliminate the electronic noise in the PCD signal, the noise in the 1-channel PCD-CT image is inversely proportional to the CT dose. However, when c is large, the EID signal noise is still dominated by the Poisson noise; when the CT dose is decreased, the additional electronic noise becomes dominant, which is obvious from Table 1. The CNRs of various concentrations of iodine inserts were plotted in Figure 2. When the CT dose is relatively high (>30 mGy), the performance of EID-CT and 1-channel PCD-CT are close, especially for the iodine solutions with low concentrations. However, when the CT dose is low (<30 mGy), the PCD-CT outperforms the EID-CT in this task mainly due to PCD's capability of reducing electronic noise. Quantitatively, for the 3 mgI/mL iodine solution, the CNR obtained with 1-channel PCD-CT is 5% better than the CNR of EID-CT when $c = 300$, and about 1.78 times better when $c = 10$, and for 0.5 mgI/mL, the improvement of PCD is 14% and 46% when c=300 and 10 respectively.

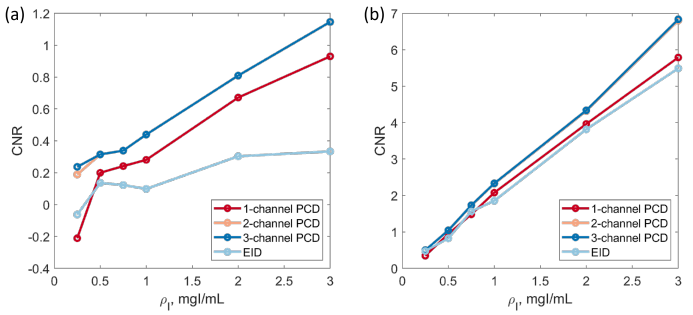

Figure 2: CNR as a function of iodine concentrations for low and high CT dose cases: (a) $c = 10$ and (b) $c = 300$.

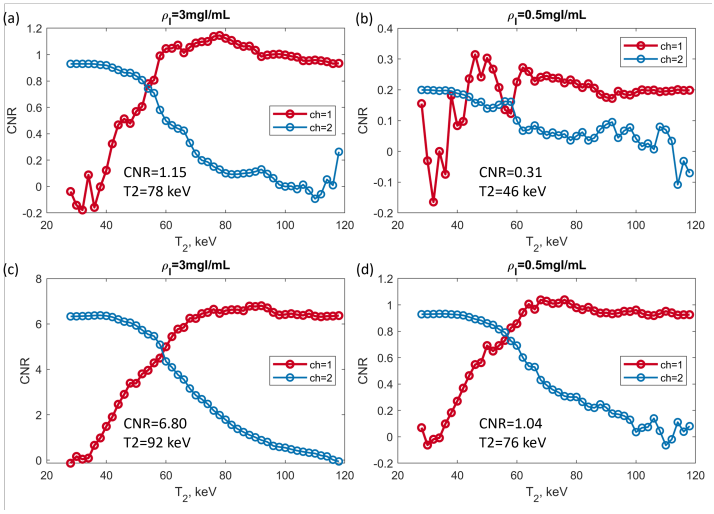

Figure 3: CNR curves of each energy channel in 2-channel PCD-CT as a function of energy threshold T_2 for selected iodine concentrations at two CT dose levels. Top row: $c = 10$, bottom row: $c = 300$.

3.2 2-channel PCD-CT

For the 2-channel PCD-CT scenario, the maximum CNR achievable is noticeably improved from the 1-channel case for all concentrations, as shown in Figure 2. Note that the maximum CNR of 2-channel PCD-CT was defined as the higher CNR between the two channels. Compared with the 1-channel case, although the 1-channel case used photons from the entire spectrum, yielding lower noise level, it deteriorates the contrast achieved from using photons at low energies.

To further investigate this issue, we plotted the CNR obtained within each energy channel for all cases with different thresholds in Figure 3. The 'X'-like shape of the curves is expected, since the CNR is determined by both contrast and noise. A narrow energy channel has a lower noise level, even if it offers high contrast. Nevertheless, the best CNR is usually from the first channel that covers the low energy range, when the noise no longer dominates. The maximum CNR of 3 mgI/mL iodine solution achieved with 2-channel PCD-CT was 23.9% larger than the EID-CT's CNR at $c = 300$, and about 243.1% larger at $c = 10$; For 0.5 mgI/mL, 26% and 131.2% improvement can be achieved with 2-channel PCD at c=300 and 10 respectively.

3.3 3-channel PCD-CT

Similarly, we plotted the maximum CNR among all the 3-channel for the 3-channel PCD-CT cases in Figure 2. Compared with the 2-channel PCD-CT cases, while the 3-channel PCD-CT has one more degree of freedom to further optimize the energy thresholds, the maximum CNRs for all concentrations were only slightly better than the ones of 2-channel PCD-CT.

Here again, we depicted the CNR maps as functions of two energy thresholds T_2 and T_3 under two CT doses for 0.5 and 3 mg/mL iodine solutions in Figure 4. One interesting discovery was that competition always occurs between the first two channels simply because the third channel cannot provide sufficient contrast. Here again, when $\rho_I = 3$ mgI/mL, the maximum CNR achieved with 3-channel PCD-CT was 24.5% higher than the EID-CT's CNR if $c = 300$, and about 243.8% higher if $c = 10$. When $\rho_I = 0.5$ mgI/mL, the maximum CNR achieved with 3-channel PCD-CT was 26.4% higher than the EID-CT's CNR if $c = 300$, and about 131.6% greater if $c = 10$.

3.4 PCD-CT and EID-CT image comparisons

Lastly, the CT images reconstructed with 1-3 channel PCD-CT and EID-CT are displayed in Figure 5 for a visual comparison. Note that for 2 and 3-channel PCD-CT, we display the CT image for the energy channel that maximized the CNR of the 3 mgI/mL insert. Clearly, the PCD-CT outperforms the EID-CT in this detectability task especially for low CT dose cases mainly due to the absence of electronic noise. The iodine inserts with 2 and 3 mgI/mL were clear visible from the CT images with $c = 10$, while not from the EID-CT image. The redundant photons at high energies impact the contrast, which is obvious by comparing the brightness of the inserts at high concentration levels (outer ring), i.e. Figure 5 (g) and (h). At a relatively high CT dose level (30 mGy), the CNR of iodine with ultra-low concentrations (< 3 mgI/mL) improves significantly.

4 Discussion

It is worth mentioning that the simulation method in this work did not consider the scattering of the photon in calculating the detector signals. Scattering is one of the major sources downgrading the reconstructed CT image quality. A common remedy is to use the anti-scatter grid to reduce the scatter photon signals. Therefore, conclusions derived from this work would still be valid for the actual clinical cases.

Additionally, the detector response function was assumed to be an ideal value of unity within the energy channel thresholds. This was an approximation of the detector responses in the real-world scenario. The actual detector response may impact the energy resolution. For example, a 40 keV photon could be counted when the threshold was set to 50

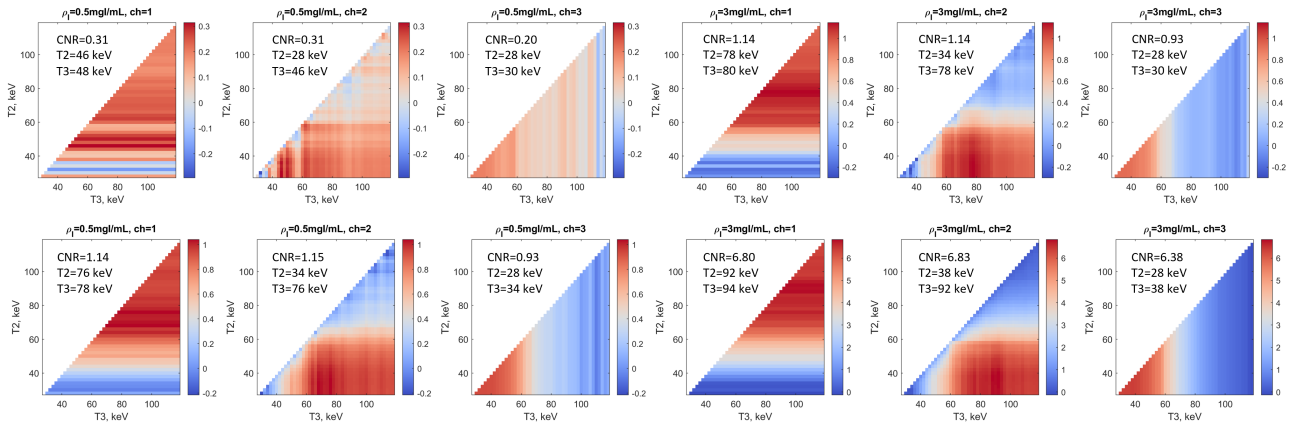

Figure 4: CNR map of 3 energy channels for selected concentrations of iodine for the 3-channel PCD-CT cases. Top row: $c = 10$. Bottom row: $c = 300$. The text insert in each subfigure displays the maximum CNR and its associated energy thresholds.

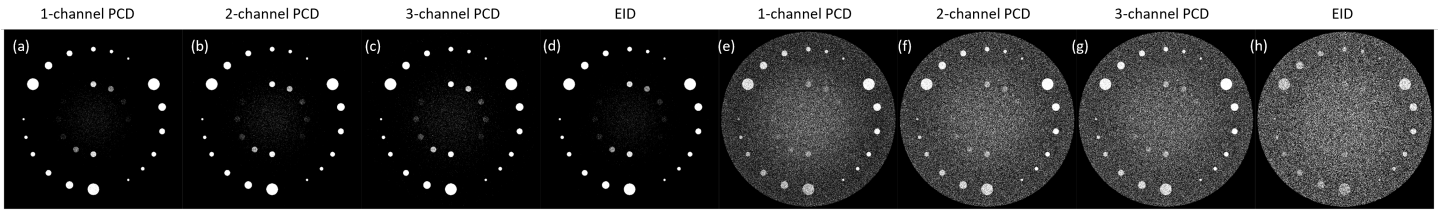

Figure 5: (a)-(d): CT images with $c = 300$, W/L:50/30 HU. (e)-(h): CT images with $c = 10$, W/L:200/30 HU.

keV. The inferior energy resolution lowers the contrast in the CT images. We have conducted an experimental study to measure the detector response function for different energy thresholds. It is our ongoing work to include this feature to our simulation pipeline to understand the impact of detector responses.

The fact that superior CNR was found in one of the energy channels of the multi-channel PCD-CT indicates that we need to abandon some photons to improve CNR. This means that there is room for further improving the setting like the x-ray spectrum and filtrations. A more interesting question is whether we can optimize the energy weights $W(E)$ on the detector as it counts photons to achieve a better CNR? There have been studies to investigate this question via simulation, although it is still a technical challenge to achieve a designed energy weighting by the circuits on the PCD. The simulation pipeline here can be employed to investigate this issue.

5 Conclusion

In this work, we developed a simulation pipeline to investigate the detectability of contrast agents with ultra-low concentrations. The iodine solutions of various concentrations were selected as the object, and 1/2/3-channel PCD and EID CTs were modeled to compute the CNR of these iodine solutions. Numerical results show that the PCD CT outperforms the EID CT in terms of CNR in general. Quantitatively, when the $\text{CTDI}_{free\ air}$ is 3.3 mGy, the 1-channel PCD-CT gains 46% higher CNR than the EID for 0.5% mgI.mL solution, and 178.9% for 3 mgI/mL. When the $\text{CTDI}_{free\ air}$ is 98.7 mGy, the CNR of 1-channel PCD-CT is close to that of EID. For 0.5 and 3 mgI/mL solutions, the CNR in the 1-channel PCD-CT is 14% and 5% greater than the EID CNRs. The 2/3-channel PCD-CT is able to improve the CNR about 26% and 24% for 0.5 and 3 mgI/mL solution respectively. The multi-channel PCD provides extra degrees of freedom in the energy dimension for finding the optimal channels.

Abstract Cancer treatment encounters challenges due to tumour heterogeneity, leading to unpredictable patient outcomes. Interstitial fluid pressure (IFP) is reported to play a role in drug resistance in solid tumors. To examine the relationship between IFP, and drug transport, the novel Cross-Voxel eXchange Model (CVXM) was applied. CVXM created various image-derived transport parameter maps, such as extravasation, convection, and diffusion maps. The fitted results were compared to the Tofts model. The CVXM convection map was converted to a gradient pressure map, which was further compared with the actual IFP measurements obtained using a microtip pressure transducer. Characteristics of IFP gradient, where the velocity flow is elevated near the periphery and decreased at the tumour center, were both found from CVXM convection maps and actual IFP measurements. CVXM provides unparallel information in understanding the pharmacokinetics of drugs in the tumour microenvironment, which will help us move closer towards personalized cancer treatment.

1 Introduction

Despite immense progress in cancer treatment, drug resistance in cancer patients remains a challenge attributed to tumour heterogeneity[1]. Among various factors that contribute to tumour heterogeneity, studies have increasingly pointed towards interstitial fluid pressure (IFP) as a main cause of drug resistance in cancer patients[2,3,4,5,6]. As solid tumours grow, they accumulate IFP at the center due to defective vasculature and lymphatic functions. This pressure gradient induces fluid convection in the surrounding normal tissue, creating a barrier obstructing the entry of large therapeutic molecules like immunotherapeutic monoclonal antibodies, nanoparticles, and radionuclides[6,7,8]. To comprehend the interplay between IFP and drug resistance, a thorough investigation into their transport mechanisms is needed.

Dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) is a non-invasive and non-ionizing imaging technique that offers quantitative analyses into the biophysical properties of drug (tracer) transport within the tumor microenvironment. Conventionally, the widely used two-compartmental Tofts model focused solely on intra-voxel exchange, representing extravasation. Augmenting from the Tofts model (TM), Sinno et al. developed the novel Cross-Voxel eXchange Model (CVXM), allowing for the quantification of various pharmacokinetic parameters of tracer transport between blood vessels and tissue, such as diffusion, convection, and extravasation[9,10,11,12]. It is hypothesized that the image-derived transport parametric maps from DCE-MRI and CVXM, will help explore the intricate relationships between drug delivery, IFP, and the tumor microenvironment.

2 Materials and Methods

2.1. Tumour model

The ME180 human cervical carcinoma xenograft model was used for in vivo studies as it closely resembles clinical tumours and as IFP of ME180 has been extensively investigated[13,14]. ME180 tumours were initiated by inoculating the mice intramuscularly with $1x10^6$ cells. The intramuscular donor tumour fragments were then used for orthotopic implantation in mouse cervix. All in vivo experimental protocols in the study were approved by the University Health Network Institutional Animal Care and Use Committee.

2.2. DCE-MRI and IFP measurement

The mice (n=2) underwent imaging when the tumour volume reached 800 cm^3 using a 7T pre-clinical scanner (Biospec 70/30 USR, Bruker) located at the STTARR facility. DCE-MRI was conducted using Gd-DTPA 1mmol/mL (Gadovist, Bayer) was used as a contrast agent. 40 microliter saline was administered to flush 15 microliter of Gd-DTPA via tail vein injection in a bolus. T1-weighted images were acquired (TR=109ms, TE=1.737ms, α=45°) with a time resolution of 14 seconds for a total scan time of 28 minutes. The spatial resolution was $0.225x0.225x0.8mm^3$. The T10 maps were acquired using the variable TR technique for every mouse before contrast administration. IFP measurements were taken immediately after DCE-MRI using a Millar microtip pressure transducer with a probe diameter of 0.33mm (SPR-1000, Millar). The microtip probe was placed in a 21-gauge needle which assists the probe to be inserted into the tumour. Measurements were taken under ultrasound guidance (Vevo 2100, VisualSonics) for probe visualization. Preliminary results were done with a higher sample size (n=6) to test reproducibility of IFP measurement with the microtip pressure transducer (data not shown).

2.3. Model fitting

Elliptical region-of-interest (ROI) was drawn for each tumour using MATLAB assuming a radially symmetric and

elliptical tumour. Concentration of the contrast agent per voxel was calculated from the signal intensity using the non-linear relationship described in Landis et al.[15]. The dynamic change in concentration across timepoints was processed to generate the pharmacokinetic parameters using both the TM[16] and CVXM. CVXM was performed as described in Sinno et al.[12]. The velocity map derived from CVXM was used to identify the calculated IFP using Darcy's law: $v = -K\nabla P$, where v is velocity, K is the hydraulic conductivity coefficient and P is pressure. $7x10^{-7}$ $cm^2/mmHg{\cdot}s$ was used for the value of K[17].

3 Results

3.1. Observation of tracer uptake

The average change in concentration of Gd-DTPA over time is shown in Figure 1. It was observed that the tumour periphery achieved maximum uptake of tracer faster than the tumour center. At 7 minutes, the mean concentration at tumour periphery reached maximum, while the concentration at the center is approximately 2-fold lower relative to the periphery. It indicates that the tumour periphery had more well-defined vasculature, allowing for the tracer to infiltrate easily. On the other hand, the tumour center showed more gradual uptake of the tracer. This indicates an obstruction likely due to a build-up of IFP at the tumour center, caused limited tracer enhancement.

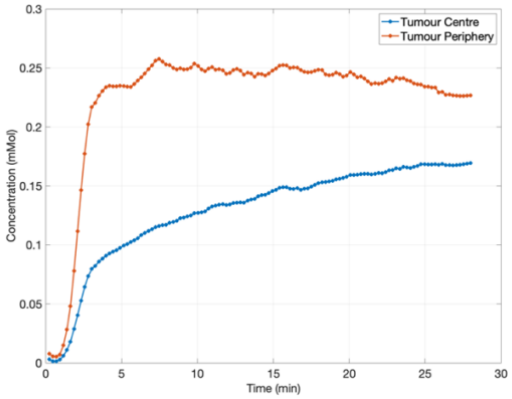

Figure 1. The mean concentration of the tracer at the tumour center and the periphery across timepoints. The plot shows the average of the samples.

3.2. Fitting results

Figure 2 displays various parametric maps of tracer transport derived from the TM and CVXM. Kext and Ktrans, representing tumour extravasation showed the same pattern in CVXM and TM. It showed high values near the periphery than the center, which agrees with the concentration uptake curve (Fig 1). Small values of Kext were observed in the areas with poor vasculature, indicating lack of blood flow at the tumour center. The value for Ve was chosen at a constant value of 0.1 for CVXM. Tofts' Ve shows heterogeneous distribution, values ranging from 0 to 3.5 on average. The mean diffusivity from CVXM was 230 ± 2.8 $\mu m/s^2$.Velocity was measured using CVXM. It was illustrated across all samples that the tumour periphery had higher velocity than the tumour center. The maximum velocity was determined to be 8.76 μm/s and 6.68 μm/s in mouse 1 and mouse 2 respectively, which fall in a common range of tracer velocity previously reported in the literature. From CVXM velocity map, null velocities were observed at the tumour center, which is expected since IFP gradient at the center is zero[2].

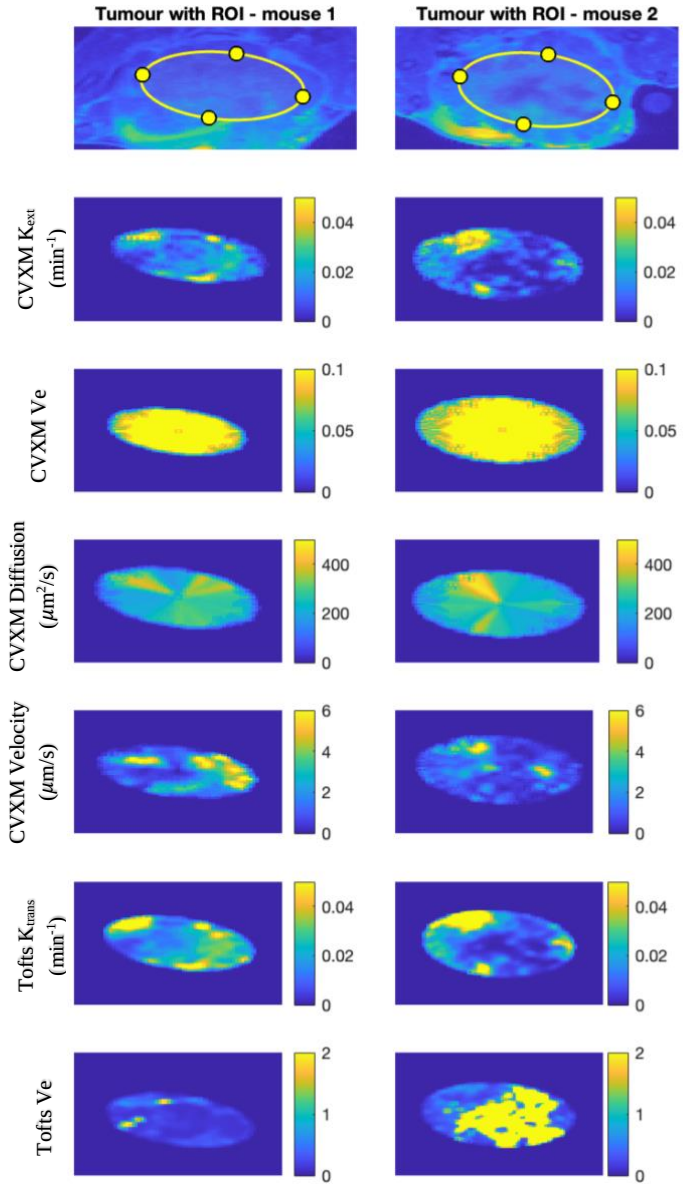

Figure 2. DCE-MRI images of the tumours at the last timepoint with ROIs drawn with yellow outline followed by the transport parametric maps.

3.3. IFP measurement

Using the microtip pressure transducer, the ranges of actual IFP were determined to be from 3.5 to 24mmHg for tumour center. Pressure measurements in the tumour periphery ranged from 0.3 to 2.3 mmHg. The mean of actual IFP was measured to be approximately 11.8 ± 6.9mmHg and 1.12 ± 0.8mmHg in the tumour center and periphery, respectively. The actual IFP values of the tumours are

summarized in Table 1. The ranges and means of IFP measured, agreed with the results from Lunt et al.[13]. IFP measurements were performed under ultrasound guidance. Figure 3 is an ultrasound of the tumour with the pressure probe inserted into the tumour. Ultrasound imaging allowed visualization of the tumour boundary. The gradient pressure map is shown in Figure 4, which was generated from the CVXM velocity map through Darcy's law. Most regions ranged from 0 to -50mmHg in gradient pressure, while some locations showed more drastic changes in pressures at the periphery.

Table 1. Summarized actual IFP values of the tumours measured using the microtip pressure transducer. The last row shows the mean of the samples (n=2).

	Center IFP (mmHg)	Periphery IFP (mmHg)
Mouse 1	11±7.3	1.6±1.0
Mouse 2	12.7±7.1	0.81±0.6
Mean	11.8±6.9	1.12±0.8

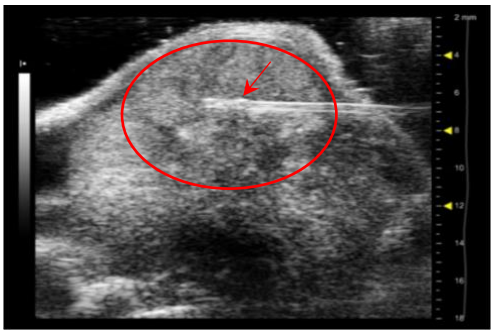

Figure 3. Ultrasound image of a mouse cervical tumour with the microtip pressure transducer inserted at the tumour center. Tumour is shown with the red ellipse and the probe is indicated with the red arrow.

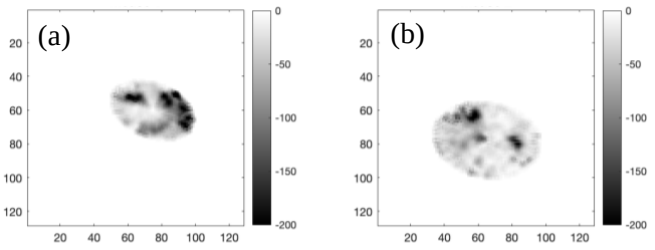

Figure 4. Pressure gradient maps of (a) mouse 1 and (b) mouse 2. Darker regions indicate rapid changes in pressure.

4 Discussion

Using CVXM, extravasation, convection and diffusion were quantified in ME180 tumours. The TM is unable to quantitate cross-voxel exchange parameters, while CVXM can describe these dynamic changes. Extravasation showed higher values at the periphery and lower values at the tumour center. This distribution pattern was observed in both CVXM Kext and Tofts Ktrans maps, and the fitted results are in alignment with the tracer uptake seen in the mean tracer concentration curve. Ve in CVXM was kept at a constant 0.1. The range of Ve should be from 0 to 1, however, the TM showed values greater than 3.5 in some areas. This characteristic originated from combinatory effect of diffusion and large gradient of Kext in some areas. These were unphysiological values, indicating a limitation in the TM. Sinno et al.[12] explains this effect of Tofts Ve further.

Convection was represented by the CVXM velocity map. It accurately showed increased flow rate at the periphery and smaller flow rate at the center. The gradient pressure map obtained also showed the same pattern. The periphery exhibited a more rapid tracer flow, which was governed by the high-pressure build-up at the center. The pattern in the velocity map and the pressure gradient map concurs with the reports of IFP gradient. IFP in tumours have been reported to have relatively homogeneous center until it reaches the tumour periphery near the normal tissue[2]. IFP is expected to drop sharply at the boundary near the normal tissue. This characteristic was further verified with the microtip pressure transducer, where a drop in pressure was observed from center to periphery.

CVXM's ability to study cross-voxel transports allow quantification of diffusion in the tumour. For a mean value of 230 μm/s^2, the diffused distance of tracer is about 5.5 voxels during the 28-minute scan time ($\sqrt{r^2} = \sqrt{4Dt}$). This was not an enough time to observe the complete action of diffusion reaching the center of the tumour. In addition, the tumour size chosen in the study was bigger than the tumours previously studied in other papers[18,19]. It can be speculated from the mean concentration (Fig 1) that that the primary means of transport at the tumour center was diffusion, rather than extravasation. With poor vasculature, the tracer is likely to be transported via diffusion at a slower rate than via extravasation. Large tumour size also increases the potential for tumour necrosis. It was observed that some voxels at the tumour center did not reach maximum tracer enhancement, while the peak enhancement reached around 7 minutes post-injection for voxels at tumour periphery. This suggests the possibility of necrotic tumour center and tracers primarily getting delivered via diffusion. The bigger tumour was a trade-off against easier access to the tumour for IFP measurement using the pressure probe. For future study, the experiments will be repeated for higher sample size (n=9). The data are acquired and are currently being analyzed.

5 Conclusion

IFP influences drug resistance in solid tumors. DCE-MRI combined with CVXM, aids in exploring cross-voxel

mechanisms of drug transport, including extravasation, convection, and diffusion. The calculated extravasation using CVXM showed similar trend to Tofts Ktrans. CVXM provides additional parametric maps to what the TM offers. Convection map from CVXM accurately illustrated the IFP gradient, showing increased velocity flow at the periphery and decreased velocity at the center. This characteristic of IFP gradient was further confirmed by microtip pressure transducer measurements. Diffusion map was also generated using CVXM. The findings from CVXM can help understand the heterogeneity in tumours and gauge the aggressiveness of the tumour. This comprehension will pave the way for personalized treatments, such as immunotherapy or drug delivery through nanoparticles, customized to the unique characteristics of each patient's tumour microenvironment. This approach holds the potential to enhance the efficacy of individualized cancer therapies.

Abstract Nowadays, radiotherapy planning is done on CT images, which results in a low tissue contrast and lack of functional information about the tumor. However, the use of MRI in this context presents a promising avenue for improvement. MRI is known for its superior capability to provide clear visualizations of organs at risk and to offer valuable tumor characterization. Due to all of this, MRI is considered as a valuable tool in improving the accuracy and effectiveness of radiotherapy planning. In this study, a new MRI protocol was introduced that includes the quantitative mapping of 13 unique functional parameters. Through the exploitation of the IVIM theory, blood perfusion and oxygen extraction fraction will be mapped alongside other important parameters, which will allow us to reveal the heterogeneity inside the tumor volume. Our aim is to use the resultant maps to accurately characterize the tumor and identify its status.

1. Introduction

Cancer is one of the principal deaths causes in the world. Head and neck cancer is the seventh most common cancer globally [1]. Due to the high anatomical complexity in this region, therapy treatment is particularly hard, and the need for a high-precision imaging modality that can characterize and gives accurate information about the biological state of the tissues arises.

Currently, radiotherapy planning is based on CT images which has low tissue contrast, and does not provide any functional information about the tumor. MRI has the potential to improve radiotherapy planning thanks to its unique ability to clearly visualize the tissues of the organs at risk, and to characterize the tumor.

It is known that tumors are very heterogeneous, even the same type of tumor can differ significantly between patients, which adds to the complexity of treatment [2]. Therefore, there exist populations of cells within the tumor with distinct biological structures and behaviors. For instance, tumor hypoxia is considered as a tough point for treatment. Low oxygen concentration plays an important role in various brain pathologies. Identifying the hypoxic regions in the tumor could help to predict the outcome of the radiotherapy, and to better modulate the dose deposition since hypoxic regions require two to three times the radiation dose than well-oxygenated regions [3].

Diffusion-weighted imaging (DWI) is an essential MR imaging method in cancer studies, it is based on measuring the Brownian motion of water molecules. The diffusion motion of the water molecules is responsible for the image intensity weighting, which can give us valuable information about tumor cellularity, viability, and microstructural environment [4]. Since blood microcirculation within a voxel mimics the motion of water, DWI will be sensitive to both water diffusion and blood microcirculation. For high b-values, water diffusion is the main contributor to signal decay, but for low b-values, both water diffusion and blood microcirculation will contribute. This is known as the Intravoxel Incoherent Motion theory (IVIM) [5].

Blood microcirculation in tumors is very valuable information in the oncology field. Tumor usually experiences irregular blood flow, blood perfusion is very spatially and temporally heterogeneous [6]. The heterogeneity of blood flow in the tumor volume will block the access of therapeutic agents to tumors, and results in the creation of distinct microenvironments within the tumor. The heterogeneity inside the tumor volume will increase tumor resistance and reduce the effectiveness of various therapies.

Another important parameter is the oxygen extraction fraction, OEF is a measure of the quantity of oxygen extracted by tissues from the bloodstream. It is mainly used in the neuroimaging field to monitor brain activity [7]. The brain consumes oxygen constantly to maintain its function, and the OEF represents the ability of the brain to extract oxygen from the blood.

In MRI, the main method used to measure the OEF is qBOLD, quantitative Blood Oxygenation Level Dependent. It is a non-invasive technique founded on the fact that any change in neural activity will result in a

change in blood flow and oxygen concentration in the brain. BOLD is based on the difference in magnetic susceptibility between oxygenated hemoglobin which is diamagnetic, and deoxygenated hemoglobin which is paramagnetic. This difference results in a local change of the magnetic field, which affects the signal in T2*-weighted imaging sequences.

The present work evaluates the feasibility of a multiparametric quantitative MRI acquisition and processing pipeline to reconstruct multiparametric maps including an oxygenation measurement to map head and neck tumor biology.

2. Materials and Methods

The designed protocol is dedicated for head and neck radiotherapy planning, and it consists of the following acquisitions:

- T_2, acquired using a 2D multiple echoes sequence, with a scan duration of 5 minutes 20 seconds.
- Chemical shift encoded, acquired using a flash 3D sequence, with a scan duration of 1 minute 21 seconds.
- Diffusion weighted, acquired using a WIP body diffusion MOCCO (990), with a scan duration of 7 minutes 51 seconds.

All the acquisitions were done on a Siemens Vida 3 tesla MR system (Siemens Healthineers, Erlangen, Germany) at the comprehensive cancer center Léon Bérard, with a frequency of one to two patients per week. All of the enrolled patients are diagnosed with a primary squamous cell carcinoma of the hypopharynx, larynx, oropharynx, or undifferentiated nasopharyngeal carcinoma. The patients were fully informed about the study, and a written consent was obtained from them according to the declaration of Helsinki. An immobilizer mask was used with each patient to reduce the motion and to simulate the treatment position, also a knee support was used to provide more comfort.

The delineation of the organs at risk and tumor volume was done on the CT images by two radiations oncologists. The following volumes were delineated: the organs at risk including the spinal cord, the parotid, the optic nerve, the brain stem, and the chiasma. The tumor volume including the gross tumor volume GTV, the low and high risk primary clinical target volume CTV. A landmark registration was performed on the GTV so it can be used with the MR acquisitions and the quantitative maps later.

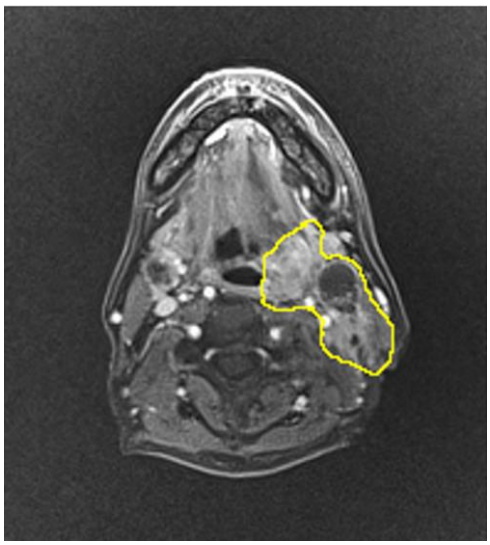

Figure 1: T1 StarVIBE image with the borders of the gross tumor volume indicated in yellow.

The R_2 mapping was obtained using a 2D TSE multi-echoes sequence, with 10 echoes ranging from 8 ms to 80 ms and having an interval of 8 ms. The relaxation rate can be calculated using the following equation.

$$S(TE) = M_0 \, exp\left(-TE/T2\right).$$

With TE being the echo time and M_0 the initial magnitude of the magnetization.

To estimate the blood volume, we first need to estimate the perfusion fraction, this can be done using the IVIM model (figure 2), with the following equation:

$$\frac{S}{S_0} = f * exp - bD * + (1 - f) * exp - bD.$$

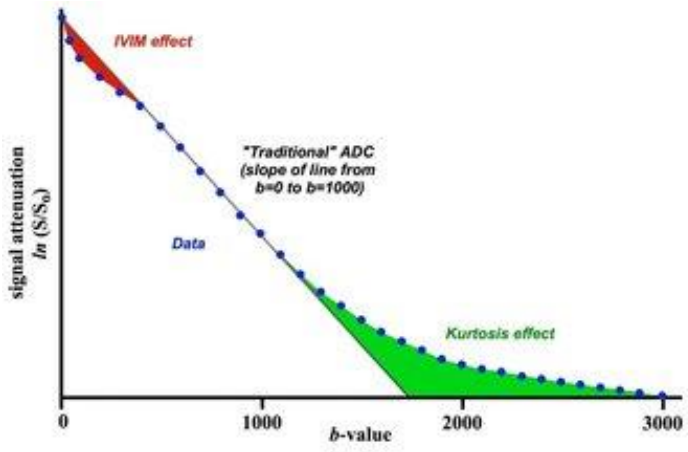

Figure 2: Decay curve of the MRI signal in diffusion-weighted images with the IVIM model (image source: https://mriquestions.com/ivim.html).

Where S_0 is the initial signal intensity, the b-value represents the magnitude and the period of the applied diffusion (i.e. the diffusion weighting in $s.mm^{-2}$) , S is the signal intensity for a given b-value, D is the molecular Gaussian diffusion related to the Brownian motion, D* is the pseudo-diffusion coefficient related to blood flow capillaries [8,9].

Now having all the necessary parameters, the estimation of the oxygen extraction fraction is straightforward.

3. Results

Using an in-house application developed in MATLAB R2023b (Matlab, Natick, MA, USA), 13 quantitative parametric maps were computed from the gross tumor volume of each patient including: blood volume, diffusion coefficient, pseudo-diffusion coefficient, fat only, water only, PDFF, M0, T_2, T_2', R_2', perfusion fraction, relative oxygen extraction fraction and venous oxygen saturation (Figure 3).

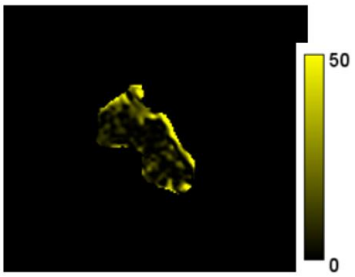

Figure 3-1: PDFF.

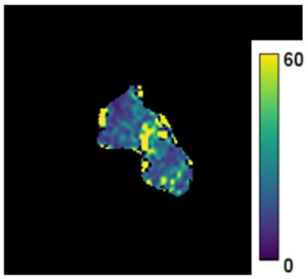

Figure 3-2: T_2.*

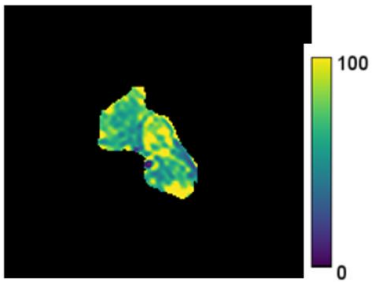

Figure 3-3: T_2.

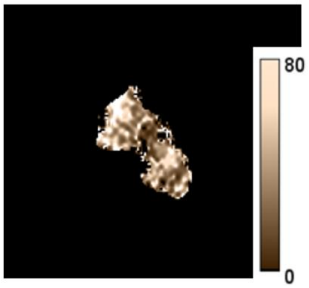

Figure 3-4: R_2`.

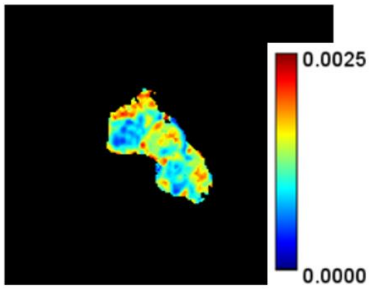

Figure 3-5: Pseudo diffusion coefficient.

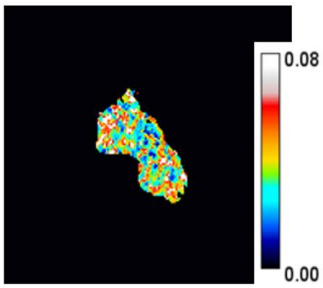

Figure 3-6: Diffusion coefficient.

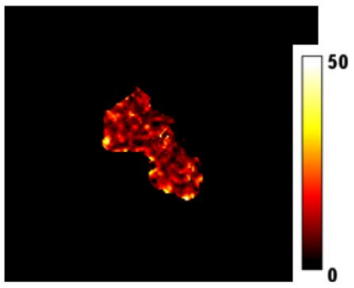

Figure 3-7: Blood volume.

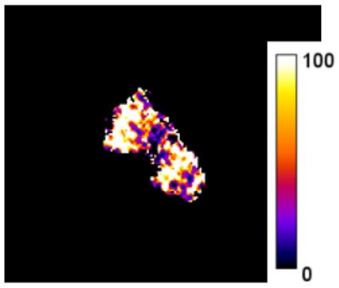

Figure 3-8: rOEF.

4. Discussion

Each map provides very important information about the tumor and it can help determine the tumor cellularity, viability, and microstructural environment, fat content and oxygeneation. For instance, the oxygen extraction fraction map reflects the hypoxic and normoxic regions inside the tumor which is a crucial information to determine the tumor's resistance to radiotherapy. These maps will can be used to accurately characterize the tumor spatial heterogeneity and personalize the therapy based on each patient case using habitat-imaging approach.

5. Conclusion

This study demonstrates the feasibility of multiparametric MRI in radiotherapy planning context, and suggests additional interests in the exploitation of quantitative MRI to improve the treatment course by spatially mapping of the tumor biology.

Abstract Deep learning presents novel opportunities for the auto-segmentation of gross tumor volume (GTV) in head and neck cancer (HNC), yet fully automatic methods usually necessitate significant manual refinement. This study investigates the Segment Anything Model (SAM), recognized for requiring minimal human prompting and its zero-shot generalization ability across natural images. We specifically examine MedSAM, a version of SAM fine-tuned with large-scale public medical images. Despite its progress, the integration of multi-modality images (CT, PET, MRI) for effective GTV delineation remains a challenge. Focusing on SAM's application in HNC GTV segmentation, we assess its performance in both zero-shot and fine-tuned scenarios using single (CT-only) and fused multi-modality images. Our study demonstrates that fine-tuning SAM significantly enhances its segmentation accuracy, building upon the already effective zero-shot results achieved with bounding box prompts. These findings open a promising avenue for semi-automatic HNC GTV segmentation.

1 Introduction

In radiotherapy, delineating the gross tumor volume (GTV) for head and neck cancer (HNC) is a critical yet challenging component of treatment planning. This complexity arises due to the proximity of adjacent organs at risk (OARs) within a constrained space and the tumors' heterogeneous appearance. Manual GTV delineation is not only time-consuming and dependent on a high level of expertise but also requires the integration of multi-modality images such as CT, PET, and MRI. Furthermore, the process is prone to inter-observer variability, which can significantly impact treatment outcomes. Consequently, there is a pressing need for a fully or semi-automatic approach that can streamline the delineation process, enhance consistency, and improve clinical workflow.

Deep learning segmentation models are increasingly recognized for their ability to discern complex image features from extensive datasets of historical images and annotations. Despite their promise, the application of HNC GTV segmentation often necessitates significant manual adjustments for certain patients[1]. Simplifying the definition of a region of interest (ROI) through bounding boxes has been shown to markedly improve outcomes[2, 3]. Furthermore, incorporating 'human-in-the-loop' interactions not only enhances model accuracy but also its interpretability[4,5,6].

Nonetheless, a major hurdle for these models is their struggle with generalization, particularly when there is a significant divergence between training and testing datasets. These could be for example trained on oropharyngeal tumors and tested on larynx tumors, or inter-modality inferences. The Segment Anything Model (SAM) has emerged as a promising solution, demonstrating exceptional zero-shot learning capabilities, trained on over 1.1 billion segmentation masks and roughly 11 million natural images[7]. SAM supports user prompts via points, bounding boxes, and text, yet its successful deployment in medical imaging (e.g., X-ray, CT, MRI) is hampered by the substantial domain gap between natural and medical images[8].

To bridge the domain gap, recent efforts have focused on fine-tuning both public and private medical image datasets[9, 10]. A notable contribution by Ma et al.[11] introduced MedSAM, a version of the SAM fine-tuned with over 1.5 million medical image-mask pairs, demonstrating significant promise in HNC tumor segmentation using CT images. However, GTV delineation in most hospitals involves integrating multiple registered image modalities (e.g., CT, PET, MRI). Given that SAM was initially trained on natural images with red-green-blue (RGB) channels, and MedSAM was fine-tuned for single-modality scenarios, the challenge of fusing registered multi-modality images remains. Consequently, there may be reservations regarding the efficacy of MedSAM's zero-shot inference on local multi-modality datasets.

In this study, we explore MedSAM's capabilities in segmenting both primary tumors (GTV-T) and the involved lymph nodes (GTV-N) across single- and multi-modality images. We assess the model's performance in zero-shot and fine-tuned scenarios on our local dataset.

2 Materials and Methods

A total of 576 HNC patients from Aarhus University Hospital treated with radiotherapy in the period 2013-2020 were included in this study. Each patient had undergone treatment planning with FDG-PET/CT, T1-weighted (T1w), and T2-weighted (T2w) MRI. The T1w and T2w images were initially registered to the CT images using rigid and then deformable registration methods. The dataset was randomly divided into three subsets: 470 for training, 94 for validation, and 97 for testing. The clinical

treatment planning process involved referencing all image modalities to delineate both GTV-T and GTV-N, with these clinical delineations serving as the ground truth.

2.1 Single- and Multi-modality

Although MedSAM is trained on datasets from various modalities, like the original SAM, it processes inputs from only a single modality at a time. For inputs involving a single modality, we adopted the approach of replicating the CT images across three channels to mimic RGB inputs, a method we refer to as 'CT-only.'

For multi-modality fusion, to accommodate four image modalities while maintaining SAM's simplicity, we devised a unique strategy: CT images were assigned to the red channel, PET images to the green channel and a blend of T1w and T2w MRI images to the blue channel. To integrate the T1w and T2w images, we first normalized them to the same intensity range and then computed the average intensity for each corresponding pixel pair. This approach is termed 'multimodal'.

2.2 Preprocessing and bounding box prompt

For preprocessing, CT images were adjusted with a window level of 40 and a window width of 400 to highlight soft tissue. PET images were clipped to a range of 0-6 SUV[12], while MRI images were adjusted to include intensities from the 0th to the 99.5th percentile of their maximum values. Subsequently, all images from these different modalities were rescaled to a 0-255 range, aligning them with the typical intensity range of natural images. After combining these into RGB channels, each 2D slice was normalized to float values between 0 and 1, preparing them as input for SAM.

Regarding the segmentation label masks, we treated each GTV-T and GTV-N object within the 2D slices as distinct segmentation targets. For SAM's prompting mechanism, we utilized a bounding box strategy. On each 2D slice, we introduced a random perturbation margin ranging from 0 to 20 mm to box out each GTV instance.

2.3 Zero-shot and finetuning of MedSAM model

We utilized the lite version of MedSAM, which employs a tiny vision transformer (TinyViT) model distilled from the larger variant, as our pre-trained SAM model base[13]. To evaluate its zero-shot generalization ability on our local dataset, we performed inference on our test set without any additional training.

For fine-tuning, the pre-trained lite MedSAM model was further trained on our local dataset for up to 20 epochs. We saved the epochs of the model that achieved the lowest Dice Loss on the validation set to ensure optimal performance.

We followed MedSAM's training protocol, employing a hybrid loss function that combines Dice loss, cross-entropy, and IoU loss. The AdamW optimizer was used, with a batch size of 8 and an initial learning rate of 3e-4. This rate was scheduled to reduce by a factor of 0.9 upon hitting a performance plateau, with patience of 5 epochs. The training was executed on two NVIDIA A40 GPUs, each equipped with 40 GB of GPU memory.

For the comparative analysis, we utilized two fully automated configurations of nnUNet[14], processing all image modalities (four image modalities) with the identical data split as SAM finetune. The first configuration functioned without a bounding box (nnUNet w/o box), whereas the second configuration included a bounding box as an additional input channel for each 2D slice, aligning with the approach taken by MedSAM (nnUNet w/ box). Both nnUNet configurations were trained for 1000 epochs in 3D full resolution.

2.4 Evaluation

To evaluate segmentation performance, we computed the mean and one standard deviation for the Dice Similarity Coefficient (DSC) as the primary metric, complemented by the 95% Hausdorff Distance (HD95). These evaluations were conducted on the entire 3D volumes of the images on the test set, comparing the segmented outputs with the ground truth for both GTV-T and GTV-N. Additionally, we monitored the fine-tuning time required for each epoch and the inference time needed to predict each slice.

3 Results

In assessing segmentation performance, we evaluated MedSAM under both zero-shot and fine-tuned conditions, using either CT-only or fused multimodal inputs. We also compared these results against the fully automatic multi-modality nnUNet, both in its standard configuration and an enhanced setup incorporating a bounding box. The outcomes, including both DSC and HD95 metrics, are detailed in Figure 1.

When examining zero-shot outcomes, multimodal inputs slightly outperform CT-only for GTV-T (0.70 vs. 0.69), whereas CT-only surpasses multimodal for GTV-N (0.75 vs. 0.68). However, following fine-tuning, both CT-only and multimodal approaches see a significant boost in segmentation accuracy, as reflected in DSC scores. Specifically, for CT-only inputs, DSC scores increased from 0.69 to 0.82 for GTV-T and from 0.75 to 0.85 for GTV-N. Similarly, multimodal inputs saw DSC improvements from 0.7 to 0.82 for GTV-T and from 0.68 to 0.85 for GTV-N with fine-tuning.

A nnUNet model without a bounding box exhibits lower performance (0.68 for GTV-T and 0.63 for GTV-N) and higher variance, however, the inclusion of bounding boxes

of each target at each 2D slice in nnUNet markedly improves results (0.88 for GTV-T and 0.89 for GTV-N). The HD95 exhibits a trend similar to that observed with DSC.

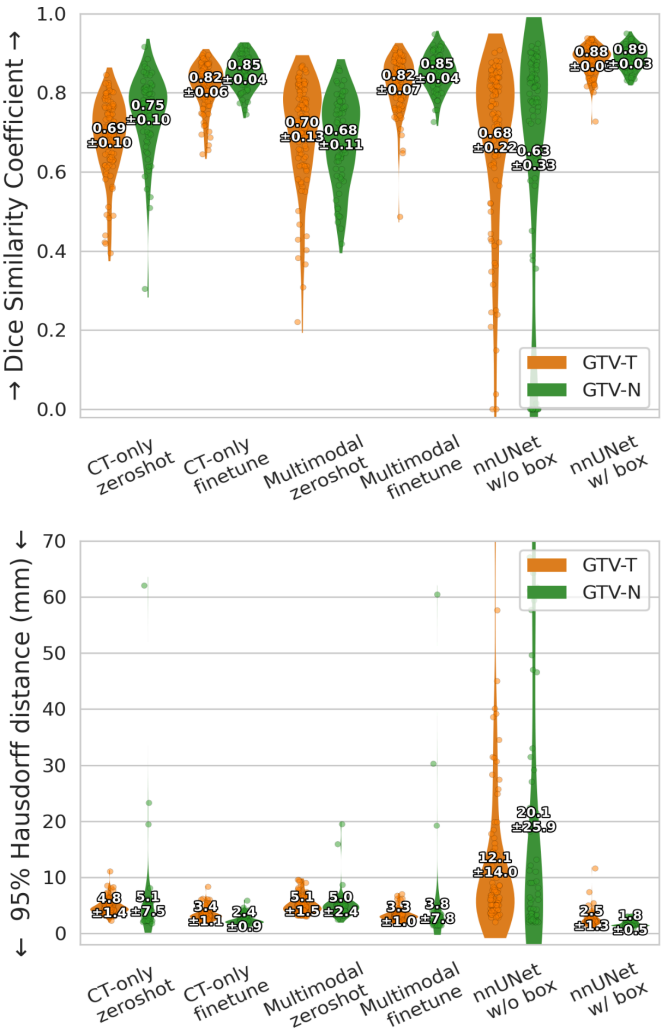

Figure 1: Comparative analysis of segmentation performance across groups for GTV-T and GTV-N, illustrated through violin plots using the Dice Similarity Coefficient (DSC) and the 95% Hausdorff Distance (HD95).

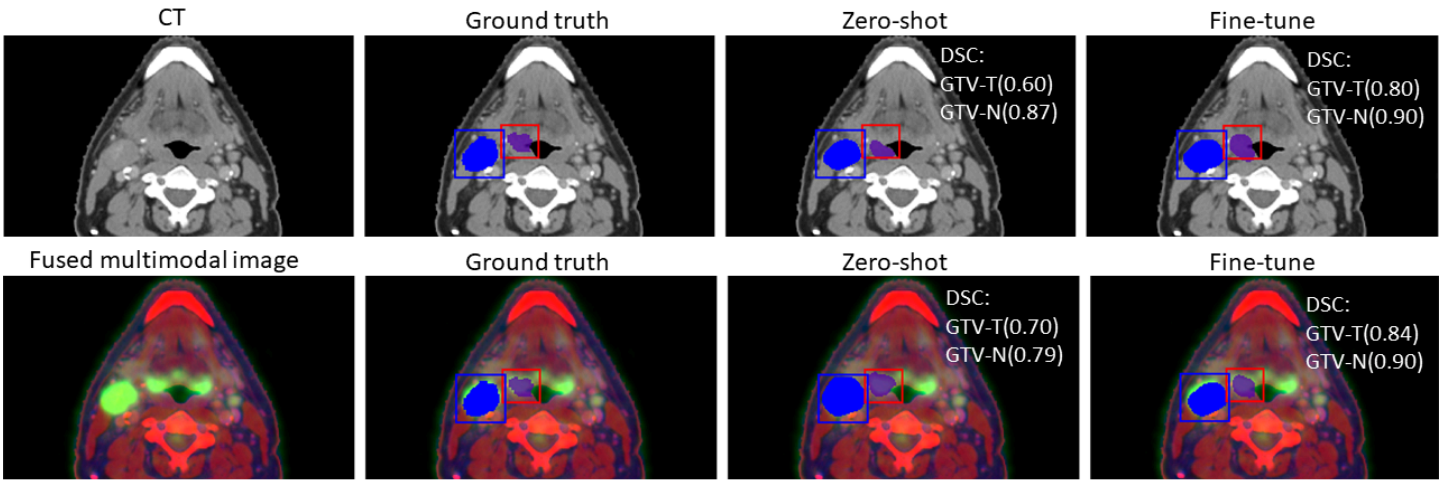
Figure 2: A case study illustration of CT-only and multimodal approaches on zero-shot and fine-tuned MedSAM for GTV-T and GTV-N segmentation.

The fine-tuning time for a lite MedSAM model using the training set (470 patients) averaged 11 minutes per epoch. We obtained the optimal fine-tuned models at epoch 8 for CT-only inputs and at epoch 4 for multimodal inputs. The prediction time for a target, given a bounding box on a 2D slice, was approximately 0.03 seconds, with no discernible difference between CT-only and multimodal inputs.

4 Discussion

In this investigation, we systematically explored the efficacy of the SAM model in segmenting GTV-T and GTV-N using local single- and multi-modality images. Even though the ground truth delineation referenced multimodality images, the CT-only input yielded comparable results for zero-shot inference with MedSAM on GTV-T. Interestingly, it achieved better results on GTV-N. The finetuning shows the effectiveness of enhancing segmentation accuracy and consistency for both groups.

Previous studies have demonstrated that fully automatic U-Net configurations, which combine multiple modalities (e.g., CT and PET), significantly outperform those using a single modality[15]. In our study, the CT-only approach with MedSAM achieved better segmentation accuracy compared to the fully automatic multi-modality nnUNet. This suggests that the inclusion of a bounding box for prompting effectively localizes the region of interest, even in zero-shot inference scenarios, as evidenced by the significant reduction in outliers highlighted by the HD95 metric. This benefit is also apparent in nnUNet's performance when utilizing bounding boxes. Conversely, the similar overall performance between CT-only and multimodal approaches in zero-shot inference could imply that the method used for fusing multimodal images may not be fully effective by SAM. This aligns with prior research emphasizing PET's crucial role in directing the network's focus to the relevant area[4,12]. Additionally, there are instances, where multimodal could enhance GTV-T boundary contrast, as depicted in Figure 2.



The significant improvement in performance following fine-tuning demonstrates the strong adaptation capability of SAM to new datasets within just a few epochs of training (8 for CT-only and 4 for multimodal). This is particularly notable in our proposed multimodal fusion strategy, considering that neither SAM nor MedSAM had previously encountered such image types. Despite their robust generalization capabilities, a gap remains between the fine-tuned models and the nnUNet when using the same bounding boxes. This gap may be attributed to nnUNet's powerful feature learning capability, stemming from its large model size.

These findings also spotlight a key limitation of fully automatic segmentation methods: their diminished focus when predicting GTV with full 3D image size. Interactions with models like nnUNet, while robust, can be more complex and time-intensive compared to simpler approaches like SAM. Predicting a comprehensive 3D head and neck image incorporating CT, PET, T1w, T2w, and an additional channel for human inputs can take up to 2 minutes when using nnUNet. In contrast, using a bounding box to prompt SAM for a single slice yielded instant responses (~0.03 seconds). Therefore, integrating SAM with U-Nets as a semi-automated annotation tool holds great promise for incorporating 'human-in-the-loop' practices in clinical settings. Such tools could not only increase the credibility and interpretability of AI models but also enable personalized treatment planning for optimized radiotherapy[4].

Our study has some limitations. Firstly, we contrasted the 2D MedSAM model with the 3D nnUNet, where the latter might benefit from contextual dependencies along the axial direction. However, given that SAM is designed for interactive use and nnUNet for fully automatic use, a direct comparison may not constitute a fair contest. The nnUNet, when equipped with a bounding box for each slice, sets a high benchmark for semi-automatic segmentation, whereas its performance without a bounding box represents a decent threshold for fully automatic segmentation. Secondly, while we selected the best-performing fine-tuned model based on its performance on the validation set to minimize the risk of overfitting, there remains a potential for catastrophic forgetting when applied to other datasets. Validating the model on a public HNC dataset could help mitigate this concern. Moreover, future studies exploring the integration of various prompting methods, including clicks, brushes (masks), or textual (language) inputs, in addition to bounding boxes, would be valuable.

5 Conclusion

In conclusion, our study demonstrated the potential of zero-shot and fine-tuning SAM for the segmentation of GTV in head and neck cancer. We found that fine-tuning significantly enhances segmentation accuracy for both CT-only and fused multimodal images, underscoring the model's robust adaptation capabilities. Our findings suggest promising avenues for enhancing semi-automatic segmentation tools in clinical settings using SAM.

Test-time Adaptation for Medical Image Segmentation based on a Joint framework with an Adaptive Wavelet-VNet and a Refine Model (WaVNet-Refine)

Xiaoxue Qian[1], You Zhang[1]

[1]Department of Radiation Oncology, UT Southwestern Medical Center, Dallas, TX, 75390

Abstract For medical image segmentation, there often exists a domain gap between acquired training and testing datasets due to variations in imaging hardware/protocols. It leads to domain shift problems that may substantially degrade the performance of deep learning-based segmentation models. Due to the high cost of manual labeling and the need for privacy protection, it is often difficult to annotate new (target) domain data for model fine-tuning or re-access source domain training data to train domain generalization models. Therefore, test time adaptation using only target domain data is a more practical but challenging solution. In this study, we proposed an adaptive wavelet-VNet for test-time image segmentation adaptation. To improve the model's robustness to domain variations, we introduced the multi-level wavelet transform into an adaptive wavelet-VNet, where multiscale wavelet coefficients are concatenated to the VNet encoder to effectively extract domain-invariant features. Meanwhile, we employed a Refine model to correct the incomplete and noisy segmentation results caused by the domain shift. The adaptive wavelet-VNet and the Refine model were unified into a test-time adaptation framework (WaVNet-Refine). We evaluated WaVNet-Refine with a multi-domain liver dataset and showed its advantages over other state-of-the-art test-time adaptation methods.

1 Introduction

Deep neural networks have greatly improved the accuracy of medical image segmentation [1], while their performance heavily relies on the underlying data distribution. In real practice, medical images often contain domain shifts due to different imaging hardware or scanning protocols. When a model trained on a source-domain dataset was tested on another from unseen target domains, its performance typically declines due to the domain shifts. To tackle this problem, a few fine-tuning and domain adaptation methods were proposed [2, 3]. However, these methods usually require labeled data in the target domain, or need to re-access the source domain data for model generalization. The labeling costs and the data privacy concerns often render them in-practical. Test-time adaptation, which only uses the label-free, target-domain data during test time for model updates, presents a much more viable alternative. However, the label-free test-time adaptation is challenging to implement, as the unknown domain gap may render the model adaptation unreliable and inconsistent.

Thus, extracting effective, domain-invariant features is crucial for the test-time adaptation models to achieve robust segmentation results. Wavelets transforms [4] are known to be robust against variations in image intensity and quality, making them highly reliable for feature extraction in various medical imaging modalities and conditions. In this regard, we introduced the wavelet transform into the test-time adaptation model, which uses a series of filters to enhance domain-invariant information while suppressing domain-specific information. Specifically, the wavelet transform converts the images into low and high-frequency wavelet coefficients. The low-frequency coefficients preserve the general appearance of anatomies, while effectively reducing variations in their intensity and contrast. The high-frequency sub-bands, on the other hand, enhance anatomical and edge details. We embedded these wavelet coefficients into a VNet backbone to enhance the network's capability in learning domain-robust features for segmentation, denoted as WaVNet.

To allow WaVNet to adapt at the test time to further address domain differences, we introduced an adaptive module, which is a shallow convolutional module deployed on the front of WaVNet, to update the low level features to accommodate the testing sample. Since there is no label from the testing sample for supervised learning, we introduced a Refine model (Fig. 1), a segmentation correction model, to generate an unsupervised loss on WaVNet's output to update the shallow adaptive module. The Refine model is designed as a reconstruction network using inadequately-trained source-domain models, based on the observation that incorrect segmentations on unseen target domains may resemble the segmentations from inadequately trained source-domain models. During test-time adaptation, the input and output of Refine model are used to calculate an unsupervised loss to update the parameters of the adaptive module. Overall, we proposed a joint framework with adaptive WaVNet and a Refine model (WaVNet-Refine) for online test-time adaptation. We evaluated WaVNet-Refine on a multi-domain liver MR imaging set for liver segmentation, and compared its accuracy against several other state-of-the-art methods.

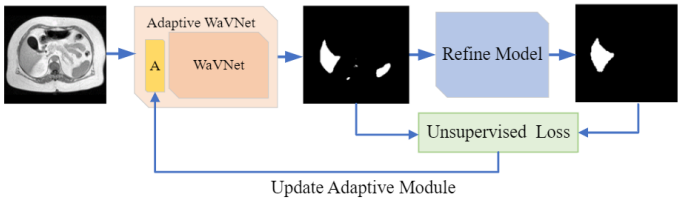

Figure 1: Overview of the WaVNet-Refine framework for test-time adaptation. A: the shallow low-level adaptive module to be updated during the test-time adaptation.

2 Materials and Methods

The overall WaVNet-Refine framework is shown in Fig.1, which comprises the adaptive WaVNet model and the subsequent Refine model. Details of the adaptive WaVNet model and the Refine model are introduced in the following.

2.1 The Adaptive WaVNet

2.1.1 Wavelet transform

Wavelet transform, a multi-resolution geometrical analysis method, uses filters to statistically analyze spectral features across various scales and orientations. Fig. 2 illustrates the use of multi-level wavelet transform to extract different scale features from a 3D image. Given a 3D input image $X \in R^{N\times N\times C}$ (N = 256 and C = 64 in this study) and a wavelet decomposition level of n = 3, the first level discrete wavelet transform (DWT) generates one low-frequency sub-band and seven high-frequency sub-bands for seven orientations, which are concatenated to compose the scale-1 features. Subsequently, performing the second-level DWT on the low-frequency sub-band from scale-1 further generates scale-2 features, and the third-level DWT generates the scale-3 features from the low-frequency sub-band of scale-2.

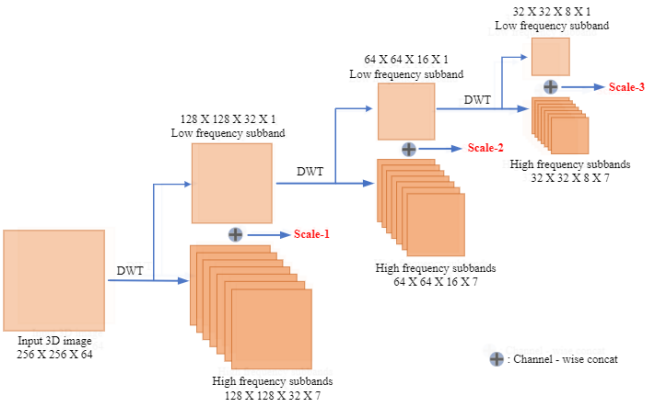

Figure 2: Multi-level wavelet transform on a 3D image.

The extracted features at different levels (scale-1, scale-2, scale-3) were integrated within the VNet architecture to promote the learning of domain-invariant features. From the perspective of signal filtering, wavelet transform and convolutional neural networks such as VNet share similar mathematical representations. The multi-level wavelet transform can be expressed as follows [5]:

$$F_{L,n+1} = (F_{L,n} * k_{L,n}) \downarrow 2 \quad (1)$$

$$F_{H,n+1} = (F_{L,n} * k_{H,n}) \downarrow 2 \quad (2)$$

where $k_{L,n}$ represents the scaling function, acting as a low-pass filter in the frequency domain; and $k_{H,n}$ denotes the wavelet function, acting as a high-pass filter. n denotes the wavelet level, and $F_{L,0}$ equals the input 3D image X .

On the other hand, a typical VNet [6] comprises multiple convolutional, down-sampling, and up-sampling layers. The convolution and down-sampling can be represented mathematically as follows:

$$F_{l+1} = (F_l * K) \downarrow p \quad (3)$$

where K denotes the convolutional filters, symbol $\downarrow$ represents the down-sampling operator, and p denotes the stride of down-sampling. When p<1, the down-sampling turns into up-sampling. l denotes the network layer, and F_0 equals X, the input 3D image .

From Eqs. 1-3, it can be observed that the wavelet transform and VNet share similar filtering operations on images, but from the perspectives of frequency (spectral) and spatial domains, respectively. Compared with the convolutional filtering of the conventional VNet, the wavelet transform extracts additional domain-invariant information through the spectral domain filtering, which can be combined with the VNet to train models that are more robust to domain variations. Correspondingly, we concatenated the three scale features extracted by the wavelet transform into the 2nd, 3rd, and 4th layers of the VNet encoder to fuse their information to generate the WaVNet, which learns hierarchical spectral and spatial features together to enhance the domain invariance of the model.

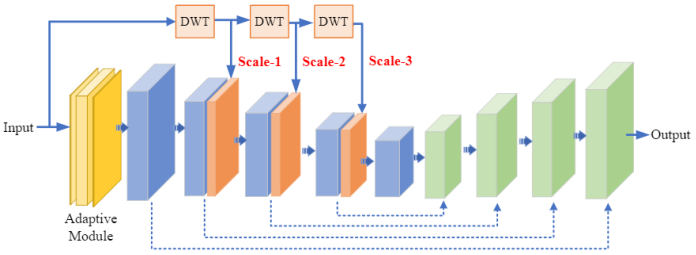

Figure 3: Details of the adaptive WaVNet, where the three-scale features extracted by the wavelet transform are concatenated with the VNet encoder to promote hierarchical spectral and spatial feature learning.

2.1.2. The adaptive module

Although incorporating the wavelet transform into VNet promotes domain-invariant learning, it is insufficient to address all domain gaps. It has been found that domain differences in medical images mainly appear in low-level features while high-level structural characteristics usually stay consistent across domains. Thus the low-level feature layers of the WaVNet can be further adapted online to address the domain gaps observed in the testing sample. Correspondingly, we developed an adaptive module for test-time adaptation. It is a shallow convolutional unit of three layers positioned at the front of the WaVNet, rendering an adaptive WaVNet. The detailed network structure is shown in Fig. 3. During test-time adaptation, we only updated the parameters of the adaptive module with an unsupervised loss generated by a Refine model, while keeping all the other network parameter frozen.

2.2 The Refine model

To update the adaptive module of WaVNet online, we need to generate a loss function for backpropagation. Due to the lack of 'ground-truth' labels from the testing samples, supervised training cannot be performed. In light of this, we developed a Refine model, serving as a segmentation corrector/evaluator, to evaluate the output segmentations from WaVNet and generate an unsupervised loss to update the adaptive module.

We used under-trained source models to generate incomplete and noisy segmentation data to train a Refine model, which helps to evaluate/fix incorrect segmentations. It is motivated by the observation that when source domain models were tested on target domain samples with distribution shifts, the segmentation results often showed

poor regional consistency, inaccurate edges, misclassifications, and noise, similar to those obtained from inadequately-trained source models. To generate under-trained source models, we used early stopping to derive a variation of WaVNet models, which were used to generate incomplete and noisy segmentation results from the source domain images. Using these incomplete/noisy segmentations as inputs, we trained the Refine model using their corresponding 'ground-truth' labels. We instantiated the Refine model as a reconstruction network, using an auto-encoder. The mean squared error (MSE) loss function was used:

$$L_{ref} = L_{MSE}(R_c(y'), y); y' = V_s(X) \quad (4)$$

where X and y denote the source images and labels, respectively. V_S represents the under-trained source models, and R_C denotes the Refine model. During training, by encoding and decoding the inputs, the Refine model gradually learned how to repair incomplete segmentations to match the labels.

3 Evaluation and Results

3.1 Datasets

We used the CHAOS liver segmentation dataset [7] to evaluate WaVNet-Refine. The CHAOS dataset includes two subsets of different MR sequences: T1 DUAL (40 cases) and T2 SPIR (20 cases). The T1 DUAL images are further divided into 20 in-phase (IP) and 20 out-phase (OP) images, which have the same repetition times but different gradient echo times and can be considered as different domains. The three-domain data were arranged into six comparison groups (IP (source) to OP (target), OP to IP, IP to T2, OP to T2, T2 to IP, and T2 to OP), each with 20 source samples and 20 target samples. For source domains, we used 15 randomly-selected samples for training and 5 for validation. For target domains, we randomly-selected 15 samples for supervised target domain model training (for comparison with our method) and 5 for adaptation and testing. All images were uniformly resampled to (1.5, 1.5, 1.5) mm³, cropped to (256, 256, 64), and normalized to [0, 1].

3.2 Implementation details and comparison methods

We used the original VNet [6] as the baseline model and applied a three-level DWT with the db1 wavelet [4] to construct the WaVNet. The channel number of the adaptive module was set to (1, 64, 1). The Refine model was implemented as a four-layer VNet with a sigmoid activation function at the end. The adaptive WaVNet was trained for 2000 epochs as the source model. We also trained five additional WaVNet models for (20, 40, 60, 80, 100) epochs to generate five under-trained models, and used them to output 100 incomplete segmentations (20 for each) as the training samples of the Refine model. The Refine model was trained for 1000 epochs. For online test-time adaptation, we fixed all WaVNet-Refine parameters except for those of the shallow adaptive module, and separately updated the network for two iterations using each single test sample. All the trainings are based on a batch size of 1, with the SGD optimizer and a learning rate of 0.0005.

We compared seven methods to evaluate the efficacy of our method: **1. No adaptation (NA)**: we trained a VNet model using the source domain's training samples for 2000 epochs, and tested on the 5 testing sets of the target domain. **2. From scratch (FS)**: we trained a VNet model using the target domain's 15 training cases for 2000 epochs, and tested on the 5 testing sets. **3. Test time adaptation: tent (TN)** [8]: We trained a VNet model on the source domain for 2000 epochs, performed test-time adaptation on the target domain's 5 testing sets using the entropy minimization loss for 10 epochs. **4. Test time adaptation: regional nuclear norm + contour regularization (RN)** [9]: Similar to TN, but used regional nuclear-norm and contour regularization losses for test-time adaptation. **5. WaVNet (WV):** Similar as WaVNet-Refine, without the Refine model or test-time adaptation. **6. VNet-Refine (VR)**: Similar to WaVNet-Refine, but without the wavelet transform. **7. WaVNet-Refine (WR)**: the framework proposed in this study. We use two metrics: the Dice coefficient (Dice) and the 95th percentile Hausdorff distance (HD95) to evaluate the segmentation results.

3.3 Segmentation results comparison

The Dice and HD95 results for liver segmentation, obtained using seven different methods across three domains' datasets, are detailed in Tables 1 and 2.

Method	*IP to OP*	*OP to IP*	*IP to T2*	*OP to T2*	*T2 to IP*	*T2 to OP*	*Mean*
NA	79.77	65.33	49.78	62.46	65.12	63.57	64.34
FS	88.40	90.19	90.23	90.23	90.19	88.40	89.61
TN	84.90	76.61	60.91	64.87	77.51	64.10	71.48
RN	84.49	77.94	65.45	71.54	74.89	68.93	73.87
WV	82.96	70.89	67.93	69.04	69.72	66.82	71.23
VR	86.56	82.45	65.50	73.68	75.43	70.32	75.65
WR	87.17	83.90	78.41	79.69	79.96	74.64	80.63

Table 1: Average Dice (%) of the seven methods on the liver dataset, each result of different methods/testing groups was averaged over 5 testing/adaptation cases.

Method	*IP to OP*	*OP to IP*	*IP to T2*	*OP to T2*	*T2 to IP*	*T2 to OP*	*Mean*
NA	26.33	65.11	80.31	78.35	67.93	45.42	60.58
FS	23.07	11.31	6.884	5.472	11.31	23.07	13.52
TN	24.98	49.39	78.58	62.95	38.25	37.41	48.59
RN	24.06	33.25	63.41	42.91	35.58	37.55	39.46
WV	13.26	35.84	24.88	20.65	29.35	28.02	25.33
VR	11.52	12.60	32.79	18.37	25.06	28.44	21.46
WR	9.01	11.36	25.01	18.00	19.82	15.89	16.51

Table 2: Average HD95 of the seven methods on the liver dataset, each result of different methods/testing groups was averaged over 5 testing/adaptation cases.

Serving as the no-adaptation benchmark, NA in Table 1 yielded the poorest results among all, showing the impacts

of domain shifts. With direct access to the target domain's images and labels for supervised training, the FS method achieved the best results. However, obtaining labeled data from the target domain can be challenging, especially when the domain shift is not made aware, or the domain shift happens frequently along different directions. Using the wavelet-incorporated VNet, WV offered better segmentation results than NA, while still suffering from the domain shifts and the lack of test-time adaptation. The four methods (TN, RN, VR, and WR) all outperformed the NA method, showing the benefits of test-time adaptation. However, compared with VR, TN and RN were based on statistical loss functions and did not use the Refine model. The Refine model helped VR to repair and evaluate the segmentation results using prior information for more effective test-time adaptation and achieve more accurate segmentation. Comparing VR with WR, the wavelet transform helped WR to capture more domain-robust features and made it the overall most accurate test-time adaptation methods.

Compared to the DICE coefficient shown in Table 1, the HD95 metric in Table 2 is more sensitive to detailed contour edge inaccuracy. The existing test-time domain adaptation methods, TN and RN, showed much inferior results compared with VR and WR for HD95. WR achieved a similar mean HD95 as the supervised FS method.

The qualitative segmentation results were shown in Fig. 4. The subpanels (a) and (b) showed the segmentations on two different slices using various methods, respectively. The WaVNet-Refine segmentation results are closer to the two target-domain supervised learning methods and the 'ground-truth', showing the effectiveness of combining domain-robust feature learning with Refine model-guided test-time domain adaptation.

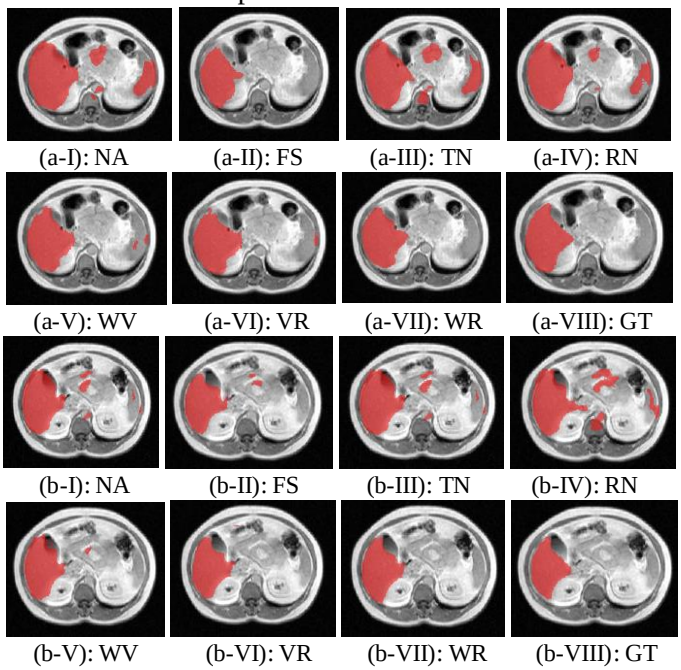

Figure 4: Visual comparison of segmentation results for two different slices (a, b), using the seven methods. (I) no adaptation (NA), (II) from scratch (FS), (III) tent (TN), (IV) regional nuclear norm + contour regularization (RN), (V) WaVNet (WV), (VI) VNet-Refine (VR), (VII) WaVNet-Refine (WR), and (VIII) Ground truth (GT).

4 Conclusion

We proposed a novel online test-time adaptation method, WaVNet-Refine, to address the challenges of domain shifts in medical image segmentation. WaVNet incorporates wavelet transforms to enhance domain-robust feature learning for segmentation, and the Refine model can further rectify and evaluate the segmentations from WaVNet to generate an unsupervised loss, which is used to fine-tune WaVNet during test time via a low-level feature adaptation module. WaVNet-Refine achieves substantial accuracy enhancement as compared with the other test-time adaptation methods, allowing more robust cross-domain segmentation. The test-time adaptation potential of WaVNet-Refine could benefit from additional domain-invariant learning, as well as other segmentation fine-tuning tools including atlas-based and prior contour-based learning. Additional evaluations on more anatomical sites and datasets are warranted.

Abstract Adaptive radiotherapy requires images of planning CT-like quality and segmentations of structures for treatment plan evaluation and its adaptation. We propose an unsupervised framework which can jointly generate synthetic CTs and segment Organs at Risk, without requiring any segmentations on CBCT during training or inference. The presented results show feasibility of such an approach with improvement in CBCT images in terms of L2 histograms distance, mean absolute error and normalized cross correlation with respect to virtual CTs. The proposed framework generates segmentations that require further editing to be clinically acceptable but shows great promise considering the relatively small training dataset used. This proof-of-concept study has potentials for clinical uses, such as being an assistive tool in current manual segmentation, and future development as plan verification tool or a fully automated replanning.

1 Introduction

Adaptive radiotherapy requires images with comparable quality to planning Computed Tomography (pCT) for accurate treatment plan verification and its adaptation [1]. Daily acquired Cone Beam CT (CBCT) are of too low quality to allow for this, as they commonly contain reconstruction artefacts and have poor Hounsfield Units [HU] preservation [2]. Furthermore, organs at risk (OAR) and target volumes would need to be delineated from CBCTs for quantitatively verifying and adapting treatment plans. Manual delineation of those structures is very laborious and is routinely done only at the treatment planning stage on a pCT scan. Currently, when a patient's treatment plan is no longer valid, a new pCT needs to be acquired and segmented to prepare a new treatment plan. That process is not only time and resource consuming but may also introduce delays in a patient's treatment delivery [3]. A more efficient approach would be to convert CBCTs to synthetic CTs (synCT) and automatically delineate the structures on CBCT, allowing for offline or online adaption of the treatment plan.

Machine learning methods have already been shown to be capable of providing high quality synCTs, which can be used for dose calculation and structure segmentation [4]. Delineating structures from CBCTs remains challenging. While routinely delineated structures on pCT scans can be employed to train CT-dedicated segmentation methods, the absence of comparable delineations for CBCTs poses a challenge in the development of supervised machine learning methods.

In this work we propose a framework for joint synthetic CT (synCT) generation and structure segmentation from daily CBCT, which learns to perform both tasks simultaneously. The framework does not require the pCTs and CBCTs to be paired, and only requires segmentations on the pCTs and does not require segmentations on the CBCTs.

2 Materials and Methods

Retrospective data from Cambridge University Hospitals NHS Foundation Trust were used in our study. The Addenbrookes Secure Therapeutic Radiology Image Dataset (ASTRiD), IRAS Number 312143 database protocol provided the overarching ethics approval for the pCT and/or CBCT images. The CBCTs suitable for use in this study require full body field of view (FOV), allowing for potential use in dose calculation and treatment adaptation. We identified 38 patients whose CBCT scans could be included in this work, 29 of these were used for training and 9 for testing. On average there were 20 CBCT scans per patient. The pCTs from 144 patients were used, along with their corresponding structures. That dataset consisted of patients for which CBCTs were included in our experiment, and those where CBCTs were not suitable for the study. We included 4 structures in this study: bladder, rectum, left and right femur bones. To ensure consistency in the superior-inferior anatomical coverage between CBCTs and pCTs, we sampled slices from pCTs starting from the bottom of the rectum (3 slices below the rectum) up to above the bladder (3 slices above the bladder). This superior-inferior anatomical region corresponded to the FOV coverage of the CBCTs. The CBCT intensities were linearly scaled to best match the global intensity profiles of the pCTs.

We based our approach on 2D cycle-consistent Generative Adversarial Networks (cycleGAN) [5]. We adapted our previous framework that can generate high quality synthetic CTs from clinical CBCTs utilizing modified cycleGANs [6]. We introduced a two head generator, which consisted of a shared encoder and partially shared decoder. The decoder splits into separate image and segmentation decoders. The image and segmentation paths in the decoder shared 3 upsampling stages and then the rest of the decoder's layers (5) were image or segmentation specific.

We refer to it as mid split of the decoder. The proposed framework uses global residual learning, where the image generators predict only corrections to be applied to the input images [5]. Additional structure consistency was employed between the input and output images of the generators to enhance anatomical correspondence between the input images and their synthetic versions.

As the segmentations are only available for pCTs, the CT discriminator was adapted to evaluate not only images but to take image and corresponding segmentations as an input, creating a multichannel tensor. We also included a cycle consistency segmentation loss in the form of weighted Dice and Cross Entropy between the original pCT segmentations and the segmentations generated for synthetic CBCTs (when real CT were converted to synthetic CBCTs), A schematic diagram showing the proposed framework is illustrated in Fig. 1. The proposed framework requires unpaired CBCTs and CTs (with segmentations for CTs only) at the training stage, and just CBCTs at the inference stage.

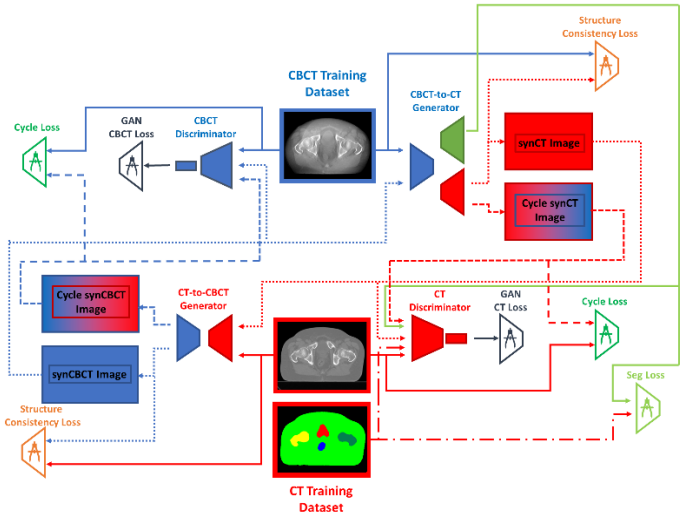

Fig.1 A schematic diagram of the framework.

The framework was first trained for 200 epochs with the weight for the cycle-segmentation loss set to 0, essentially training only image generation. For CT discriminator, which takes a multichannel tensor as an input, we propagated synCT to all channels. We used Adam optimizer with an initial learning rate of 0.0002 for the first 100 epochs, which was then linearly reduced to 0 over the following 100 epochs. Subsequently, the encoder and image decoder for CT generator were frozen to allow for segmentation decoder and CT discriminator to be trained for another 200 epochs. For that step the input of the CT discriminator was a multichannel tensor of synCT and segmentations. The same optimization and learning rate scheduler were used.

The output segmentations were post-processed with morphological operations, including hole filling and closing operations. The left and right femur bones were separated based on their spatial location.

To evaluate the synCTs, we created virtual CTs (vCTs) for the testing dataset by registering the pCTs to the CBCTs using NiftyReg [7] with locally normalized cross correlation as the similarity measure. To ensure a meaningful evaluation in terms of Hounsfield Units [HU], we performed intensity correction of the each CBCT image to a corresponding vCT, adjusting their mean value and standard deviation to match those of vCT. This operation was performed individually for each CBCT scan, in contrast to intensity correction performed globally during training. No intensity correction was applied to synCTs. The image evaluation was conducted based on mean absolute error (MAE) and normalized cross correlation (NCC). We also compared histograms of the images calculating the L2 norm between them.

Although the CBCTs used in this study had a large enough FOV to include all of the patients' anatomy, we discovered that the CBCTs contained reconstruction artefacts near the edge of the patient (see Fig. 3). This meant the CBCT scans did not provide reliable information on the anatomy close to the surface of the patient. Interestingly, the synCTs seemed to better resemble the pCTs in these regions and did not reproduce the inaccurate patient surface from the CBCTs. So that our evaluation was not negatively impacted by this, we automatically generated evaluations masks from the CBCTs using thresholding followed by morphological operations, and only performed the evaluation within these masks.

An experienced radiation oncologist (KTJ, over 10 years of experience) rated segmentations generated by our framework on its clinical usability on a scale of: clinically acceptable, requiring minor corrections, requiring major corrections, better to start from scratch. Femur bone segmentations, although they were split into left and right, were given a single score.

3 Results

The proposed framework generated synCTs that showed improved agreement with the vCTs compared to the CBCTs for all the metrics used. The histograms of all testing CBCT, vCT and synCT are shown in Fig.2, overlayed with plots approximating their shapes.

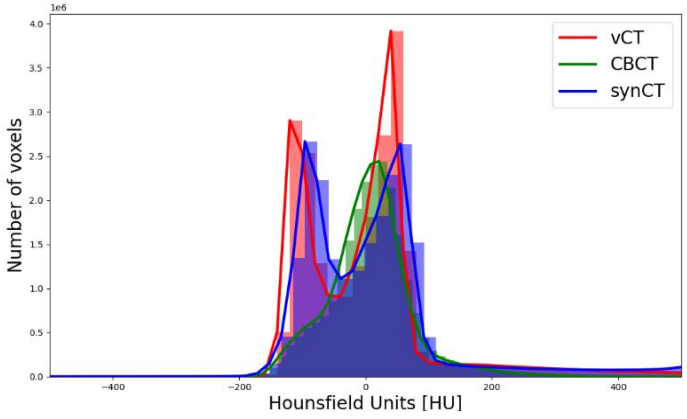

Fig.2 Histograms showing intensity distributions.

It can be noticed that the CBCT histogram has a distinctly different shape than the vCT histogram, with the synCT histogram more closely resembling the vCT histogram. The L2 norm between the vCT and the CBCT histograms was 2868 and was just 678 between the vCT and synCT.
The MAE between the vCT and CBCT (after intensity normalization) was 69.2 (std of 9.9) HU, and this was reduced to 50.7 (std of 7.9) HU between the vCT and synCT. The NCC improved from 0.77 (std of 0.04) for CBCT to 0.84 (std of 0.07) for synCT.

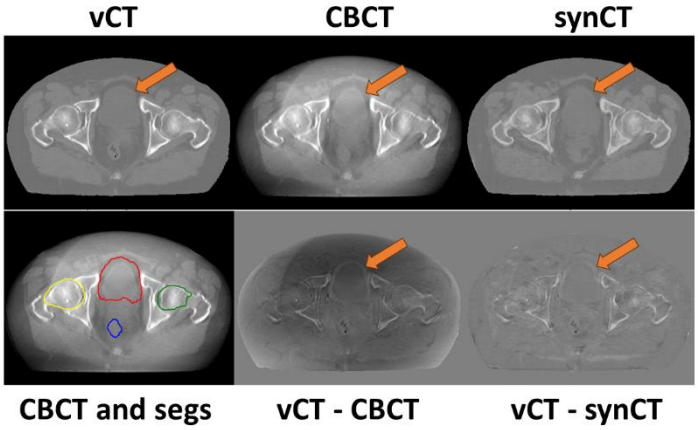

Fig.3 A comparison between the vCT, CBCT and synCT.

A visual comparison of the vCT, CBCT and synCT is shown in Fig. 3. The difference image between the vCT and CBCT, and the vCT and synCT, are also shown in the figure. It can be noticed that while the vCT shows generally good anatomical agreement with the CBCT, in some areas, such as the bladder, (as shown in Fig.3) there is a noticeable misalignment of the anatomy. That is highlighted with orange arrows in the figure. An example of the segmentations generated by our method overlayed over CBCT are also shown.

Tab.2 Qualitative evaluation of the segmentations.

	Acceptable	Minor edits	Major edits	Start from scratch
Bladder	0	1	3	5
Rectum	0	5	3	1
Femur	0	4	4	1

The qualitative evaluation is summarized in Tab. 2. The bladder was the worst performing structure, with over half of the cases (5) being scored as better to start from scratch. However, the segmented bladder volume was always roughly in the correct spatial position, usually being slightly over segmented. The rectum and femur bones both had scores almost equally distributed between requiring minor (rectum: 5, femur: 4) and major (rectum: 3, femur: 4) edits. For both structures only one case was scored as better to start from scratch.

4 Discussion

The presented results for image evaluation show improvement in the image quality from the CBCT level closer to the vCT. It is important to notice that the vCT is not a perfect representation of the ground truth image (i.e. a pCT paired with the CBCT). The registration of the pCT to the CBCT was capable of compensating for most of the differences, however it was not able to fully recover all anatomical differences, particularly for bladder and other highly deformable organs whose shape might change considerably day to day. At the same time, structures like the bladder are the most important, as their correct delineation is essential for treatment plan verification and adaptation. Therefore, some level of mismatch between the synCT and vCT is expected, and the vCT approach itself is not suitable for generating images for adaptive radiotherapy purposes.
One limitation of our study is that it performed only qualitative evaluation of the segmentations. In the future this could potentially be complemented by quantitative evaluation on a subset of cases. However, generating high quality manual segmentations on CBCT is time consuming and very challenging due to the poor image quality. Furthermore, the qualitative evaluation used in our study is closer to clinical practice, where segmentations would need to be reviewed and if necessary edited for clinical use.
The rectum and femur segmentations generated by our method already show some potential for clinical use, but we acknowledge that further improvements are required, especially to the bladder segmentations, for the method to be adopted clinically. However, we think the approach has great promise as it does not require manual segmentations on the CBCTs for training, so can potentially use far larger training datasets than were used in this study, which we would expect to lead to improved results.
One reason for the limited size of the training dataset in this study is that we discovered after collecting the data that the CBCT scans for many of the patients had a small FOV that excluded a significant amount of the patient's anatomy, and hence were not suitable for use. Even the CBCTs with a larger FOV that were used had reconstruction artefacts near the body surface due to the truncated data. Our method actually produced synCTs and body segmentations that plausibly resembled how we would expect the anatomy to appear in these regions (based on how it appears in the pCTs), but it is impossible to determine how accurate these were, hence we excluded this region from the image evaluation and did not evaluate the body segmentations. This highlights an important point for any methods that attempts to generate synCTs and auto-segmentations from CBCTs for plan verification and adaption: most CBCTs acquired clinically are not intended for this use, and if they are to be used for this in the future then it is important to acquire them with a large FOV that accurately reconstructs complete the patients' anatomy.

Training a GAN to jointly generate images and segmentations is a novel approach (as far as we are aware) – therefore there is no well-established training strategy. While a lot of research has been done training generative models, such as GANs and cycleGANs [8], or on how to best train a supervised segmentation model [9], a joint approach is yet to be investigated.

We observed that a shared decoder was more challenging to train, as one task usually dominated the training, leading to deterioration in the performance of the other. We investigated different splits between the image and segmentation decoders, going from completely separate decoders for each task, to a shared decoder that only splits in the layer just before the outputs were generated. When using independent decoders, we observed that the generated segmentations were not well aligned with the synCT. We found that a mid-level split in the decoder provided some level of information exchange between the two tasks and gave a well-balanced compromise which led to the best results. On the other hand, we found the training could be unstable when training both tasks simultaneously, therefore we decided to train the encoder and image generation decoder first, and only then train the segmentation decoder. Further work is required to explore other training strategies and establish the optimal approach - this includes the possibility of using a validation dataset to detect over- or under-fitting of either task facilitating better stopping criteria (but this requires a larger development dataset than we had available here).

Another limitation of our study is the lack of comparison to other methods. However, to the best of our knowledge, there are no other published methods that can produce a synCT image and segmentations using just the data we used in this study. The existing studies were mostly relying on propagating contours from the pCTs, which we have already identified as not suitable for highly deformable organs such as the bladder. Those propagated contours could be used directly or facilitated training of a supervised CBCT segmentation method [10]. An alternative approach would be to employ a cascade, when one method would be dedicated for generating only synCT, which would then be segmented using a segmentation tool trained on pCTs [11]. Both approaches do not address the problem simultaneously and introduce a lot of uncertainty along the way, starting from challenges with accurate registration of the structures between pCT and CBCT, through the quality of synCT generation which would heavily influence the quality of segmentations. The evaluation of our method against such approaches will be the focus of future work.

A final limitation of the method we presented here is that it is 2D based and so processes each slice independently. We experimented with 3D networks but found their increased memory footprint greatly limited the depth of the networks we could employ, which led to poor results. In the future we will investigate the use of '2.5D' networks, that take multiple adjacent slices as input and generate the outputs corresponding to the central slice.

5 Conclusion

In this study we presented a proof-of-concept method for jointly generating synthetic CT and OAR segmentation from CBCT. As the method uses an unsupervised approach it does not require paired CBCTs and pCTs and does not require segmentations on the CBCTs. We demonstrated our method on a relatively small dataset and showed that such an approach is possible and can provide promising results.

Abstract Radiotherapy clinical trials can benefit from an accurate segmentation model to help ensure consistency of contour definitions across patients treated in the trial, however, only a small dataset is often available initially as trial recruitment begins and deep learning segmentation models typically require large datasets for training. In this work we investigate the effect of retraining a segmentation model as more data becomes available throughout a trial. Models were trained for Clinical Target Volume (CTV) segmentation in the TOPGEAR (gastric cancer) clinical trial. There were 5 iterations of model training with datasets containing only 10 cases in the initial model, then increasing in increments to 43 in the last iteration. Each model was tested on a hold-out set of 50 cases, where the Dice Similarity Coefficient (DSC), Surface DSC (sDSC), Mean Distance to Agreement (MDA) and Hausdorff Distance were computed between the segmentation model and the manual contour. The DSC improved from 0.8 to 0.82 between the initial model and the last model. Improvement was also observed for other metrics suggesting the proposed methodology for retraining a segmentation model would be useful for prospective clinical trials.

1 Introduction

Current state-of-the-art models for the segmentation of structures in medical images commonly utilize deep learning. Relatively large datasets are typically required to achieve high quality results, however, they can be difficult to obtain especially in the medical domain. These datasets are often obtained from retrospective clinical datasets which may already have segmentations available for model training.

For radiotherapy clinical trials, ensuring that contour definitions across different patients and participating centers are consistent with the trial protocol is important for patient safety and outcome analysis [1]. Training an auto-segmentation model to predict an estimate of the contour that conforms to trial protocol is one approach to providing automated contour quality assurance (QA) [2].

If the clinical trial is successful, this model may be used to ensure future patients receive treatment consistent with the trial protocol. To train such a model the entire dataset could be used to train a model following the completion of the trial.
However such a model may also be used during the trial to provide feedback to centers and allow contours to be corrected prior to patients being treated and reduce burden on manual quality assurance resources. In this scenario, it may not be feasible to prepare a sufficiently large training dataset for use in the trial as the structure to be segmented may be novel and defined as part of the clinical trial itself.

The TOPGEAR clinical trial defines a novel Clinical Target Volume (CTV) for treatment of gastric cancer patients [3]. In this work, we explore a methodology for training a CTV segmentation model for TOPGEAR by simulating the initial phase of the trial. Although the trial has now completed recruiting patients, the clinical trial dataset is used to demonstrate how this process would be applied to a prospective clinical trial to help determine how much data is required to train a useful segmentation model.

2 Materials and Methods

Australasian Gastro-Intestinal Trials Group (AGITG) AG0407GR/TROG 08.08 "TOPGEAR" (NCT01924819) is a phase II/III trial for patients with resectable gastric cancer. Patients were recruited and randomized to either a chemoradiation arm or chemotherapy only arm, both prior to resection. The CTV defined in the trial protocol to be used to deliver radiation to patients in the chemoradiation arm requires expertise to contour. The trial protocol describes which anatomy to include or exclude from the CTV which is defined on the patient's Computed Tomography (CT) scan. To help ensure consistent definition throughout the trial, manual contour quality assurance was conducted on the first 5 patients treated at each participating center followed by every third patient thereafter. By the time the trial closed to recruitment, 174 patients from the chemoradiation arm had a manual review of the treatment plan conducted, including of the CTV.

To help reduce the resources required for manual review of the TOPGEAR CTV contours, we defined a methodology for training an auto-segmentation model able to predict a valid CTV structure on an unseen case. Rather than utilize the entire available 174 patient dataset upfront to train a CTV segmentation model (which may also be useful to help

QA future treatments intended to conform to TOPGEAR's protocol), we used this opportunity to define and evaluate a methodology for training a model throughout the course of a clinical trial with the goal that the model could be used with increasing confidence and accuracy as the trial progresses.

Of the 174 cases, 50 were randomly selected as a hold-out set to be used for validation of models trained. The remaining cases were split into groups of 10 and used for training. This split was performed randomly to help generalize the methodology to clinical trials more broadly and reduce bias in the order in which patients were treated in TOPGEAR (where some centers treated more patients at the start of the trial than others).

The initial set of 10 cases had the CTV defined by 5 Radiation Oncologists on each case. This set was deemed feasible to obtain for the first 10 patients in a clinical trial or prior to a clinical trial. While having several observers on this data was useful for determining the amount of inter-observer variability present in the data, these structures were combined into a single structure using the STAPLE method for this work [4].

An additional 4 sets of 10 cases from the trial dataset were then used to complete a total of 5 iterations of model training. Furthermore, upon review of the trial cases together with 2 experienced Radiation Oncologists (who were directly involved in developing the trial protocol), it was determined that not all cases that were reviewed during the trial were acceptable due to significant artifacts in the imaging (e.g. poorly reconstructed 4DCT) or use of the wrong primary dataset (e.g. use of the average intensity projection from a 4DCT resulting in blurry outlines of structures from motion artifact). Therefore, these cases were either corrected or excluded when correction wasn't possible (due to issues such as poor image quality).

Another notable property of the initial set of 10 cases was that there were no contrast enhanced cases included in this set. In the iterations that followed, contrast enhanced cases were included (approx. 25%), to help improve segmentation accuracy on those scans.
Table 1 defines the subsets of data used at each iteration of CTV segmentation model training.

To train the segmentation model, the 2D nnUNet was used [5]. A total of 5 models were trained over 5 iterations with each model being trained using data from previous iterations as well as additional data. The trained models were then applied to each case in the hold-out set. The Dice Similarity Coefficient (DSC), Mean Distance to Agreement (MDA), Hausdorff Distance (HD) and Surface DSC (sDSC) were computed between the auto-segmentation and the manual segmentation. A one-sided t-test was also performed to determine the significance of the improvement between iterations based on the p-value (significant when $p<0.05$).

Table 1: The number of cases which required correction (Corr) or were excluded (Excl) in each subset of 10 cases. The total dataset size column is the final number of cases included for training at each iteration.

Subset	Cases	Corr	Excl	Used for training	Total Dataset size
Initial	10	-	-	10	10
Iteration 1	10	0	3	7	17
Iteration 2	10	6	3	7	24
Iteration 3	10	3	0	10	34
Iteration 4	10	5	1	9	43

3 Results

The mean of each of the metrics improved with increasing iterations of the model (except for HD and MDA in iteration 2). Figure 1 plots the mean value of each metric calculated using the hold-out set. The significance of the improvement from each iteration to the next as well as between each iteration and the initial model is also provided.

The mean DSC improved from 0.80 to 0.82 from the initial to the final model. A significant improvement was seen between each model based on DSC, except in iteration 2. The sDSC showed similar improvement based on the mean (from 0.57 to 0.60 between initial and final models) and significance (all significant except iteration 2 and 4).

The surface distance metrics showed overall improvement in mean from the initial to the final model (from 39.6mm to 35.6mm for HD and 5.3mm to 4.7 for MDA), however, the overall significance was lower between iterations than for DSC and sDSC.

Figure 2 visualizes the manual contour and the segmentations from the initial and final model for an example case from the hold-out set.

4 Discussion

Throughout the 5 iterations of model training performed, the overall model performance improved. The abdominal anatomy is a relatively challenging area for auto-segmentation due to large anatomical differences between patient anatomy and the presence of gas pockets. By including contrast enhanced images, the iterations following the initial model, accuracy improved on these scans in the hold-out set.

With 5 iterations of model training, it is difficult to conclude whether the segmentation quality is beginning to plateau

and how many more training cases would help improve model performance to a specific level. However, the methodology does demonstrate overall model improvement at each iteration indicating that this approach may be useful for use in a prospective clinical trial.

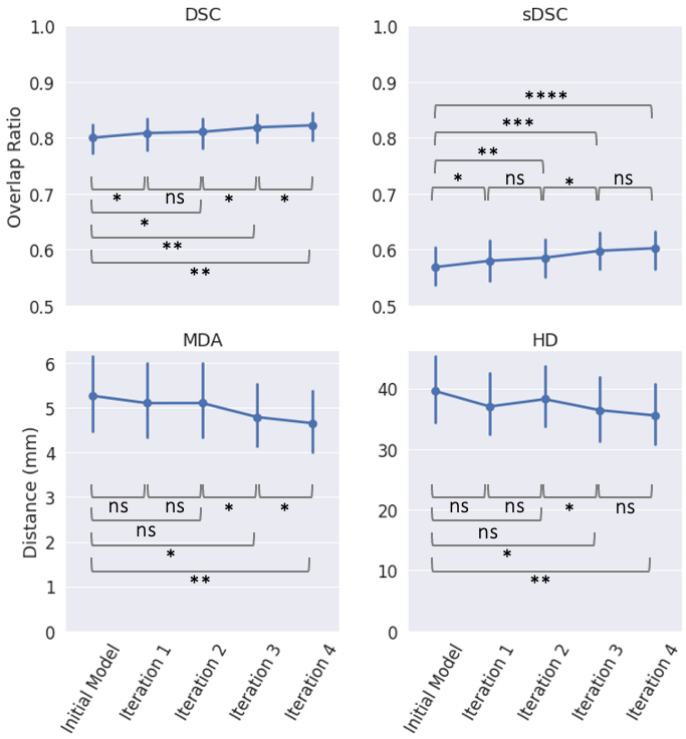

Figure 1: Improvement of the mean Dice Similarity Coefficient (DSC), Surface DSC (sDSC), Mean Distance to Agreement (MDA) and Hausdorff Distance (HD) with standard deviation error bars across models trained (blue). Improvement between each iteration to the next and each iteration to the initial model are also indicated (black) where ns: not significant, *: p<0.05, **: p<0.01, ***: p<0.001, ****: p<0.0001.

Since a significant improvement was not determined between each iteration of model training, a hard stopping criterion is difficult to define. Further iterations may contain data which will benefit the overall performance of the model, even if the previous iteration didn't improve significantly. Further investigation is required to determine the target value of a metric to ensure the model is useful for the task of contour QA. Since uncertainty is present in the data, which can be determined through inter-observer variation, metrics assessing the segmentation quality can only be expected to reach this level as a maximum.

The use of active learning may further benefit model accuracy while decreasing manual review resources required [6]. This would involve automatically selecting the cases in the next training iteration that would most benefit model performance. Like this, cases which are most likely to significantly improve model performance can be included in further iterations of model training while others are excluded.

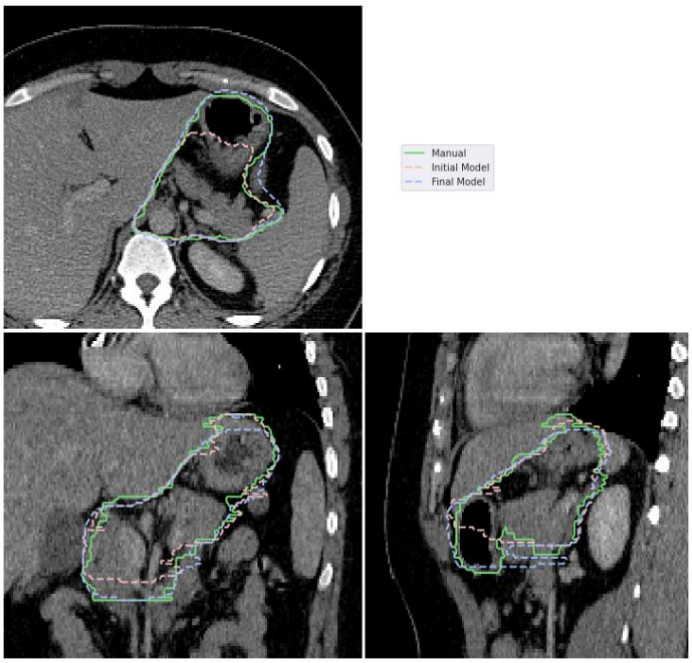

Figure 2: Cross section of an example case from hold-out set visualizing the manual CTV contour (green), the initial model's segmentation (red) and the final model's segmentation (blue). The initial DSC for this case was 0.84 which improved to 0.88 for the final model.

5 Conclusion

The methodology for CTV segmentation throughout the TOPGEAR clinical trial demonstrated improvement of segmentation accuracy across models trained. Further research is required to determine the benefit of training beyond 5 iterations as well as experimentation with active learning approaches to maximize model performance given the manual review resources available. Different segmentation approaches such as the 3D nnUNet will also be explored. Finally, these models will be applied to the task of contour quality assurance within the TOPGEAR trial.

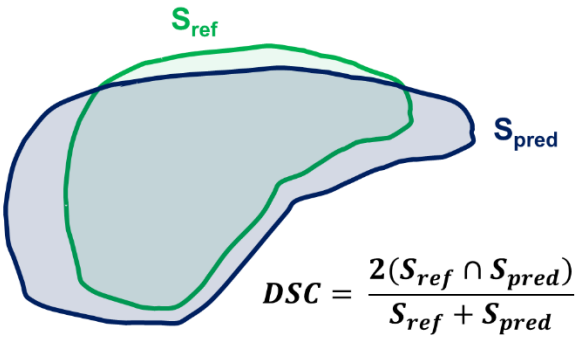
Abstract The Dice Similarity Coefficient (DSC) is the current *de facto* standard to determine agreement between a reference segmentation and one generated by manual / auto-contouring approaches. This metric is useful for non-spatially important images; however, radiation therapy requires consideration of nearby Organs-at-Risk (OARs) and their radiosensitivity which are currently unaccounted for with the traditional DSC. In this work, we introduce the OAR-DSC which accounts for nearby OARs and their radiosensitivity when computing the DSC. We illustrate the importance of this through cases where two proposed contours have similar DSC, but lower OAR-DSC when one contour expands closer to the surrounding OARs. This work is important because the OAR-DSC may be used by deep learning auto-contouring algorithms in a radiation therapy specific loss function, thereby progressing on the current disregard for the importance of these differences on the final radiation dose plan generation, delivery, and risks of patient toxicity.

1 Introduction

Automated structure contouring, also known as auto-contouring, is a method to automatically extract desired regions in an image. Typically, ground truth contours are made manually by in-field experts and compared to the predictions from an auto-contouring algorithm. One standard *de facto* metric of measuring the agreement between the ground truth and predicted segmentations in the current era of deep learning is the Dice Score, or more formally the Dice Similarity Coefficient (DSC) [1,2], as described in Figure 1.

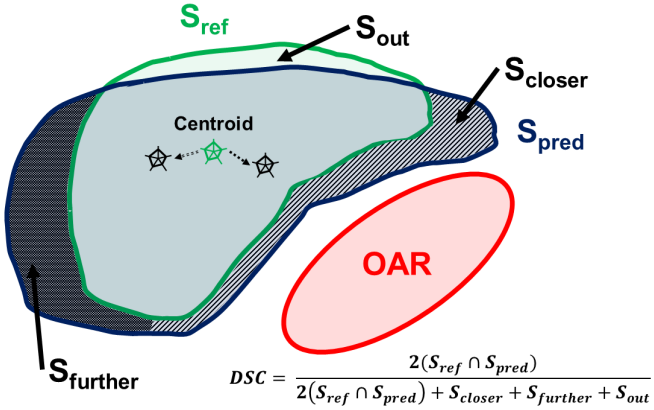


The DSC has subsequently extended to and now dominates the relevant literature in the field of radiation oncology to compare ground truth segmentations of tumors and surrounding normal tissue sensitive to unintended radiation, also known as Organs-at-Risk (OAR). Since deep learning models are often trained using a negative / positive feedback system where lower DSC is penalized and higher DSC is reinforced, equivalent DSC will produce the same feedback during model training, regardless of where the errors occurred. This is because the original formulation of DSC does not account for spatial information since it did not need to for identifying performance of auto-segmentation of objects in images.

Therefore, relating this concern back to the field of radiation oncology, two predicted tumor contours with the same DSC will both be equally encouraged even if one contour disagrees closer to the OAR, resulting in a potentially increased probability of toxicity to the OAR given the segmentation is accepted for radiation dose plan creation. Further, only one prior work to the author's knowledge has attempted weighting the DSC for radiotherapy applications, however the dose was considered which necessitates unmanageable computational resources at this time [3]. Hence, in this work we introduce the concept and formulation of the OAR-Weighted DSC (OAR-DSC) which accounts for spatial location of disagreements between ground truth and auto-contouring generated contours in relation to the surrounding OARs in 2D.

2 Materials and Methods

To account for surrounding OARs, the DSC can be rearranged and calculated as follows in Figure 2.



expression can be weighted to achieve the OAR-DSC as will be shown below.

This formulation is further described where S_{ref} is the reference ground truth segmentation, S_{pred} is the predicted auto-contouring, S_{closer} is the joint region of voxels not in S_{ref} whose inclusion brings the centroid of S_{ref} closer to the OAR, $S_{further}$ is the joint region of voxels not in S_{ref} whose inclusion brings the centroid of S_{ref} further from the OAR, and S_{out} is the remaining region in the reference ground truth segmentation not covered by the predicted auto-contouring. This also applies to potential voxels inside S_{ref} which overlap with the OAR; however, these will receive the maximum penalty weighting as will be shown below in the description of the OAR-DSC.

To achieve the OAR-DSC, a weighting factor, w, was applied to S_{closer} as a function of its distance to the OAR to artificially decrease the DSC. This weighting factor cannot be greater than 1 and no weighting factor is applied to $S_{further}$ to counteract the effects of S_{closer} since this could lead to artificially inflated DSC which may be misleading.

The weighting factor is determined with a simple parameterized exponential decay and scaled if in the presence of multiple OARs based on the maximum distance from the reference contour and the nearest distance to the OAR, d. A detailed derivation for a given OAR (i.e., OAR_i) is given:

$$OAR\text{-}DSC = \frac{2(S_{ref} \cap S_{pred})}{2(S_{ref} \cap S_{pred}) + \frac{S_{closer}}{w_{OAR^i}} + S_{further} + S_{out}}$$

Where:

$$w_{OAR^i} = \frac{1}{n_{S_{closer}}} \sum_{j=1}^{n_{S_{closer}}} e^{\alpha\left[\frac{d_{max,OAR^i}}{d_{max,OAR}}\left(\frac{d^j_{pred}}{d^j_{pred}+d^j_{ref}}\right)-1\right]}$$

In this representation, an iteration across all the voxels in S_{closer} is done and at each step, d_{max,OAR^i} is given as the maximum of all the nearest distances from the reference contour to the given OAR_i, $d_{max,OAR}$ is given as the maximum of all the nearest distances from the reference contour to the OAR across all considered OARs, d^j_{pred} is the nearest distance from the current voxel to S_{pred}, and d^j_{ref} is the nearest distance from the current voxel to S_{ref}. The α parameter is representative of the radiation sensitivity of the OAR, therefore increasing values of α will result in decreasing OAR-DSC for the same case. It is important to note that when α = 0, then w_{OAR^i} = 1, which implies that the OAR-DSC is simply equivalent to the DSC. The OAR-DSC can be computed for each OAR and averaged together to provide a comprehensive score to account for all OARs. A graphical summary of the steps required to calculate the OAR-DSC can be seen below in Figure 3.

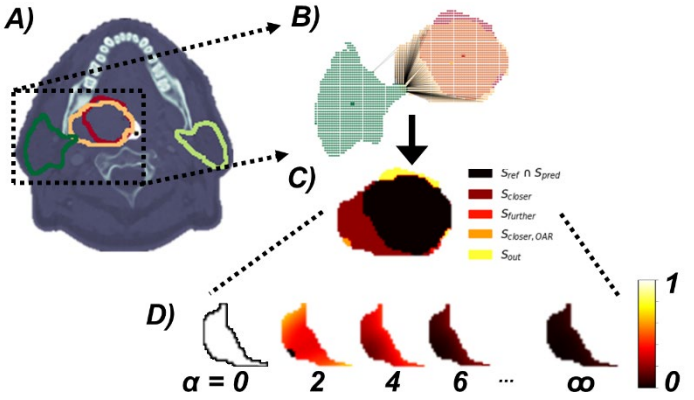


Figure 3: Detailed graphical summary of the derived maps for the computation of the OAR-DSC of the head and neck region. A) desired target and OAR contours are shown on an anatomical Computed Tomography (CT) image, B) the contours and their voxels are extracted and distances are computed to the OAR, C) voxels are classified into the relevant categories for the OAR-DSC, and D) weighted maps are computed for the voxels inside of S_{closer}. Note, the map for α = 0 is all 1 which is white and is represented with a black contour.

Example cases of the OAR-DSC applied in different anatomical sites was done by utilizing the open-source Contouring Collaborative for Consensus in Radiation Oncology (C3RO) segmentations for the head and neck, gynecological, and gastrointestinal sites [4]. Ground truth reference contours and OAR contours were given by the Simultaneous Truth and Performance Level Estimation (STAPLE) expert segmentations while simulated auto-contouring contours were given by select non-expert segmentation cases. The time required to compute the OAR-DSC compared to the DSC is negligible (~5 seconds for two OARs and six α values) due to the vectorization of the operations. The code for calculating the OAR-DSC given contours in Neuroimaging Informatics Technology Initiative (NIfTI) format with some examples from the C3RO segmentations is freely available at: https://github.com/Lucas-Mc/OAR-weighted_Dice-Score.git.

3 Results

Applying the OAR-DSC to a few sample cases from C3RO illustrates the following results.

	α					
	0	2	4	6	8	10
OAR-DSC (left case)	0.74	0.71	0.67	0.64	0.61	0.58
OAR-DSC (right case)	0.78	0.68	0.56	0.47	0.42	0.40

Figure 4: Comparison of two head and neck cancer cases with similar DSC for the GTVp, yet different proximity to the OARs (left and right parotid). The cumulative OAR-DSC was calculated for each case at different α levels, demonstrating increased consideration for the OARs in the right case.

Figure 4 show a comparison for a head and neck cancer case of two contours with similar DSC scores, yet very different implications for the treatment planning, delivery, and control of toxicity due to the proximity to the OARs (left and right parotid). In fact, the predicted target contour for the primary Gross Tumor Volume (GTVp) which invades the left parotid OAR is rated with a higher unweighted DSC (α = 0), thus being preferred in a deep learning training session. Therefore, the OAR-DSC was calculated for each at different α levels, demonstrating increased consideration for the OARs in the right case as its OAR-DSC falls below the left case with increasing α values.

	α					
	0	2	4	6	8	10
OAR-DSC (left case)	0.52	0.50	0.48	0.45	0.42	0.39
OAR-DSC (right case)	0.52	0.40	0.29	0.21	0.15	0.11

Figure 5: Examples of OAR-DSC as it applies to the gynecological region.

Figure 5 shows a sample case for the gynecological region with the nodal Gross Tumor Volume (GTVn) set as the target volume and small bowel set as the OAR. Notice how the left case appears that it should have a lower OAR-DSC than the right case, however this is not the case since a majority of the non-matching voxels work to move the centroid of the reference contour further away from the OAR. The non-matching voxels also border the OAR more closely in the right case increasing the weighting factor and decreasing the OAR-DSC.

	α					
	0	2	4	6	8	10
OAR-DSC (left case)	0.76	0.76	0.76	0.76	0.76	0.76
OAR-DSC (right case)	0.76	0.71	0.65	0.59	0.53	0.48

Figure 6: Examples of OAR-DSC as it applies to the gastrointestinal system.

Figure 6 shows a sample case for the gynecological region with the Clinical Target Volume to receive 5400 cGy (CTV_5400) set as the target volume and bowel bag set as the OAR. Although both the left and right cases have contours with a DSC of 0.76, the contour in the right case extends closer to the OAR and thus has a decreasing OAR-DSC at higher α levels. The left case keeps the same OAR-

DSC throughout since it is entirely contained within the reference contour.

4 Discussion

Since the OAR-DSC inherently includes the DSC at α values of 0, this metric has demonstrable translatability to current clinical practice due to simple adjustments of α moving from traditional DSC to an OAR-weighted DSC. However, consideration should be given to standardize the α values and correlate them with validated radiation sensitivity outcomes, such as those provided by QUANTEC including mean and max dose constraints which could be translated to scalable α values [5].

The limitation of this approach is that care should be taken to account for all desired OARs during the determination of the OAR-DSC, otherwise the auto-contouring algorithm will be unaware of their presence and possibly suggest contours near the OARs. However, this is analogous to the current practice where no considerations are taken for OARs and even more considerate since at least some weighting is being done. Further, this formulation does not specify requirements for utilizing the Gross Tumor Volume (GTV), Clinical Target Volume (CTV), Planning Target Volume (PTV), or Planning organ at Risk Volume (PRV), however these could be included as the boundaries for the segmentations and used in the same way. This practice, however, should be standardized to ensure comparable OAR-DSC across anatomical sites and centers. It is possible to extend the formulations introduced here to add separate weightings to GTV and CTV or OAR and PRV if equal concern is not desired for the margins as compared to the definite volumes. The formulation also currently uses relative distances between the voxels and OARs to determine radiation sensitivity fraction, but future work could apply absolute distance-based weighting instead based on radiobiological concerns and setup uncertainty (i.e., less than 2 mm should receive the maximum loss weighting). A final limitation of the OAR-DSC is that the OAR segmentations would have to be generated first in a fully automated contouring workflow so that they can be considered when generating the target contours.

Future work includes investigating alternative metrics which could be modified to fit in this framework, such as the surface DSC, and how the OAR-DSC can be expanded to enable more computationally efficient workflows [6]. Additionally, a 3D implementation of the OAR-DSC would enable consideration of all surrounding OARs instead of just those which are in-plane.

5 Conclusion

We have introduced the OAR-DSC, a novel method to account for location-specific deviations between an auto-contouring contour and reference contour in relation to surrounding OARs in 2D. Thereby, cases where two proposed auto-contours have similar DSC, we have shown that the OAR-DSC differs between the two especially in cases where one contour expands closer to the surrounding OARs. This metric can be used by deep learning auto-contouring algorithms as a method to add a radiation therapy specific loss function to the generated contours, progressing on its current disregard for the critical influence of these differences on the final radiation dose plan and its risks to the probability of patient toxicity.

Towards Automatic Identification of Missing Tissues using a Geometric-Learning Correspondence Model

Eliana Vasquez Osorio[1,2] and Edward Henderson[1]

[1]Faculty of Biology, Medicine and Health, University of Manchester, Manchester, UK
[2]The Christie NHS Foundation Trust Hospital, Manchester, UK

Abstract Missing tissue presents a big challenge for dose mapping, e.g., in the reirradiation setting. We propose a pipeline to identify missing tissue on intra-patient structure meshes using a previously trained geometric-learning correspondence model. For our application, we relied on the prediction discrepancies between forward and backward correspondences of the input meshes, quantified using a correspondence-based Inverse Consistency Error (*cICE*). We optimised the threshold applied to *cICE* to identify missing points in a dataset of 35 simulated mandible resections. Our identified threshold, 5.5 mm, produced a balanced accuracy score of 0.883 in the training data, using an ensemble approach. This pipeline produced plausible results for a real case where 25% of the mandible was removed after a surgical intervention. The pipeline, however, failed on a more extreme case where 50% of the mandible was removed. This is the first time geometric-learning modelling is proposed to identify missing points in corresponding anatomy.

1 Introduction

Anatomy of patients undergoing medical treatment often has large 'atypical' changes. In particular, for reirradiation cases in the head and neck region, mandible surgeries due to osteoradionecrosis [1] are common, resulting in large anatomical mismatches. The missing tissue between images presents challenges to registration algorithms, with few methods explicitly accounting for them [2]. In this study, we propose a pipeline to identify missing tissue on surface meshes of structures using a previously trained geometric-learning correspondence model. This step will enable robust contour-based registrations in particular for estimating cumulative dose metrics in the reirradiation setting.

2 Methods

We used a model previously trained to identify dense point correspondences for head and neck organs at risk [3]. The correspondence model was trained using an unsupervised approach, where both the geometry of the shapes as well as the imaging information of the planning CT scans were used during training to improve model performance. This model has been shown to be effective for identifying inter-patient correspondences for the brainstem, mandible, parotid glands, spinal cord and submandibular glands.
At inference time, the model receives two meshes representing the structures, i.e., the source and target meshes, and assigns a vertex on the target mesh to every vertex from the source mesh (defined by n vertices). More formally, the correspondence between the source and target vertices is represented as the vector $M^{s\to t}$, of n positions, where the correspondence for a given $i-th$ vertex is $M^{s\to t}(i)=j$, with j being the index of the corresponding vertex on the target mesh. Note that the model's predictions are not symmetric, as some target vertices may not be assigned to a source vertex.

2.1 Identification of missing tissue

We propose to identify missing tissue by levering the discrepancy between correspondences predicted by the model when the role of the input meshes are reversed. The first step is to quantify the discrepancies between the correspondence predictions. For this, we estimated the inverse consistency error based on the correspondences, *cICE* figure 1, using the following equation:

$$cICE_i = d(x(i), x(M^{t\to s}(M^{s\to t}(i))))$$

where $d()$ is the Euclidean distance between two points, $x(i)$ is the 3D coordinates of the $i-th$ source vertex, $M^{s\to t}$ and $M^{t\to s}$ are the correspondence vectors predicted by the model for the two directions, i.e., the *forward* (source to target) and *backward* (target to source) correspondences. In the ideal case, $M^{t\to s}(M^{s\to t}(i))$ is equal to i, rendering $cICE(i)$ to zero. As the correspondence model generates discrete predictions, noise is expected on the vertex assignment. Therefore, we applied a median filter to the *cICE* on the source mesh to mitigate for this effect.
Our assumption is that points with the largest discrepancies are missing on the target mesh. Therefore, we classify all

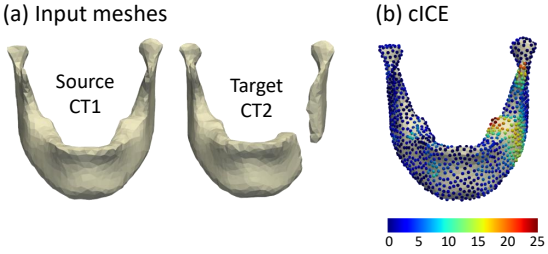

Figure 1: Example of input meshes and the derived *cICE*. Notice that large *cICE* values are located in regions of point mismatch between the source and target meshes.

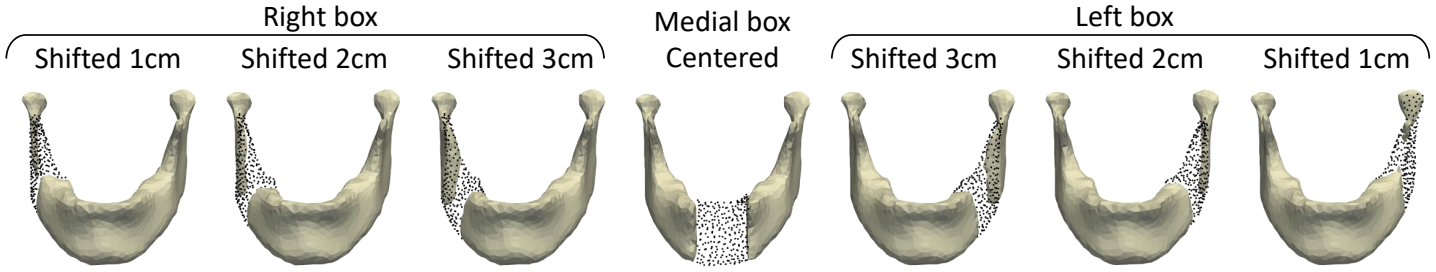

Figure 2: Simulated cuts for the CT2 mandible of a patient.

vertices in the source mesh with a *cICE* value above a given threshold t as missing in the target mesh. As we applied a median filter in the previous step, we again apply a median filter to 'dilate' the selection, in an operation similar to morphological opening filter of binary masks.

2.2 Pipeline optimisation

Mandible contours from 5 patients who underwent reirradiation in the head and neck region were used for this optimisation. Each patient had their mandible delineated on two CT scans: CT1 and CT2, where CT2 was the planning CT scan of the the most recent radiotherapy course. We framed our implementation to predict points present in the CT1 mandible and missing in the CT2 mandible meshes. We optimised two aspects: 1) we compared the performance of an ensemble of multiple correspondence models versus a single model, and 2) we optimised the value of the threshold t.

2.2.1 Ensemble vs single model

As using ensemble approaches have been shown to improve deep-learning performance **??**, we evaluated whether such an approach improved our predictions. For these, we used the predictions of five corresponding models previously generated as part of a 5-fold cross validation[3]. We used a simple ensemble approach: majority vote where only points identified as missing by at least three of these single models were kept.

2.2.2 Threshold optimisation

We conducted a simulation study to find the optimal value of the threshold t for which we generated simulated mandible resections as training data. We evaluated a range of 19 thresholds, ranging from 1 to 10 mm. We selected the best threshold as the one that maximised the prediction accuracy over all training data.

Training data generation We generated training data by artificially cutting the CT2 mandibles using 3cm-wide boxes positioned in different locations, see figure 2. We consistently applied this cutting procedure by using ROI algebra in the scripting interface in RayStation v12.0.100.0 (research) and exporting the generated cut mandibles as masks in MHD format. These masks were then processed to generate triangular meshes following the same pre-processing steps as presented previously [3]. In total, we generated 35 mesh pairs where between 11% and 28% of the mandible volume was removed.

Golden standard Notice that the ground truth is directly available for the CT2 mandibles via the cutting boxes. However, to evaluate the predictions made by our pipeline, these ground truth needed to be 'projected' to the CT1 mandible. Therefore, we used the forward correspondences for the complete CT2 mandibles to generate the golden standard for missing points on the CT1 mandible mesh: for every mesh pair, a given point was classified as missing if it corresponded to a point within the cutting box. We harmonised the golden standard across the five folds using a majority voting filter, i.e., a given point was classified as missing if it was identified as missing by at least 3 single models. See figure 3(a) for an example.

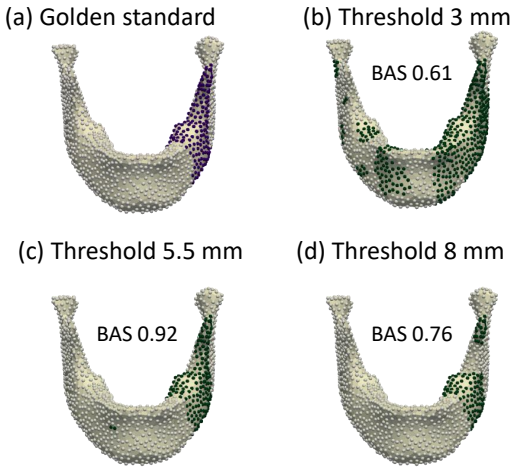

Figure 3: Golden standard for the mesh pair shown in figure 1(a), where the dark points have been identified as missing. (b-d) points identified as missing after applying the proposed pipeline for different thresholds and their balanced accuracy score (BAS). These thresholds are applied to the *cICE* presented in figure 1(b).

Prediction evaluation We evaluated the prediction of missing points for different thresholds against the golden standard using an accuracy score. As we expected to have

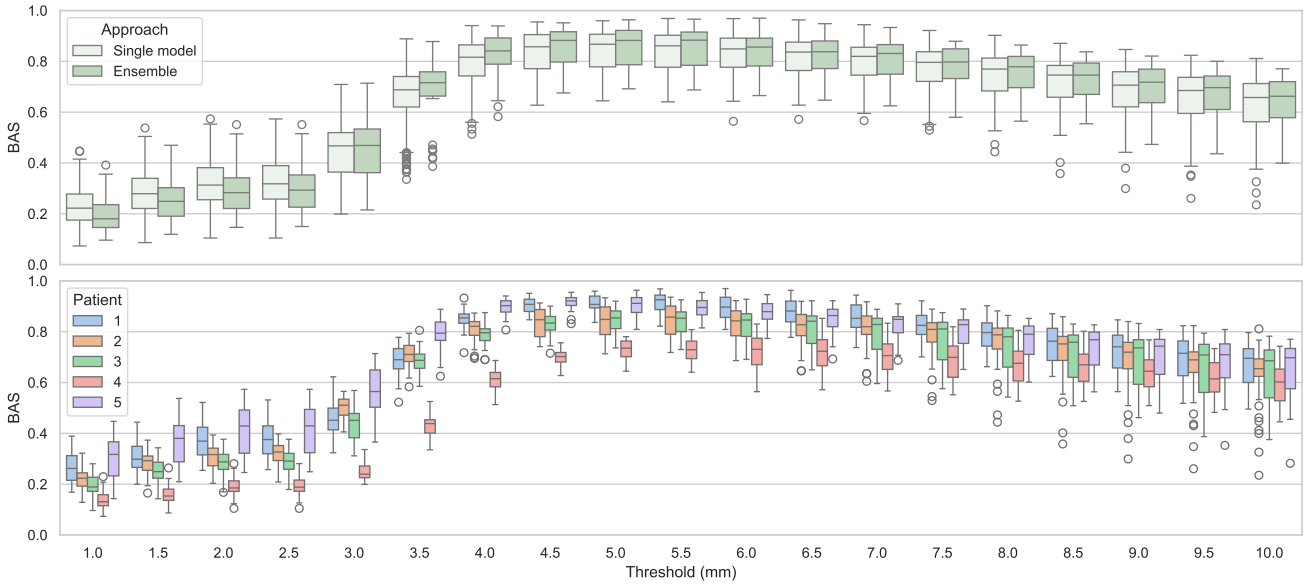

Figure 4: Balanced accuracy score (BAS) for all simulations and tested thresholds, discriminating by single model vs ensemble approach (top) and by patient (bottom).

classifications with imbalanced class distributions, e.g., most points are not missing in CT2, we used the balanced accuracy score (BAS). BAS has been demonstrated to be robust to imbalanced class distributions [4] and it is defined as the average of recall obtained on each class, figure 3. We used the implementation provided in scikit-learn v1.3.2.

2.2.3 Qualitative evaluation of generalisation

We applied the most optimal pipeline and threshold to two extra cases where the patients underwent mandible surgery in between the two radiotherapy courses due to osteoradionecrosis. These patients lost 25% and 50% of the mandible during the surgical intervention, respectively.

3 Results

Figure 4 shows the performance of the pipeline. BAS above 0.8 are observed for both approaches at thresholds between 4.0 and 7.0 mm, with the largest median being 0.867 for the single model approach at 5.0 mm and 0.883 for the ensemble approach at 5.5 mm. The performance of the classification pipeline was different for some patients, with results for patient 4 systematically lower for most thresholds. The pipeline performed best for patients 5 and 1, followed by patients 2 and 3.

Figure 5 shows the results of applying the ensemble pipeline with threshold 5.5 mm on two extra patients who underwent surgical intervention due to mandible osteoradionecrosis after their first radiotherapy course. The results on ORN patient 1 are plausible with the largest region identifying the most anterior part of the mandible. Two small regions, up in the mandible head and the coronoid process were also identified. The prediction for ORN patient 2 was not successful, as most of the points were identified as missing. However, the calculated *cICE* followed a similar pattern as other mesh pairs but with a much higher magnitude, compare figure 6 and 1.

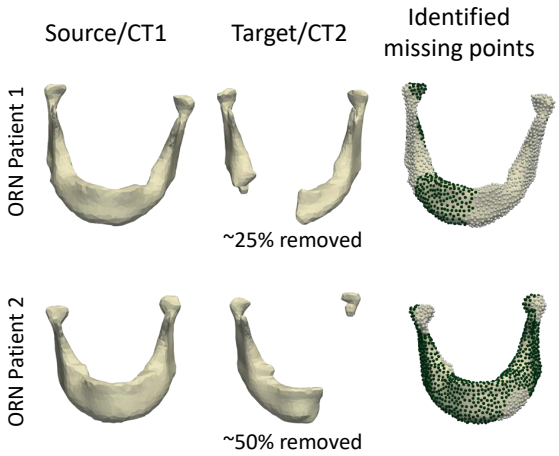

Figure 5: Performance of the ensemble pipeline using the found optimal threshold of 5.5 mm to data of two patients who underwent mandible surgery due to osteoradionecrosis after their first radiotherapy course.

4 Discussion

In this study we proposed, implemented and optimised a pipeline to identify missing tissue on intra-patient organ meshes based on a previously trained geometric-learning correspondence model, previously shown to be effective at identifying inter-patient correspondences for head and neck organs. For our application, we relied on the prediction discrepancies between the forward and backward correspondences quantified via correspondence-based inverse consistency error or *cICE*, where points with *cICE* above a given threshold were identified as missing. We optimised this

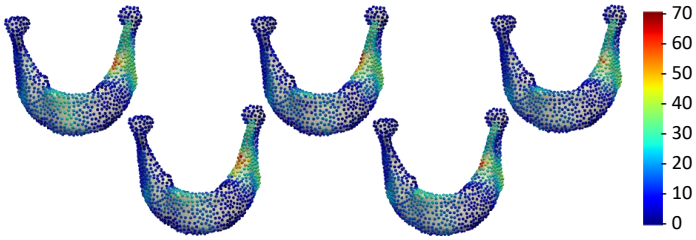

Figure 6: *cICE* for all folds for ORN patient 2. Note the pattern similarity with *cICE* presented in figure 1

threshold in a dataset of 35 simulated mandible resections by evaluating the balanced accuracy score (BAS) between the golden standard and the predictions. Our identified threshold, 5.5 mm, produced a BAS of 0.883 in the training data using an ensemble approach. This pipeline was then shown to produce plausible results for a real case of a patient where 25% of their mandible was missing after a surgical intervention. The pipeline, however, failed to identify missing points on a more extreme case, where 50% of the mandible was removed.

This is the first time that geometric-learning correspondence models are used to identify missing vertices on organ meshes. A recent related work using a deep-learning approach is the method proposed by Andresen and colleagues [5] where they use a convolutional neural network to jointly perform non-rigid registration and segmentation of non-corresponding anatomy. They applied their proposed network to inter-patient MR scans with artificially added stroke lesions. The reported Jaccard indices[1] ranging between 0.59 and 0.62 highlights the need to find better solutions for identifying missing tissues.

Comparing our method to more traditional approaches within radiotherapy, the work published by Vasquez Osorio and colleagues [6] is relevant. The authors used an adapted version of the thin-plate spline robust-point matching algorithm to register automatically segmented features between livers contoured on CT and MR. They demonstrated that outliers present in both datasets could be identified by using fuzzy correspondences, even for large numbers (such as 55% of input points). Similarly, the work by Myronenko and Song [7] has been shown to generate robust registration results in the presence of noise and missing points, which could then be indirectly used to identify outliers/missing points. However, a common disadvantage is the long computational time.

This pipeline was shown to produce plausible results for a case where 25% of their mandible was missing. However, the pipeline failed in the second, more extreme case, where 50% of the mandible was removed. Several factors can be related to this failure. First, the extreme case was out of distribution for the training dataset (11%-28% of the mandibles removed). Therefore, the 5.5 mm could be a very conservative value for this case, especially as the *cICE* reached 70 mm, see Figure 6. Defining an adaptive thresholds, informed by the difference in areas or volumes between the input meshes, and evaluating the pipeline in other 'softer' organs are areas of future development.

Another limitation was the use of an model originally trained for a different purpose. The correspondence model was trained with complete organs which always consisted of a single connected mesh. Designing a correspondence model that explicitly includes classification of missing points is also a promising avenue of research. In this case, the procedure described in section 2.2.2 could be used as data augmentation strategy. Additionally, using volumetric meshes (composed of tetrahedra) rather than surface meshes (composed of triangles) and incorporating imaging at inference time may also provide extra robustness.

Conclusion We have demonstrated how a correspondence model and a post-processing pipeline can be used to identify missing tissue on surface meshes of structures of the same patient using a previously trained geometric-learning correspondence model. Further work to enable its use on more extreme cases is required. We are paving the way to robustly utilise contour-based registrations for radiotherapy applications, such as cumulative dose estimations in the reirradiation setting.

Abstract Postoperative radiotherapy (poRT) may negatively impact flap outcomes in head and neck cancer (HNC) patients. This study sought to develop a fully automatic method for flap segmentation, to facilitate future attempts at evaluating dose-volume effects on HNC flaps. 148 HNC patients' flaps were delineated by two experts to generate ground-truth segmentation masks. The nnUNet and MedSAM frameworks were used to train flap segmentation. The Dice Similarity Coefficient (DSC), Intersection Over Union (IOU) and Hausdorff Distance metrics were used to evaluate the neural network performances. The nnUNet outperformed MedSAM. It achieved median DSCs of 86.9% in the test set for soft tissue flap segmentation. Features resulting in poorer performances of automatic segmentation were pedicled flaps, moderate-to-severe artifacts (present in 42% of patient poRT CTs), and low-volume centers.

Keywords: Radiotherapy, Head and Neck Neoplasms; Surgical Flaps; Radiation Tolerance; Automatic Segmentation; Neural Networks

I Introduction

The definition of target volumes and organs-at-risk (OAR) in the postoperative setting is complex, the native anatomy being modified by tumor resection, substantial tissue defect and inflammation, edema, fibrosis, surgical clips. Reconstructive surgery with a flap aims at restoring the functional and esthetic impairment of tumor resection, but it adds complexity to the delineation task.

The surgical literature suggests that radiotherapy (poRT) damages flaps. To date, volumetric, textural and functional studies are lacking. Beyond multidisciplinary patient management, a fully automatic flap delineation is a prerequisite to the assessment of the causality of radiation-induced deterioration of flaps. However, flap delineation is a new, challenging and time-consuming task for radiation oncologists. Following guidelines for the delineation of common soft-tissue flaps [1], interobserver variability of flap delineation achieved a Dice Similarity Coefficient (DSC) of 0.70 [2], of similar magnitude as in international consensus studies of tumor and OAR delineation [3].

Our goal was therefore to develop a fully automatic segmentation of soft-tissue flaps, which has never been reported. If successful, this should provide a unique opportunity to assess current irradiation practice and characterize flap dose-volume effects in a future work.

2 Materials and Methods

The imaging dataset consisted of poRT planning DICOM-RT data from a GDPR-compliant GORTEC prospective study (*NCT03576417*). Out of 152 patients (33 centers) who had a flap on poRT planning CT between 2019 and 2021, 4 were excluded due to missing DICOM slices, leaving 148 CT and RT structure sets containing tumor volumes and organs. Ground truth flap contours were created according to flap delineation guidelines [1]. Contouring by two independent experts was blind to patient characteristics and outcomes.

Two deep learning frameworks were used. The nnU-Net ('no-new-Net') is a robust and self-adapting framework based on vanilla (i.e native, unmodified) 2D and 3D U-Nets [4]. It is the standard approach for automated segmentation of medical images. A more recent framework based on transformers, MedSAM "Segment Anything Model" fine-tuned using medical images was also used. This 2D approach requires as input a region of interest containing the object of interest. As the nnU-Net outperformed MedSAM (Supplementary materials) without requiring a user-defined input (i.e., flap region), we focus on the nnU-Net from here onwards. The nnU-Net framework trained an out-of-the-box generic U-Net [5] on our dataset [4], randomly split into training and test sets of 120 and 28 patients. Images were resampled to a voxel size of $1.17\times1.17\times2mm^3$ (median voxel size). Images and Ground Truth masks were resampled using 3rd-order spline and nearest-neighbor interpolation, respectively. Data augmentation consisted of all the nnU-Net random flips, affine transforms (rotation, translation and/or scaling to the volume) elastic deformation (deformation following a grid mesh) of CTs and segmentation maps, brightness/contrast modifications and image quality reduction. Parameters of the nnUnet framework (implementation and training; optimizer, decreasing learning rate, dropout rate, cross-validation setting, hyperparameters, etc) are provided (Suppl materials). Standard metrics were Dice Similarity Coefficient (DSC), Intersection Over Union (IOU), relative/absolute differences in mean dose between automatically & manually delineated flaps.

Importance of clinical and imaging characteristics on flap segmentation

The impact of flaps (x_1, …, x_n), and image characteristics were assessed with respect to the models' performance. The average DSC with the 5-fold models was computed for each patient (training and test sets), and all characteristics were extracted either from the DICOM or by visual Quality Control and computed in a correlation matrix. A XGBoost modeling was fit to these features to determine the function $\hat{f}$ that best approximates f such that:f(x1, …, xn) = DSC with a maximum depth of XGBoost set to 15. A SHAP value graph showed feature importance of the XGBoost model.

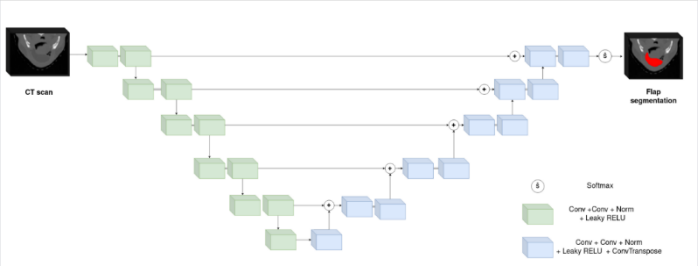

Figure 1: Flap UNet framework

3 Results

3.1. Population and flaps characteristics

Most (69.4%) flaps were in the oral cavity (Table 1). They consisted of soft tissues only (62.4%) with bone resection without (9.4%) or with bone reconstruction (28.2%). Free flaps represented 92.6% of cases, others were pedicled flaps. Median flap volume was 50.5 cm3 (range 3.9-199.8 cm^3). Metallic artifacts due to dental filling/crowns/implants or fixation plates were present in 71.8% of the cases, including 42.3% hampering delineation. Other parameters could vary between patients. A substantial proportion of the flaps were included in the high-dose radiotherapy region: median % of flap volume in the high-risk planning target volume (PTV) was 82.6% with many flaps having most high-risk PTV seemingly centered onto the flap (Figure 2D). Median % of flap volume in the low-risk PTV was 92.7%.

3.2. Performance of deep-learning segmentation

On the test set, the nnU-Net achieved a mean DSC of 74.0% (median 86.9%), mean IoU of 64.1% (median 76.9%) for soft tissue flap segmentation. Mean DSC by medSAM was 63% only, showed irrelevant results (Suppl materials) & was therefore abandoned. This lower performance could be attributed to the 2D nature of the method, & inability to correlate adjacent slice information leading to large flap delineation errors from one slice to the other. The prediction and ground truth of the five flaps that achieved a DSC ≤50% in at least two folds were examined visually. Suboptimal segmentation was either due to under-representation of some flaps (pedicled) or image characteristics (artefacts).

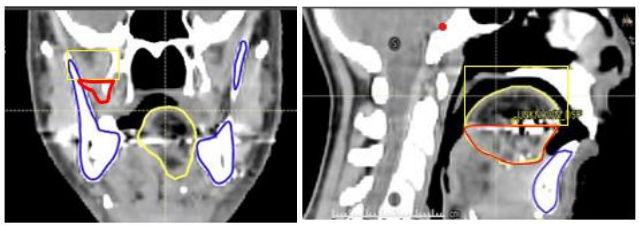

Figure 2: challenging segmentation task; flap (yellow) best seen delineated manually by using coronal (left) and sagittal (right) planes due to dental artefacts in axial planes

3.3. Quantitative impact of clinical or imaging characteristics of automatic segmentation

Table 1 shows the number of patients per center, high (>15), medium (2-14), low (1-2), flap location, whether the flap was pedicled or a free flap, whether bone was resected/not, & with/without bone reconstruction, X-Ray current and exposure (physical characteristics of the acquisition), voxel size & volume (voxel spacing, slice thickness), artifact severity (0 (no artifacts), 1 (slight), 2 (moderated) 3 (severe)), & the DSC of each patient on the 5 fold models. Of note, planning CT were extracted following dosimetry, i.e. Tomotherapy CT had been transformed into proprietary format of lower spatial resolution. The correlation matrix showed correlations between DSC & pedicled or free flap (-0.20) and artifact severity (none/slight versus moderate/severe) (-0.23). The DSC correlated with center volume. The XGBoost model fit to the data of the whole dataset to predict DSC reached a r^2 value of 0.944. SHAP values (Figure 2) indicating the importance of each feature in the prediction of the DSC showed strong negative impact of pedicled flaps, moderate-to-severe artifacts & low volume centers; positive impact of flap location in the oropharynx or oral cavity, high volume centers, & a bone flap on mean DSC of soft tissue flap segmentation.

Characteristics	**Number (%)**

4 Discussion

Although flaps are critical to improve functional outcomes, radiation oncologists pay little attention to flaps when planning poRT [6]. Deep mutual understanding of technical aspects of medical/surgical disciplines is critical to patient care beyond collaborative selection of treatment indications. Flap segmentation at the poRT planning step represents a great opportunity to address the effects of radiotherapy on flaps objectively, such as flap shrinkage by fatty atrophy, conversion from muscle to fat, fibrosis, & correlations of changes with dose distribution & functional toxicities. Flap segmentation can also help to improve our understanding of the patterns of failure in the presence of flaps.

Based on a multicentric flap database, we showed that current practice consisted in including the flap (median % of flap volume over 80%) in the high-dose region (i.e. region believed at high-risk for tumor colonization) and ≥96% in the radiotherapy field. Whether this constitutes a cognitive bias or relies on true knowledge of the patterns of failure in the presence of flaps was beyond the scope of this study but is hypothesis-generating.

Compared to a mean DSC of 0.70 for interobserver variability of manual flap delineation by experts in the field [2], our study showed good accuracy of the trained nnUNet method, achieving median and mean DSC of 0.87 and 0.74. Given the highly challenging nature of flaps segmentation compared to other segmentation tasks such as PET/CT tumor delineation in HNC where mean DSC is within 0.77-0.80 for the best algorithms, the accuracy of the flap nnUNET is more than satisfactory.

Our study also showed that dose difference between the automated & manually delineated flaps was too small to be clinically relevant. We will therefore use this fully automatic flap segmentation in our future works to assess segmentation performances, flap radiomics & dose-volume effects (volume, texture) longitudinally based on diagnostic & follow-up images. Finally, our seminal segmentation work could also serve as the basis for future clinical trials.

Limitations to this study include an imbalanced dataset where pedicled flaps represented a minority of the cases, an observation that however well represents current practice. Pedicled flaps are usually reserved to patients with significant comorbidities and who cannot stand prolonged anesthesia. Pedicled flaps were more segmentation error-prone. However, the pedicled is less exposed than the flap body, the latter being next or in the tumor bed. Thus, the fact that our method only segments the body is relevant to radiotherapy practice. We also observed a predominance of oral cavity flaps, which illustrates the critical functions of this anatomic site where substance loss resulting from tumor resection can substantially modify swallowing and speech. It also illustrates the preponderance of surgery in this tumor site, where oropharyngeal and laryngeal tumors can more often undergo definitive chemoradiation. Interestingly, the presence of a bone flap seemed to improve soft tissue flap segmentation despite the fact that bone flaps were underrepresented. We also showed the importance of image quality. Contrary to diagnostic images, RT planning often relied on non-contrast enhanced acquisitions in our dataset (often due to limited resources at the time of planning CT). Voxel size was chosen to fulfill the delineation and computational times requirements of the busy clinics, sometimes at the price of a poorer spatial resolution (often to limit the number of CT slices to delineate and the dose calculation time). In our dataset, it should be noted that for TomoTherapy cases, dosimetry CT were extracted for ground truth and automated delineation, however manual delineation was performed on a native CT in practice; a factor that might have altered the quality of the ground truth. This aspect emphasizes the good performances of our method and its robustness with respect to low spatial resolution and low contrast images. We used a robust deep learning method, which today is considered the state of the art for medical image segmentation. Although new models have been proposed (such as transformers), their advantage in limited size datasets such as in medical studies as in our case, is not yet confirmed, and our results demonstrated no medSAM added value.

Another concern, independently of the current segmentation method, was the suboptimal management of artefacts, despite broad access to minimization algorithms (MAR) softwares in routine CTs. We could not investigate the impact of MAR as use of MAR was not consistently indicated in the DICOM tags. More systematic & comprehensive tagging of DICOM fields of radiotherapy planning CTs should be encouraged to improve quality and standardization of radiotherapy CTs. Artefacts were very frequent & significantly altered both manual & automatic segmentation, leading to missegmented flaps with the automated algorithm and also altered manual delineation although one can rely on the three planes visualization to counteract artefacts dominating in some planes. It should be noted that removing artefacted images from training datasets would limit the generalization of the models. Therefore our choice was deliberate to deal with image quality as encountered in routine practice. By inputting a full head and neck CT scan to our inference pipeline, accurate segmentation was achieved.

Future investigations may explore other strategies, such as multiclass segmentation of OAR & flap, multitask architectures for flap classification, pre-processing of images for reducing artifacts & harmonize image properties, as well as pre-training on larger medical datasets.

Finally, we trained the first deep learning-based segmentation method dedicated to flap segmentation. This has potential major practical implications for poRT planning. We also observed that radiation oncologists included the flap in the high-dose target volumes. Our trained model should be a reliable too for longitudinal clinical research studies on radiotherapy, evaluating radiation-induced contributions to sequelae and tumor relapses, optimizing reconstructive surgery and radiotherapy combinations toward more customized postoperative radiotherapy.

Abstract Purpose: To create a 4-dimensional (4D) rat model of lymphocyte recirculation between the blood and other lymphatic compartments to for dynamic dose accumulation and effect assessment during irradiation. Methods: A graph representation of the lymphatic compartments was created, including 1. major organs divided into a blood and a lymphatic part; 2. the lymphatic network including lymph nodes (LNs) and Peyer's patches. This graph was converted into a physiologically based pharmacokinetic (PBPK) model as both a system of differential equations and a stochastic model. By overlaying the lymphocyte migration kinetics with a 3D model of rat anatomy, the dose could be dynamically accumulated under different irradiation scenarios. Results & Conclusions: Irradiation of blood compartments contributes negligibly to the total dose to the recirculating lymphocyte pool. Radiation-induced depletion of viable lymphocytes in the blood is caused by irradiation of secondary lymphatic organs and their subsequent redistribution among lymphatic compartments.

1 Introduction

Radiation-induced lymphopenia (RIL) has been studied extensively because of its adverse effect on treatment outcome [1]. Since the depletion is measured in the blood, it is often assumed that blood irradiation itself contributes significantly to this phenomenon. Consequently, modeling approaches have thus far been focused on the blood dose [2, 3]. However, it is known that lymphocytes continuously migrate between the blood and other lymphatic compartments. In particular, (naïve) lymphocytes enter lymph nodes (LNs) and Peyer's patches in the gut through high endothelial venules (HEVs). From there, the lymphocytes may migrate through a chain of LNs before returning to the blood via the thoracic duct or the right lymphatic duct. Thus, the routes and kinetics of lymphocyte recirculation depend on the architecture of the lymphatic network. In addition, lymphocytes can be retained in the microvasculature of organs by two different mechanisms. First, because of their size, lymphocytes may need to deform to squeeze through the capillary network [4]. Second, lymphocytes may roll along and attach to endothelial cells in post-capillary venules (PCVs), thus becoming 'marginalized' in the organ microvasculature [5]. Finally, lymphocytes released from open-ended arterioles in the red pulp of the spleen separate from the blood stream and are directed to the white pulp, where they reside for some time before eventually being released back into the blood circulation [6]. For all these reasons, the blood alone provides only a very limited view of the true dynamics of lymphocytes; a much deeper understanding of lymphocyte recirculation kinetics is needed to study causes and effects of the depletion of circulating lymphocytes.

The aim of this study is therefore to create a 4D model of lymphocyte recirculation in which we can track individual "lymphocyte parcels". Overlayed with a radiation dose rate, a lymphocyte dose distribution can be obtained, from which surviving fractions can be calculated. Finally, simulated lymphocyte concentrations in the blood can be monitored and potentially compared with measurements.

The rat provides a good starting point: it has a well-studied lymphatic anatomy and many experimental studies on lymphocyte kinetics have been performed in rat. Moreover, our simulation results can be potentially be validated by carefully designed experiments.

2 Materials and Methods

As a first step in the construction of a 4D model of lymphocyte recirculation in rat, a physiologically based pharmacokinetic (PBPK) model of lymphocyte flow was constructed. In this compartmental model, blood circulation was considered the distributor of lymphocytes through the body. We extended the blood compartments of the lungs, liver, and intestines with a 'lymphatic' compartment, denoting marginalized lymphocytes. The blood compartment of the spleen (red pulp) was similarly equipped with a lymphatic compartment (white pulp) (Fig 1a). We represented this model as a directed graph whose edges represent the anatomical connections between compartments (nodes). This allowed for rapid and insightful architecture modification. A graphical representation of the LN connectivity was also incorporated, guided by anatomical reports from literature [7]. A total of 38 LN compartments were added, each representing either a single LN or a group of LNs (Fig1b). A rate variable k_{ij} was associated to each graph edge specifying the exchange rate from compartment i to j. From the graph we extract the rate matrix $\boldsymbol{K}$ as the adjacency matrix weighted by the rate variables. This rate matrix specifies the kinetics of lymphocyte recirculation.

Both a method based on ordinary differential equations (ODE) and a stochastic method were developed to simulate the kinetics of lymphocyte migration for a given $\boldsymbol{K}$. In the ODE method, the following system is solved:

$$\frac{dy_i}{dt} = \sum_j K_{ji}\, y_j - K_{ij} y_i$$

where y_i is the number of lymphocytes in compartment i. In the stochastic method, a walk over the graph is simulated for a large number of particles with each particle representing some amount of lymphocytes. The rate matrix is converted in a transition matrix $\boldsymbol{T}$, denoting the jumping

probabilities between compartments in an incremental time step Δt:

$$T_{ij} = \left[K_{ij} + I_{ij} \cdot \left(1 - \sum_j K_{ij} \right) \right] \Delta t$$

where $\boldsymbol{I}$ is the identity matrix. The rate matrix determines the mean transit time of each compartment by $MTT_i = 1/\sum_j K_{ij}$. However, where the ODE approach only models exponential transit time distributions, the stochastic approach allows us to choose these distributions ourselves.

Outflux rates from blood compartments were obtained from Brown et al. [8] as the ratio of the outflow and the blood volume: $k_{ij} = Q_{ij}/BV_i$. However, fluxes between lymphatic compartments are not well established. Nevertheless, experimental data on the kinetics of lymphocyte migration in laboratory animals based on the injection of radiolabeled lymphocytes [3, 4] and thoracic duct cannulation studies [11] are available and can be used to fit the unknown exchange rates. Previously, Ganusov & Auerbach fitted migration rates for the rat [12]. We have extended this effort by 1. fitting a PBPK-based model in which blood circulation distributes lymphocytes among vascular compartments and the fitted parameters correspond to measurable quantities; 2. by explicitly incorporating the lymphatic architecture of the rat; 3. by performing the fitting based on Bayesian methods that account for the multiplicative measurement noise. With as many as 38 lymph nodes (LNs) included, we did not fit a separate outflux rate for each, but assumed that both the number of lymphocytes in each LN and the influx from the blood through HEVs were proportional to the LN volumes, which were obtained from literature. With these assumptions we can fit a single parameter γ for all LNs and set:

$$k_{out}(LN_i) = f_i * \gamma$$

Where f_i is a LN-specific factor explicitly calculated from the LN volume and its connectivity in the graph. We fitted the model using the fast ODE representation as this requires many evaluations. The "probabilistic inference on noisy time series" (pints) python package was used, and the stability of the solution space explored using MCMC sampling methods [13]. The fitting was performed with respect to the experimental data by Smith & Ford [9]. Once fitted, the $\boldsymbol{K}$ matrix can be imported into the stochastic representation of the model and appropriate transit time distributions can be selected. We then validated our fit on another experimental study describing the temporal appearance of radiolabeled lymphocytes collected during thoracic duct cannulation [11].

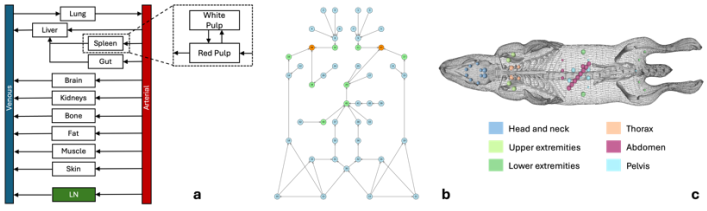

*Figure 1: **a)** PBPK model of lymphocyte migration. **b)** Graphical structure of rat LNs, which is completely contained in the LN box from **a)**. **c)** 3D distribution of LNs in a rat phantom.*

Next, the effect of irradiation was investigated. To determine which LNs are in a given radiation field, their physical location in the rat must be considered. Therefore, again guided by anatomical descriptions [7], the LNs were positioned in a 3D model of a rat phantom (Fig 1c). Additionally, 10 Peyer's patches were uniformly distributed over the surface of the small intestines. Hypothetical treatment plans were then generated for the rat phantom for a variety of sites using an analytical pencil beam method (Fig 2).

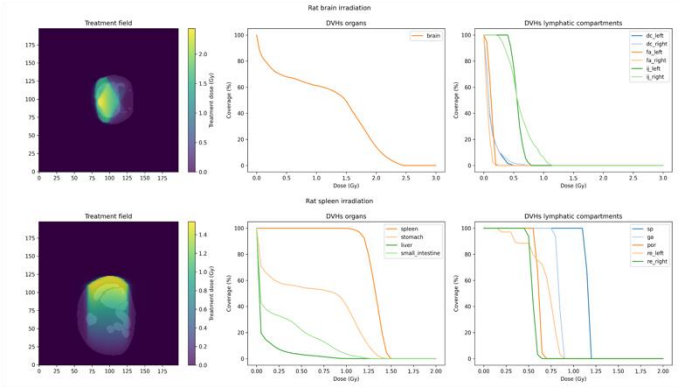

Figure 2: Dose distributions and DVHs for photon irradiation of the rat brain (top) and spleen (bottom).

Using the stochastic model to simulate a large number (500000) of individual 'lymphocyte parcels', each parcel accumulates dose as it travels through the compartments, thereby encountering various dose rate values. Hence, the accumulated dose depends on both the spatiotemporal path of each parcel and the dynamics of the radiation delivery, resulting in a heterogeneous lymphocyte dose distribution. To get an idea of the impact of the radiation on the viability of the lymphocytes, the cell viability was determined probabilistically with a chance $p_k = e^{-\alpha D_k}$, where D_k is the accumulated dose in lymphocyte parcel k during one fraction of the irradiation regimen and α is a radiosensitivity parameter. Then the spatiotemporal redistribution of viable cells after irradiation was determined using the lymphocyte recirculation model.

3 Results

A good fit to the experimental data was found (Fig 3), and different MCMC runs consistently found the same optimum. All secondary lymphatic organs (spleen, (mesenteric) lymph nodes and Peyer's patches accumulate a large amount of lymphocytes, while only a few percent (2.6%) of the total lymphocyte pool circulate in the blood. The marginalized pools of lymphocytes slowly traversing the lung and liver are comparable in number as the lymphocyte pool in the blood.

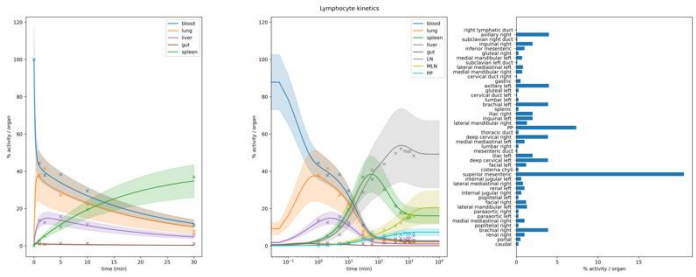

Figure 3: Fitting result for short- and long-term migration kinetics of lymphocytes. On the right, the percentage of recovered activity across different lymph nodes when equilibrium is reached.

The *in-silico* cannulation study provided further validation of our obtained fit. Even though the exact profile of lymphocyte appearance did not precisely match, the peak of lymphocyte recovery is obtained after about 12 hours, consistent with experimental data (Fig 4).

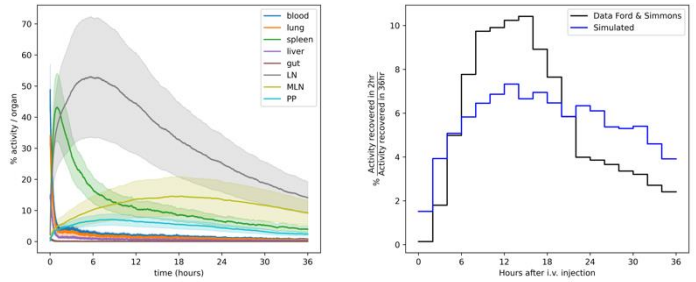

Figure 4: Simulated thoracic duct cannulation. Left: the resulting kinetics of lymphocyte depletion in various compartments. Right: collection of lymphocytes over time compared to experimental data.

We took a closer look at what happens in the main organs playing a role in lymphocyte migration aside from LNs and Peyer's patches. We denote by f the probability that a lymphocyte separates from the blood stream in an organ to become marginalized in the case of non-lymphatic organs, or to cross from the red pulp to the white pulp in the spleen. *MTT* denotes the mean time particles spend in this lymphatic compartment. The values are listed in Table 1. Interestingly, almost all lymphocytes entering the red pulp of the spleen cross over to the white pulp and spend a long time there, indicating the important role of the spleen in immune regulation.

	Lung	Liver	Gut	Spleen
f	0.42	0.44	0.22	0.88
MTT	24 s	59 s	9 s	1.85 h

Table 1: Fraction f of lymphocytes in organ blood going to the corresponding lymphatic component, and the mean transit time (MTT) in that component.

Lymphocyte dose distributions were calculated for 4 sites (brain, right lung, small intestines, and spleen) for hypothetical irradiation scenarios in which radiation was delivered by one or more photon beams delivering a fractional dose of approximately 2 Gy in 20 seconds. Figures 5 and 6 show the resulting lymphocyte dose profiles and DVHs for brain and spleen irradiation, respectively. It is clear that the lymphatic compartments contribute much more to the total lymphocyte dose than the blood compartment, whose contribution is negligible. This is not entirely surprising given the small fraction of recirculating lymphocytes found in the blood at equilibrium. Table 2 lists the expected fraction of lymphocytes still viable after one and 20 fractions of dose.

While most of the radiation damage may not occur in the blood, the decline of viable cells in other lymphatic compartments will, through the process of lymphocyte recirculation, over time become apparent in the blood. In Figure 7, the dynamics of the decline of viable cells after splenic irradiation – initially most dramatic in the spleen itself – was plotted over time. 18 hours after irradiation, a new equilibrium is almost reached, in which the density of viable lymphocytes in each compartment attains its new value, equal to its original value multiplied by the expected fraction of lymphocytes that remain viable after the irradiation.

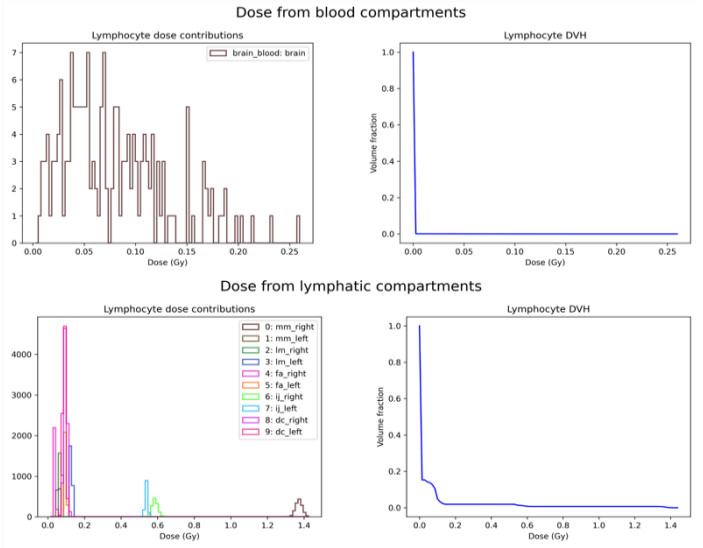

Figure 5: Lymphocyte dose for brain irradiation.

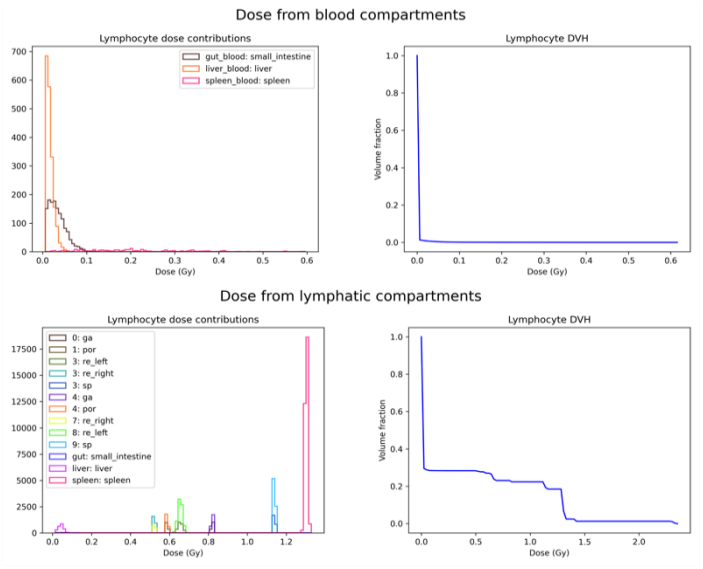

Figure 6: Lymphocyte dose for spleen irradiation.

	Fraction dose (Gy)	Viable fraction	Viable fraction (20×)
Brain	2.0	0.994	0.88
Right lung	1.75	0.988	0.79
Small intestine	1.6	0.954	0.39
Spleen	1.5	0.928	0.22

Table 2: Maximum treatment dose and the expected viable fraction of lymphocytes after one irradiation fraction and after 20. An α of 0.25 Gy^{-1} was assumed.

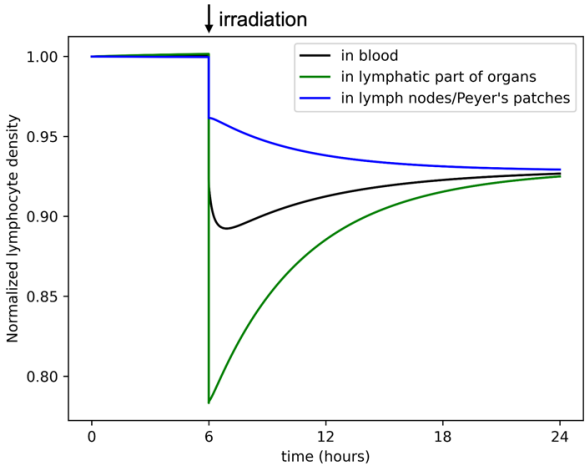

Figure 7: Kinetics of redistribution of viable lymphocytes between compartments remaining after splenic irradiation.

4 Discussion

We have developed a new framework to simulate lymphocyte recirculation in the rat. By combining the kinetics of lymphocyte migration with a 3D model of rat anatomy, including LNs and Peyer's patches, a 4D model of lymphocyte recirculation was obtained that can be used for lymphocyte dose calculations.

Blood dose contributes marginally to overall lymphocyte depletion. Instead, it was consistently observed that irradiation of secondary lymphatic organs such as LNs, Peyer's patches and the spleen resulted in large lymphocyte doses and marked reductions of viable lymphocytes throughout the compartments, including the blood.

Having developed a rat model, we acknowledge that most experimental data on radiation effects are performed in mice, while clinical reality mostly considers humans. While it is highly likely that our findings are qualitatively transferable, it is not obvious how to quantitatively scale the model. While this may be feasible for mice, which are anatomically similar to rats [14], creating a human recirculation model may be more involved.

While we have considered all lymphocyte on equal footing, in reality different subsets may have different recirculation properties. In particular, T cells have been shown to recirculate more rapidly than B cells [10]. Furthermore, antigen-experienced cells do not cross HEVs to enter lymph nodes but rather infiltrate and drain from non-lymphatic tissue [5]. Thus, the simulated pathways mostly apply to lymphocytes with a naïve or central memory phenotype.

5 Conclusion

Our results suggest that blood dose is unlikely to contribute significantly to the lymphocyte depletion often observed after radiotherapy. Rather, the dose to secondary lymphoid organs appears to be the determining factor.

Abstract PULSAR (Personalized, Ultra-fractionated Stereotactic Adaptive Radiotherapy) is designed to administer tumoricidal doses in a pulsed mode with extended intervals, spanning weeks or months. This approach leverages longer intervals to adapt the treatment plan based on tumor changes and enhance immune-modulated effects. We seek to elucidate the potential synergy between combined PULSAR and PD-L1 blockade immunotherapy using experimental data from a Lewis Lung Carcinoma syngeneic murine cancer model. Employing a Long Short-Term Memory (LSTM) Recurrent Neural Network (RNN) model, we simulate the treatment response, treating irradiation and anti-PD-L1 as external stimuli occurring in a temporal sequence. Our findings demonstrate that: 1) The model effectively simulates tumor growth by integrating various parameters such as timing and dose, and 2) The model has potential to provide mechanistic interpretations of a "causal relationship" in combined treatment, offering a novel perspective.

1 Introduction

PULSAR (personalized ultra-fractionated stereotactic adaptive radiotherapy) aims to deliver tumoricidal doses in a pulsed mode with long intervals. It offers several advantages. Longer intervals allow considerably more normal tissue recovery after injury. At the same time, longer interval provides time for the tumor and tumor microenvironment (TME) to undergo changes, and thus allows for more meaningful adaptation based upon the evolving characteristics of the tumor (e.g., the change of tumor size, shape, and biomarker expression). Achieving this in conventional radiation therapy is challenging because not only is the tumor unlikely to undergo significant changes between two closely spaced radiation doses, but repeated dosing over a short interval may impede potential synergies in combined radiation therapy and immunotherapy. Despite promising progress, combination of the two treatments has yielded lackluster results in both clinical and preclinical studies. Whether synergy exists or if the efficacy mainly resides within each modality, remains an intriguing research question.

One aspect of particular interest is determining the optimal timing and sequence to harness the immune-mediated antitumor effects in combined radiation therapy (RT) and immune checkpoint blockade (ICI) therapy (e.g., PD-L1, CTLA4).[1-10] For instance, one clinical trial studied the outcome of multisite Stereotactic Body Radiation Therapy (SBRT) followed by pembrolizumab, reporting an overall response rate of 13.2% in advanced solid tumors.[6] The PEMBRO-RT phase 2 clinical trial in non-small cell lung cancer demonstrated a doubling in overall response when patients were treated with SBRT (3×8 Gy) followed by pembrolizumab.[7] The synergistic impact of combining RT with ICI therapy has been extensively explored in preclinical models as well. One study delivered 10 to 24 Gy in 1 to 3 daily, or every other day fractions and began PD1/PD-L1 checkpoint blockade therapy within a day of radiation.[5] Another preclinical study included 3 daily SBRT fractions of 8 Gy, followed by anti-CTLA4 treatment, beginning on the day of the last fraction.[8] Both studies demonstrated additive benefits when ICI blockade given concomitantly with radiation. Moreover, there are conflicting reports regarding the optimal timing of PD-L1 therapy in relation to radiation. While some studies showed no additive benefit when PD-L1 therapy was administered six days after a single dose of radiation,[9] others suggested clear benefits of PD-L1 therapy given even 21 days after radiation.[10]

Our team has performed an exploration of PULSAR in conjunction with anti-PD-L1 therapy using both immune activated and resistant syngeneic mouse models.[11] Tumor growth was studied as a function of radiation dose and dose scheduling. The results revealed that the effectiveness of anti-PD-L1 therapy depended on how the radiation was sequenced relative to the timing of ICI therapy. For instance, less tumor control was seen with the anti-PD-L1 drug if radiotherapy was given daily or every four days, compared to an interval of ten days. This motivates us to dive deeper into to answer the following question: How do the responses resulting from radiation therapy and ICI therapy interact temporally with each other? The Lewis Lung Carcinoma (LLC) cell line was chosen as the tumor model due to its aggressive nature and immunogenic properties in our study. Acknowledged as a "cold" tumor characterized by low T cell infiltration and high myeloid suppressive cell infiltration, LLC offers valuable insights into the temporal behavior of the adaptive immune response.[12] This is crucial for studying the synergy in vivo, given the longer time required for the adaptive immune response to develop and reach its full effectiveness. In addition, differing from most preclinical models using radiation and with either daily or every other day fractions, we tested radiations pulses with a longer spacing.

Our goal is to develop a modeling tool to better understand the interaction between radiation therapy and anti-PD-L1 therapy, discerning whether synergy exists or if efficacy is confined to each treatment modality independently. Given the complexities of both physical and biological processes involved, it is a very challenging task to model the response of individual components such as tumor growth, radiation damage, immune response, TME and T-cell dynamics.[13-19] Instead of going with a conventional analytical approach (e.g., solving differential equations), we deployed an AI using an LSTM-RNN (**Fig. 1**). RNN is a generalization of feed-forward neural networks that have an internal memory, offering unique strengths in identifying correlation in sequential signals.[20-23] Radiation and anti-PD-L1 were viewed as two external stimulation pulses occurring in a temporal sequence. To isolate the role of radiation, we calculate the difference map, which disentangles the interplay between tumor growth and radiation, highlighting the sole contribution of radiation. AI model may offer unique mechanistic interpretations regarding a "causal relationship", from a completely novel perspective.

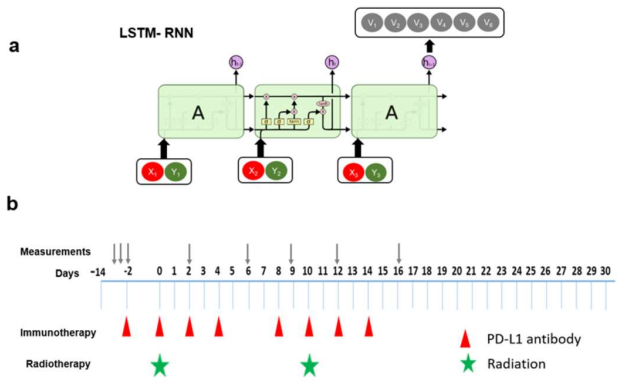

Fig. 1. a. The LSTM-RNN (recurrent neural network) model. b. The timing diagram of the combined therapy in our study. For immunotherapy, either anti-PD-L1 or isotype control was administered. For radiation, different doses were delivered (10, 15, 20, 40 Gy). The first pulse of radiation was always delivered 14 days after the implantation. Tumor volume measurements were carried out sequentially on certain days.

2 Materials and Methods

Data pre-processing. For each treatment group, seven or eight animals were studied, and the measurement of tumor volume exhibited large variance **(Fig. 2**). From a machine learning standpoint, this diminishes the discernible correlation, if any, between an input sequence and an output sequence. For training the LSTM-RNN model, data augmentation was necessary. The details of data processing are summarized below. The total time course was set to be 21 days (three weeks) for all samples to ensure data consistency.

We had 26 treatment groups in total. Each group included the volume change trajectories of seven or eight animals. We initially computed the mean and standard deviation using the tumor volumes of seven or eight animals on a specific measurement day. Assuming a Gaussian distribution for the average response, we then generated 50 samples randomly from this distribution. To address the issue of large error bars (**Fig. 2**), we intentionally reduced the standard deviation by a factor of five, which we believe might be achieved by employing more accurate volume measuring techniques. We acknowledge that the described data augmentation lacks statistical rigor but is the only feasible approach given the available data. As a side note, we consider the inclusion of 50 samples through data augmentation as a strategy to mitigate overfitting and enhance generalization.

A total of 1300 samples were used for machine learning (26 groups and 50 samples per group). Each sample consisted of a sequence of 28 steps with two inputs and one output. The two inputs corresponded to radiation dose and anti-PD-L1, respectively. For radiation, a single value encoded the dose, representing the killing effect using an LQ model which is dose dependent.[13] Otherwise, it was set to zero. In the case of anti-PD-L1, the input was coded as 0 or 1, indicating the absence or presence, respectively. These two inputs were concatenated at each step. The output represented the change in tumor volume between two consecutive measurements. For example, if we conducted six measurements for each animal, there would be five non-zero values. Positive change signifies volume increase, while negative change signifies volume decrease. This choice is primarily attributed to the design of our animal experiments preceding the consideration of AI modeling.

RNN modeling and training details. We developed a LSTM-RNN model using the Pytorch package, consisting of 100 hidden units at each time step and a fully connected layer in the last time step to predict volume change. The model used a "many to one" rather than a "many to many" structure. The LSTM-RNN used recurrent connections to keep track of the context hidden in the sequence (i.e. internal memory). The ADAM algorithm with default settings was used for optimization (learning rate = 0.001, beta1 = 0.9, beta2 = 0.999, epsilon = 1×10^{-8}).[24] Training was implemented on a PC with a NVIDIA GeForce RTX 3090 and an Intel(R) Core(TM) i7-10700K CPU. The batch size was 100 and the total epoch iteration was 5000. The loss function defined in Eqs. 1 and 2 was calculated based on the non-zero points (e.g. with measurements performed) only. It represents the discrepancy between the predicted volume change ($\Delta VC'_i$) and experimental counterpart (ΔVC_i), where i is the index of measurement. ΔVC could be either positive or negative.

$$\Delta VC_i = Volume_{i+1} - Volume_i \qquad (i=1, 2, 3, 4, 5) \qquad (1)$$

$$Loss = \sum_i (\Delta VC_i - \Delta VC'_i)^2 \qquad (2)$$

In total, 1200 samples (24 groups, 50 samples in each group) were used for training (80%) and 100 samples for testing (20%). We performed cross-validation using the following approach: two groups were randomly selected and excluded from the training dataset, and this process was repeated five times to train five models. Subsequently, these five models were applied to a new sequence to assess their robustness. This is different not a holdout validation, as no measurement data available for the new sequence. In our trial, no significant differences were observed among the five models, and we selected only one for subsequent analyses. It is important to note that our primary focus is not on quantitative aspects, given the inherent challenges in achieving both precision and accuracy.

Interpretation of hidden units and predictive modeling. To gain deeper insights into the internal signal flow within the LSTM-RNN model, specifically regarding the "causal relationship", we extract the values of 100 hidden units for 18 time steps. By performing arithmetic operations on the maps of hidden units between two groups (e.g., with or without anti-PD-L1, with or without radiation), we attempted to separate the respective effects of each treatment and provide plausible explanations. Additionally, we proceeded to assess the model's predictive power, aiming to estimate the outcomes of new delivery sequences not included in the experiments. To determine overall tumor control, analogous to the endpoint in clinical studies, we utilized the accumulated volume change (AVC) as the criterion (Eq. 3). We tested three cases: case 1 (two pulses of 10 Gy with a 10-day interval), case 2 (two pulses of 20 Gy with a 10-day interval), and case 3 (a single pulse of 40 Gy), with a cycle of anti-PD-L1 on four or two consecutive days. We analyzed AVCs at various offsets ranging between 1 and 14 days. For example, an offset of five days implies that five days after the delivery of the first radiation pulse, anti-PD-L1 is administered on four consecutive days. While there are numerous permutations to explore, we provided only two cases above to exemplify the potential role of the LST-RNN model.

$$AVC = \sum_{i=1}^{5} \Delta VC'_i \qquad (3)$$

3 Results

Experimental stud. To exemplify the influence of radiation schedules on tumor control in combined treatment, we summarize the experimental findings of a subset of groups in **Fig. 2**. In the absence of radiation, there is no significant difference observed between the group 1 (without anti-PD-L1) and group 2 (anti-PD-L1) (**Fig. 2a**). Similarly, when comparing group 6 (a single pulse of 40 Gy, anti-PD-L1) and group 8 (two pulses of 20 Gy with a 10-day interval, anti-PD-L1) (**Fig. 2b**), both effectively suppress tumor growth. The tumor control between 40 Gy and 20 Gy, appears comparable in the presence of relatively large error bars, as indicated by the data points following the first pulse on day 14. In **Fig. 2c** where a single pulse of 20 Gy was delivered on day 14, there is a noticeable benefit in tumor control for group 4 (anti-PD-L1) compared to group 3 (without anti-PD-L1), which becomes apparent two days after the first pulse. In **Fig. 2d**, when two radiation pulses (20 Gy with a 10-day interval) are delivered, we observe a general trend similar to **Fig. 2c**. The difference becomes more pronounced after the second pulse, between group 7 (without anti-PD-L1) and group 8 (with anti-PD-L1).

AI-based modeling and prediction. **Fig. 3a** illustrates the convergence of both the training and validation loss of the LSTM-RNN model after approximately 2000 iterations. The validation loss exhibits a minor

The accumulated volume change (AVC) for new schemes not included in the experimental study.

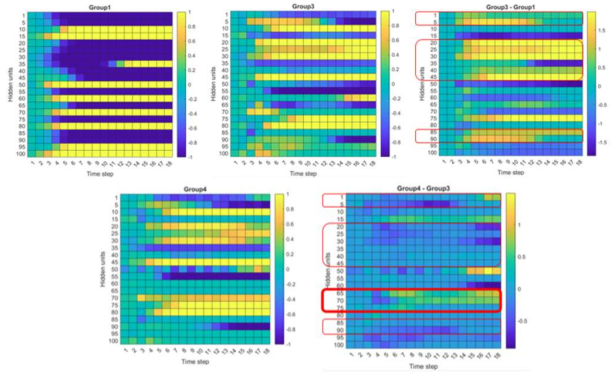

Fig. 4. Analyses of hidden units inside the LSTM-RNN model, which has 100 hidden units at each step and 18 steps in total. The first time step on the horizontal axis corresponds to the day when the first anti-PD-L1 was administered.

deviation from the training loss, suggesting the absence of significant overfitting. The results of the testing are displayed in **Fig. 3b**, showcasing an overall favorable prediction accuracy concerning volume change. The majority of differences at each time point reside within the range of -100 to 100 mm^3, except for a single point in group 11, which surpasses 300 mm^3 on day 16. Considering that the tumor volume in the control group exceeds 600 mm^3 around day 20 (**Fig. 2a**), the predictive accuracy offered by the LSTM-RNN model is deemed satisfactory.

To illustrate the potential use of the LSTM-RNN model for in-silico analysis, the response of AVC for different treatment schemes is depicted in **Fig. 3c** These schemes involve either two or four consecutive daily administrations of anti-PD-L1, slightly different from the every other day administration in the experiments. In the case of a single pulse of 40 Gy (case 3), optimal tumor control is achieved with an offset of seven to eight days. Four doses of anti-PD-L1 result in slightly improved tumor control compared to two doses, with a minimum volume of 350 mm^3 (left) versus 468 mm^3 (right). By contrast, for both case 1 and case 2 (two pulses of either 10 Gy or 20 Gy with a 10-day interval), AVC remains relatively stable, except for an abrupt increase observed in case 1 on the left end. This suggests that the synergistic therapeutic effect is anticipated to be similar, irrespective of when anti-PD-L1 is administered after the first radiation pulse. Another surprising observation in case 1 is the noticeable difference in AVC between two and four anti-PD-L1 administrations, with volumes of approximately 1750 mm^3 (right panel) and 2250 mm^3 (left panel), respectively. In other words, for a radiation pulse of relatively low dose, such as 10 Gy, doubling the dose of anti-PD-L1 adversely affects the treatment outcome, possibly due to treatment toxicities or other mechanisms. The reason for the two aforementioned patterns needs additional exploration, which could be attributed to the real interaction between radiation and immune response, or to the limited generalization capability of the LSTM-RNN model.

Analysis of hidden units and interpretation. To gain further insights into the "causal relationship", we extracted the values of 100 hidden units for each of the 18 time steps and performed arithmetic operations. For instance, we examined the difference between group 1 and group 3 in **Fig. 4** (top), where both groups received the isotype control, but only group 3 received a single pulse of 20 Gy on the third time step. Therefore, in group 1, the temporal evolution of the map of the hidden units primarily reflects the process of tumor growth, while the map of group 3 capture the processes of both tumor growth and the influence of radiation. Therefore, the difference map between the two groups, denoted as Group 3 - Group 1, disentangles the interplay between tumor growth and radiation, highlighting the sole contribution of radiation. We speculate that the presence of more positive values within the highlighted regions yields more effective tumor control (e.g., vertical index: 1-5, 20-45, 85-90, three highlighted boxes).

The impact of anti-PD-L1 is demonstrated in **Fig. 4** (bottom), by comparing group 3 (isotype control every other day) and group 4 (anti-PD-L1 every other day). Both groups received a single pulse of 20 Gy on the 3rd time step. The difference between the two reveals the effect solely attributable to anti-PD-L1, as manifested in a newly highlighted region (vertical index: 65-75). This region contains predominantly positive values and does not overlap with the three previously highlighted regions linked to radiotherapy. While the selection of a region lacks solid evidence and requires additional validation, the results are somewhat expected, considering the distinct mechanisms through which radiation and anti-PD-L1 operate. Moreover, inside this region, we see the effect begins to emerge approximately seven steps after the first pulse and continues throughout the treatment.

4 Discussion

The LSTM-RNN model has demonstrated its unique strength in modeling the process of tumor control in combined therapy up to three weeks. It capitalizes on its inherent ability to process sequential information, which makes it well suited for achieving our objective (**Fig. 1a**). Its recurrent computation property is advantageous as it prevents the growth of the number of model parameters as the number of time steps increases, particularly beneficial when dealing with small datasets.

Each group in our study corresponds to a specific input configuration, consisting of radiation dose and anti-PD-L1 drug dose. In essence, the LSTM-RNN model attempts to find the mapping between inputs and outputs for all 26 groups, which resembles a challenging curve fitting task considering the intricate and unknown mechanisms of interaction involved. Two additional challenges we encountered are: 1) the presence of many zeros in the input sequence (e.g., representing days without either radiation or anti-PD-L1 treatment), and 2) the absence of tumor volume measurement on multiple days. As a matter of fact, we conducted comparative tests and found that a feed forward network (FNN) performed much less effectively than the LSTM-RNN model. We also tested a "many-to-many" structure aiming to predict responses for all time points, including those with missing measurements. However, the results of this approach are inferior compared to the "many-to-one" structure employed in this manuscript. Such disparity is attributed to the increased difficulty for an AI model in establishing temporal correlations when a sequence contains numerous missing data points.

Another novel of our approach is the utilization of hidden units to identify temporal correlations between radiation and anti-PD-L1 (**Fig. 4**). This allows us to gain insights into the "causal relationship" from a completely new perspective. However, the biological interpretations drawn from observing the dynamics of hidden units in our work should be approached with caution. The latent representations in our model, as well as selecting different regions, are very abstract and require additional evidence to support our speculations. In this regard, we would like to reemphasize that our current goal is to identify the general trend in tumor control and potential synergy in a qualitative manner, rather than focusing on quantitative accuracy. Further quantitative analysis and interpretation may need to be postponed until additional biological correlates become available.

Additionally, the LSTM-RNN model may support in silico studies (**Fig. 3c**), generating essential data to address other relevant research questions in the field of combined PULSAR and ICI therapy. Various factors can be combined as inputs, such as dose per pulse, pulse structure, anti- PD-L1 dose, and relative timing. Moving forward, we will conduct a more in-depth exploration of various permutations to identify the optimum treatment strategies for maximizing the synergy between PULSAR and ICI therapy, in parallel with the design of the next phase of experiments. In our view, daily fractions are very unlikely to be the optimal choice.

Ordinary Differential Equation (ODE)-based mathematical models are extensively used for analyzing complex biological systems. These models include components such as tumor cells, immune effector cells, antigens, regulatory cells, antibodies, and natural killer cells. For instance, Eftimie et al. developed models focusing on tumor cells and immune effector cells, resembling a predator-prey model.[25] Serre et al. utilized discrete-time equations to model the synergy between immunotherapy and radiotherapy.[26] In the future, we plan to adopt a similar approach and compare the performance between the ODE-based and AI models. The two may complement each other and enhance the interpretation. Additionally, in our current study, the AI model focuses on the mean output of each group, without accounting for inter-animal variation. A broader question arises regarding the level of personalization in combined PULSAR and immunotherapy. In the long run, it might also be possible for us to take into account different temporal responses and identify optimum treatment strategy for each animal through reinforcement learning, similar to two previous studies.[27, 28]

5 Conclusion

We have successfully demonstrated that the proposed LSTM-RNN model exhibits unique strengths in predicting tumor growth and identifying potential "causal relationships", based on the results of preclinical experiments. Our study introduces a novel perspective on studying the temporal interaction between radiation and ICI therapy. When utilized as an in-silico modeling tool, the LSTM-RNN model has the potential to maximize therapeutic effects through the optimization of variables such as pulse interval, radiation dose, drug dose, and timing. By implementing more rigorous experiments and dedicating future efforts to biomarker identification, we can deepen our comprehension of biological mechanisms and improve quantitative capabilities.

Abstract

This study introduces a Python-scripted pipeline for integrating white matter tractography atlases into stereotactic brain radiotherapy (SBRT) treatment planning. The method utilizes a probabilistic atlas of 52 white matter fibers, offering an accessible and automated approach to visualize and analyze white matter tracts in individual patients undergoing SBRT. The pipeline involves image preprocessing, affine then non linear registration to a common space, and dose map transformation with different interpolation methods. The results demonstrate accurate registration and suggest that bSpline interpolation provides optimal consistency in dose distribution. The study aims to derive dose constraints for white matter tracts, offering a potential tool for guiding therapeutic decisions in SBRT. The pipeline enhances the accessibility of white matter structural connectivity in radiotherapy planning.

1 Introduction

Understanding the white matter (WM) anatomy has been facilitated by recent advances in neuro-imaging, such as Magnetic Resonance Diffusion Tensor Imaging (DTI). Complementarily, anatomo-functional atlases of the WM tracts (WMT) and their associated functions have been elaborated based on awake surgery thanks to brain mapping through direct electrical stimulation [1,2]. All these major achievements underscore the crucial importance of preserving WMT in order to maintain patients' neurocognition and quality of life.

At the same time, stereotactic brain radiotherapy (SBRT) has dramatically changed the outcome of brain metastasis (BM) patients. While focal control and extended progression-free survival have been achieved, decreasing neurocognitive side effects of these patients is of major importance [3,4].

In clinical routine, WM structural connectivity is not considered in SBRT treatment planning of BM. This can be explained by the lack of accessible resources to facilitate such an approach.

Recently, Yeh et al. provided in open access a probabilistic atlas of 52 white matter fibers derived from tractographic data of 1065 healthy subjects. This atlas is normalized to the ICBM 2009a non-linear asymmetric space[5].

Here we introduce an automated method that is easily accessible, and straightforward, enabling the visualization of WM tracts provided by Yeh et al. probabilistic atlas on individual patient pre-SBRT imaging (MRI and CT scan) and planning dose maps. Ultimately, the methodology will enable WMT dose-volume histograms (DVH) to be calculated, making it possible to implement tract sparing dosimetry.

2 Materials and Methods

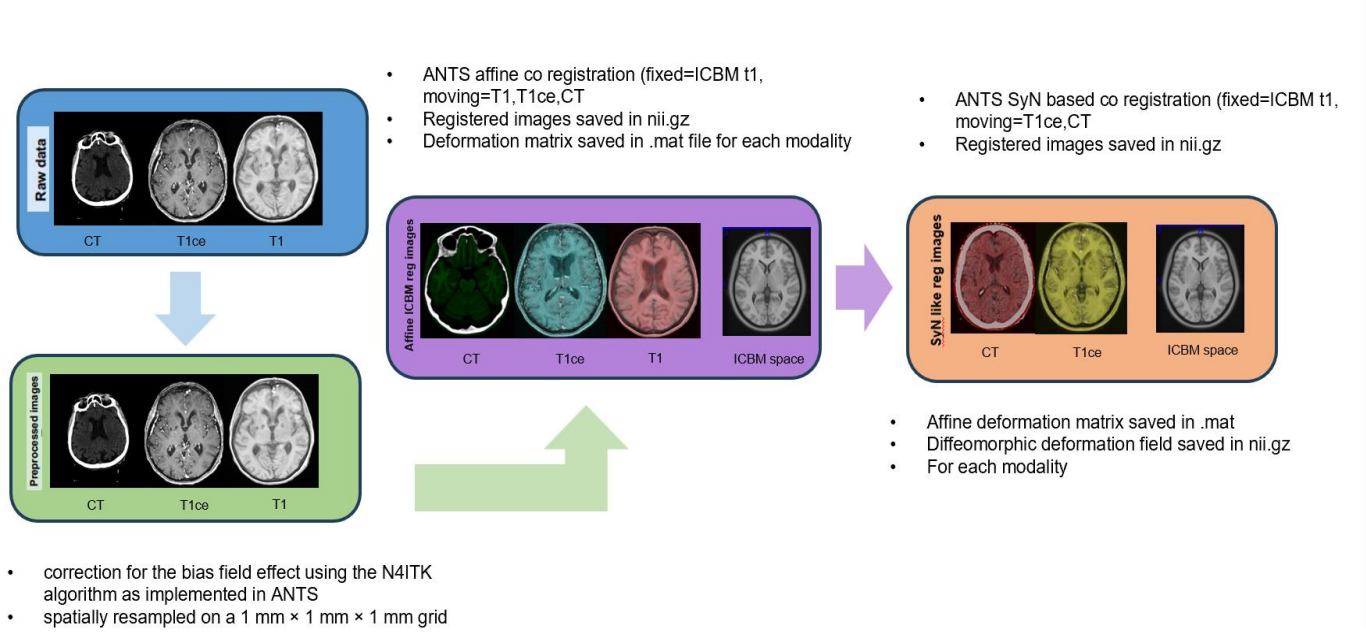

Figure 1. Co registration to ICBM2009a nonlinear asymmetric space: affine then non linear SyN registration.

We focused on BM patients treated for small (< 2cm) lesion(s) with one 20Gy fraction SBRT in our institution.
All pre-SBRT brain images (T1 gadolinium enhanced MRI and CT scan) were preprocessed as follow: DICOM to NIFTI conversion, correction for the bias field effect using the N4ITK algorithm as implemented in Advanced Normalizations Tools for Python (ANTSPy) ecosystem [6] for MRIs, resampling on a 1 mm × 1 mm × 1 mm grid and brain extraction (HD-BET tool for MRIs and CTseg tool by SPM for CTs). Using ANTSPy, an affine registration to the ICBM 2009a nonlinear asymmetric space (T1 ponderation) was performed, follow by a nonlinear registration (Symmetric diffeomorphic image registration (SyN)) (Figure 1).

For both MR and CT, Mutual Information was used as similarity metric for the affine and SyN co-registrations . As opposed to the affine stage, skull stripped images were used for the SyN step for moving and fixed images. To improve the accuracy of the SyN deformable registration, especially on cortical sulci and ventricles, brain cortex masks were auto segmented from the affine output images (CT or MR), corresponding to WM + grey matter (ANTS Atropos [6] for MRI and SPM CTseg for CT scan [7]), and were included in the parameters of the ANTS registration function. Cortical masks were then produced by auto-segmentation on the CT and MRI images obtained after affine + SyN transformations.
The anatomic accuracies of the final registrations (MR to ICBM space and CT ICBM space) were evaluated by computing DICE metric from cortical auto segmentations. We also computed DICEs after affine registration step only to verify the anatomical advantage of the combined final registration (affine + SyN).

With the goal to compute doses received by the WMT, transformation matrix from CT affine registration and CT deformation field from nonlinear registration were applied to the dose maps considering four different interpolators (bSpline, linear, gaussian and lanczosWindowedSinc) for both affine and SyN part, resulting in 16 different combinations of dose warping.
As well, the transformation matrix were applied to RT structures segments with GenericLabel interpolator.
Finally, to evaluate the consistency of warped dose maps and select the best interpolator combination, clinically relevant DVH metrics, such as organs at risk (OAR)(e.g., brainstem, brain, brain-PTV, cochlea, optic nerves, chiasm) mean dose and dose delivered to at least 0.035cc of the organ (D0.035cc) and PTV mean dose and dose delivered to 95% of the PTV (D95) were compared between initial dose map and the 16 final transformed dose maps depending on the interpolator type. DVH extraction was performed using PlatiPy python library.
Comparison of clinically relevant DVH metrics from initial dose maps and warped dose maps were made using boxplot representation of dose distribution.

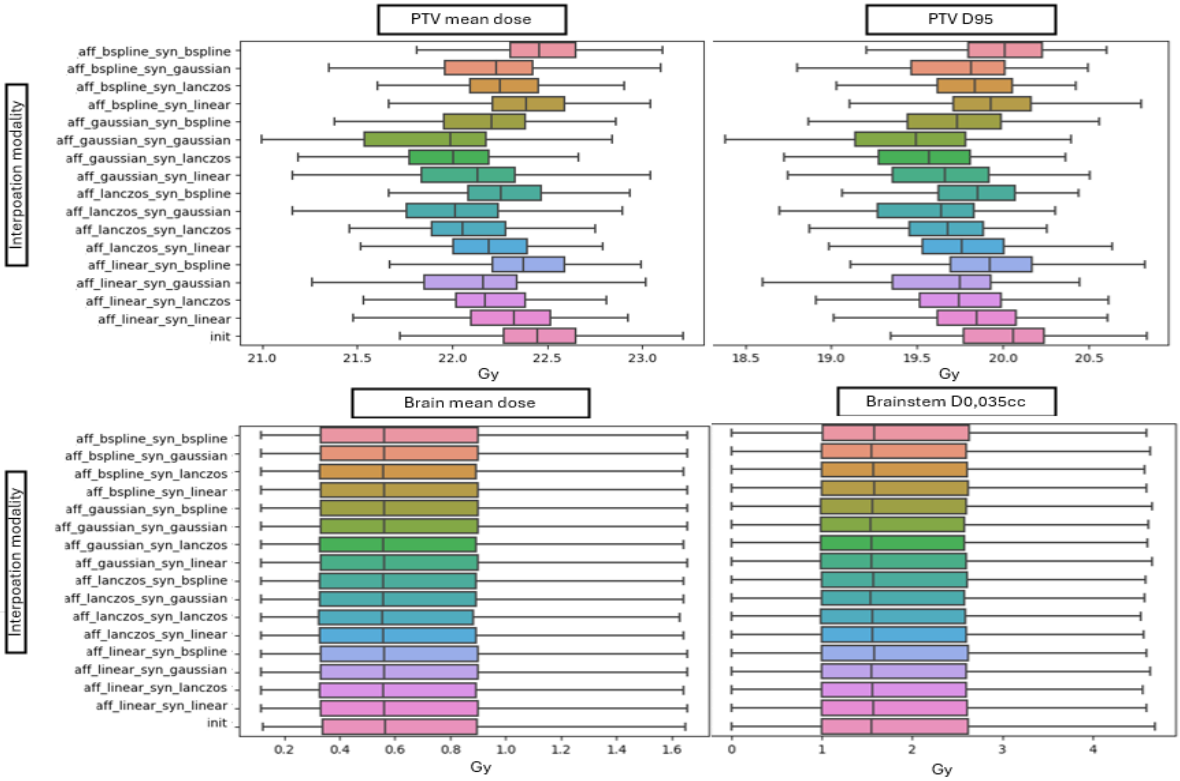

Figure 2. Boxplots of several DVH metric value distribution depending on the dose warping modality.

Init = initial dose map ; 16 dose warping modalities : bSpline, gaussian, linear and lanczos interpolator for affine and SyN registration.

3 Results

We applied our fully Python scripted pipeline to 112 patients treated by one 20Gy fraction SBRT for small BMs (<2cm).
For the T1 gadolinium enhanced MR to ICBM registration, mean DICE index of brain cortex was 0.82 (range: 0.66-0.89) for the affine step and 0.91 (range: 0.81-0.94) when the affine + SyN steps were applied. For the CT to ICBM registration, the corresponding values were equal to 0.79 (range: 0.54-0.89) and 0.89 (range: 0.62-0.92), respectively. For the dose transformation, 4 patients with cortex DICE index <0.80 were excluded to avoid erratic DVH values.
Figure 2 illustrates PTV D95% and mean dose, brainstem D0.035cc and brain mean dose distribution in boxplots, depending on the warping dose modality (linear, bSpline, gaussian and Lanczos interpolator for affine and SyN part). Dose distributions were quite similar between initial dosimetry and the 16 warped dose maps for OARs D0.035cc and Dmean. The transformation using bSpline interpolator for both affine and SyN parts seems to be the better option for PTV mean dose and D95, as the distribution of the dose values were closer to the initial dose map for this warping dose modality.

4 Discussion

Here, we implemented a fully Python scripted pipeline allowing the visualization of brain pre-SBRT MRI and CT scan, dose plan and WM tracts on an open-source tractography atlas (as illustrated in Figure 3).

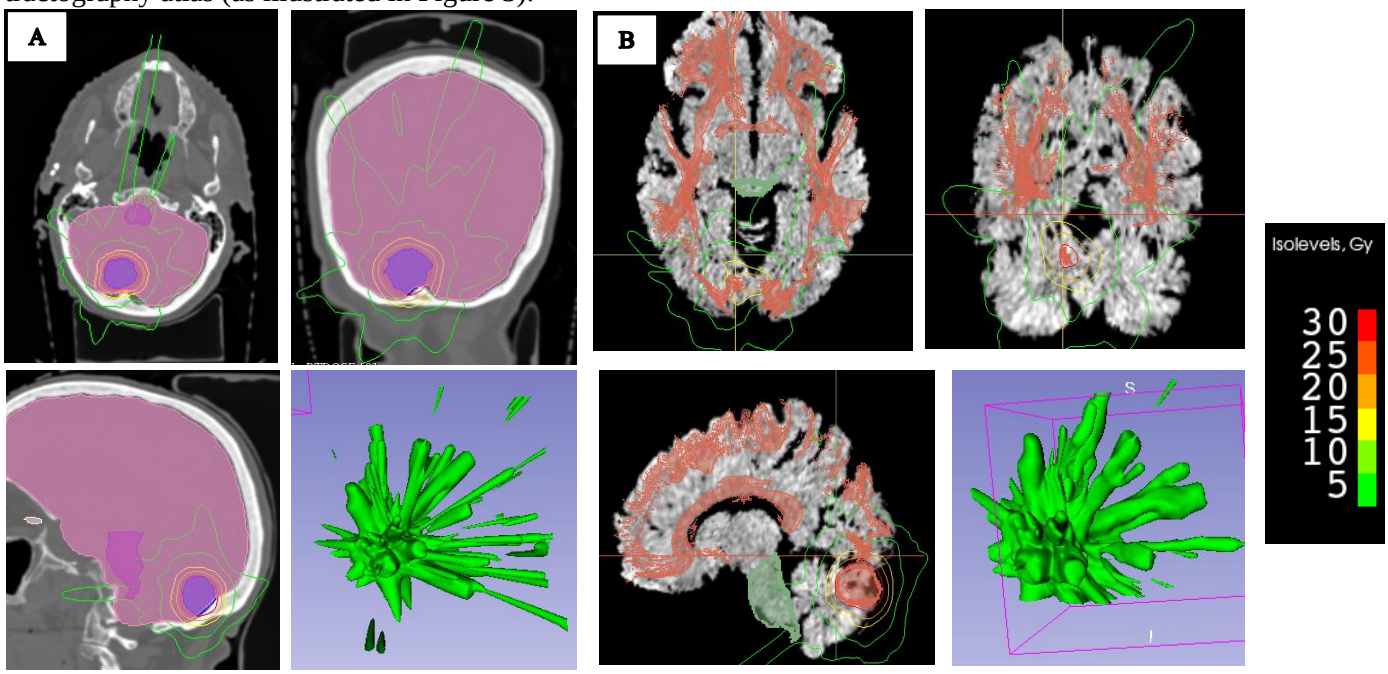

Figure 3. Workflow application on a patient treated with 1x20Gy SBRT for a right cerebellar BM.

A. Initial treatment planning on brain CT scan. B. Transformed brain CT scan and its associated dose map.

We choose to propose both MR and CT registration pipeline for different purpose. Because of its best anatomical accuracy, the T1 enhanced MR registered images could be used in a clinical setting for tract visualization and its relation to tumor volume before SBRT planification and could be a tool to guide the radiation oncologist therapeutic decision. On the other hand, because planning dose maps and RT structures segments are derived from the planning CT, the CT registered images will allow DVH calculation on WM tracts. We seek to derive dose constraints to WM tracts by applying our pipeline to a large amount of BMs patients already treated by SBRT in our institution. As it stands, the computational time is about 30 minutes per patient on a NVIDIA RTX A1000 Laptop 4 GB GPU, but we seek to improve the performance of the pipeline with more powerful GPU.
Regarding our choice of Mutual Information as similarity metric, several intensity-based image metrics appear in the literature with varying performance depending on their application, but mutual information has advantages in dealing with scanner variations and pathomorphological changes [8] and was more suitable for BM population and for multimodality (T1 gado weighted MR to T1 weighted MR and CT to T1 weighted MR) image registration.
Furthermore, adding an individual auto segmented cortical mask in the parameters of the SyN registration provided an anatomical constraint to the registration, favoring clinical plausibility of the transformation.
Despite recent guidelines on dose mapping/accumulation in radiotherapy [9], there is still some discussion on how dose distributions should be resampled when deforming them with a transformation and no consensus has been made on the choice of the interpolation method. To address this, we choose to evaluate 4 different type of interpolation for affine and SyN dose warping, resulting in 16 warped dose maps. It appears that for mean and maximum doses to OAR, there

is a very slight difference between the 16 interpolation methods. On the other hand, the bSpline interpolation method showed better similarity to the initial dose regarding the mean dose and the D95% delivered to the PTV. BSpline interpolation seem to provide better consistency in dose distribution when dose warping, especially for high doses.

5.Conclusion

Here, we present the first fully automated pipeline allowing registration of pre-SBRT planning imaging, dose map and atlas derived WM tracts. This easily applicable pipeline will make more accessible WM structural connectivity to the radiation oncologist community. From this method, applicable without performing DTI in a large number of patients, we seek to derive dose constraints to WM tracts. In the future we believe that this method will enable radio oncologists and physicists to propose WM sparing dosimetry.

Abstract This work aims at investigating the impact of DNA geometry, compaction and calculation chain on DNA break and chromosome aberration predictions for high charge and energy (HZE) ions, using the Monte Carlo codes Geant4-DNA, RITRACKS and RITCARD. To ensure consistency of ion transport of both codes, we first compared microdosimetry and nanodosimetry spectra for different ions of interest in hadrontherapy and space research. The Rudd model was used for the transport of ions in both models. Developments were made in Geant4 (v11.2) to include periodic boundary conditions (PBC) to account for electron equilibrium in small targets. Excellent agreements were found for both microdosimetric and nanodosimetric spectra for all ion types, with and without PBC. Some discrepancies remain for low-energy deposition events, likely due to differences in electron interaction models. The latest results obtained using the newly available Geant4 example "dsbandrepair" will be presented and compared to DNA break predictions obtained with RITCARD.

1 Introduction

At the cellular scale, energy deposition events induced by low linear energy transfer (LET) ionizing radiation create biological damage including DNA double strand breaks (DSB) that are relatively homogeneously distributed. On the contrary, high LET radiation, such as high charge and energy (HZE) ions, are well known to induce heterogeneously distributed energy deposition events that can create complex biological damage, including clustered DSB. Clustered DSB are critical damage events difficult to repair, leading to increased cell death and chromosome aberrations (CAs) compared to low LET radiation exposure. This increased biological effectiveness makes high LET ions of great interest in medicine for increasing the therapeutic efficacy of cancer treatment, an advantage utilized in hadrontherapy. However, exposure to HZE ions also comes with carcinogenesis risks, which is an issue for both hadrontherapy (secondary cancer) and long-term space travel. Cellular biological mechanisms driving cancer initiation, promotion and progression for high-LET exposure remain to be fully elucidated[1] and constitute an active field of research. In that context, Monte Carlo track structure simulations are valuable tools to identify key cellular events and quantify the mechanisms.

The track structure code RITRACKS (Relativistic Ion Tracks) [Plante 2008], together with the code RITCARD (Relativistic Ion Tracks, Chromosome Aberrations, Repair, and Damage) [Plante 2019a], allow to simulate the transport of HZE ion tracks in micro and nanostructures. The yield of DNA damage is determined by calculating energy deposited in nanovoxels containing DNA, without details of the DNA geometry. Estimation of CA yields are obtained by modeling DSB (mis)repair and classifying the aberrations. However, DNA geometry influence the yield of DNA breaks. Previous numerical studies have shown that chromatin compaction decreases the yield of DNA damage generated by ionizing radiation, with dependence on ion charge and energy [Tang 2019]. Such changes in DNA damage yield are likely to impact CA yields and are thus important to consider in DNA damage and repair simulations.

We intend to use highly detailed DNA geometries available in the Geant4-DNA toolkit to compute DNA breaks for different level of DNA compaction and combine the results with RITCARD to determine the impact of DNA compaction on CA predictions. A first necessary step to fulfill this objective is to ensure the consistency of radiation transport models used in RITRACKS and Geant4-DNA.

The work that will be presented corresponds to this first phase of the project. We compared energy deposition at micrometric and nanometric scales for different ions with LET ranging from ~0.4 keV/µm up to 235 keV/µm. The calculation of DNA breaks and their complexity with the new calculation chain available in Geant4 11.2 is an ongoing work, and comparison with RITCARD will be presented based on availability at the time of the conference.

2 Materials and Methods

2.1 Geant4-DNA

Geant4-DNA is an open-source code developed through an international collaboration, that was originally initiated in the context of space radiation and extended to medical physics applications. It includes physics processes that allow event-by-event particle transport down to very low energy (typically down to 7 eV for electrons). It includes

[1] https://humanresearchroadmap.nasa.gov/

different geometric models of DNA for a full human cell nucleus with a detailed atomic-scale structure of the molecule[2] [Incerti 2018, Kyriakou 2022]. This precision allows to account for damage coming from both direct ionization of the DNA by ion tracks and secondary electrons, and the attack of chemical species on DNA, produced by the radiolysis of the surrounding water.

The presented results were obtained with the latest version of Geant4 (v11.2) using DNA-physics option 2, for which the model of heavy ion transport (*G4DNARuddIonisationExtendedModel)* was significantly updated. Calculations of the energy distribution of secondary electrons induced by water-ion ionization showed that Geant4 v11.2 results in a much better agreement with RITRACKS compared to previous Geant4 versions. In addition, developments were made in our Geant4 example to include periodic boundary conditions (PBC), based on previous work[3], as a solution to account for energy deposition due to delta electrons generated by distant tracks, simulating electronic equilibrium in small targets. The PBC is applied to electrons. We have also implemented an efficient nano-voxel mesh scorer compatible with the PBC option in order to compute the nanodosimetry spectra. Finally, we modified the physics list to extend the maximum energy limit for the *Rudd Ionisation Extended Model* from 300 MeV/n to 1 GeV/n for ions. We also modified the physics list to use the *Rudd Ionisation Extended Model* for proton and alpha particles. For alpha particles, cross sections were calculated to extend them from 100 MeV/n up to 1 GeV/n. This allows a consistent use of the Rudd ionization model for all ions.

The Geant4-DNA version 11.2 also contains two new DNA break calculation chains, called "*moleculardna*" and "*dsbandrepair*" that allows to calculate early radiation-induced DNA damage, such as DSBs and to model repair processes. The *dsbandrepair* application also contains different atomic scale models of DNA, including both the radioresistant heterochromatin (HC) compact form and the radiosensitive euchromatin (EC) less compact form. In a second step of this benchmark process, we intend to use this example to compare results of simple and complex strand break yields in our irradiation configurations, using both EC and HC DNA forms and compare it with the RITRACK/RITCARD DSB predictions. This is an ongoing work that will not be described further in this abstract.

2.2 RITRACKS/RITCARD

RITRACKS/RITCARD has been developed by NASA, focusing on space radiation applications. RITRACKS is a Monte Carlo track-structure code that simulates the full transport of protons and high charge and energy particles using the Rudd model, as well as the secondary electrons down to very low energy, as detailed elsewhere [Plante 2008, Plante 2011a]. Recent developments include the possibility to activate PBC in micrometric volumes to account for energy deposition in targets by energetic delta electrons generated by distant tracks. RITRACKS can calculate energy deposition in nanovoxels as well as in spherical and cylindrical micrometric targets [Plante 2011b, Plante 2021]. Contrary to Geant4-DNA, RITCARD calculates DNA DSBs based on energy deposited within nanovoxels containing 2,000 kbp of DNA, encompassing both the direct and indirect effects without going down to details at the atomic scale. RITCARD also includes repair processes which can account for dose-rate effect. Finally, RITCARD allows to classify the damage events into CA, an option not yet available in Geant4-DNA.

2.3 Micro- and nanodosimetry spectra

We calculated single track energy deposition distributions in micrometric and nanometric targets for several monoenergetic ion beams. The energy imparted to the target, ε (in eV or J) is,

$$\varepsilon = \sum_i \varepsilon_i,$$

where the summation over ε_i represents all the energy deposition events (ionizations/excitations). $f_1(\varepsilon)$ is defined as the probability distribution of ε for a single ion track generating energy deposition events in the target. Comparisons were made for the following ions: $^{1}H^{+}$ (150 and 250 MeV), $^{4}He^{2+}$ (250 MeV/n), $^{12}C^{6+}$ (290 MeV/n), $^{16}O^{8+}$ (55 and 350 MeV/n), $^{28}Si^{14+}$ (170 MeV/n), $^{48}Ti^{22+}$ (300 MeV/n) and $^{56}Fe^{26+}$(300, 450 and 600 MeV/n). These ions were chosen because of their interest in hadrontherapy and space research, and experimental chromosome aberration data are available [Hada 2014, Plante 2019a, Plante 2019b]. The simulation set up for microdosimetry calculation is described in Figure 1. For both microdosimetry and nanodosimetry calculations, the geometry was set as a water box of 12 µm in the longitudinal direction (direction of ion transport), and 16 µm x 16 µm in transverse directions. It is worth mentioning that with the PBC option activated, when a delta-electron is re-injected in the world volume, it is considered as a new track, as it mimics contribution from distant tracks. To mimic particle equilibrium, PBC were applied as followed: when an electron passed through one side of the irradiated volume, it appeared on the opposite side with the same velocity vector. The irradiated box contained a micrometric target which was a centered ellipsoid volume with a transverse radius of 7.1 µm and a longitudinal radius of 2.5 µm, representing the cell nucleus of a human fibroblast in an adherence configuration[4]. The nanometric targets were cubical voxels of 75 nm side that

[2] http://geant4-dna.org/

[3] https://github.com/amentumspace/g4pbc

[4] https://geant4-dna.github.io/molecular-docs/

were distributed within the cell nucleus, which aims at representing a fragment of DNA. Single ion energy distribution $f_1(\varepsilon)$ were calculated using a logarithmic binning (1,000 bins) between 6 eV to 2×10^6 eV for microdosimetry and 6 eV to 2×10^4 eV for nanodosimetry. For microdosimetry, results are normalized so that the first moment of $f_1(\varepsilon)$ gives the average energy deposited by one track to a target. For nanodosimetry, results were normalized so that $\int_0^\infty f_1(\varepsilon)\,\mathrm{d}\varepsilon = 1$.

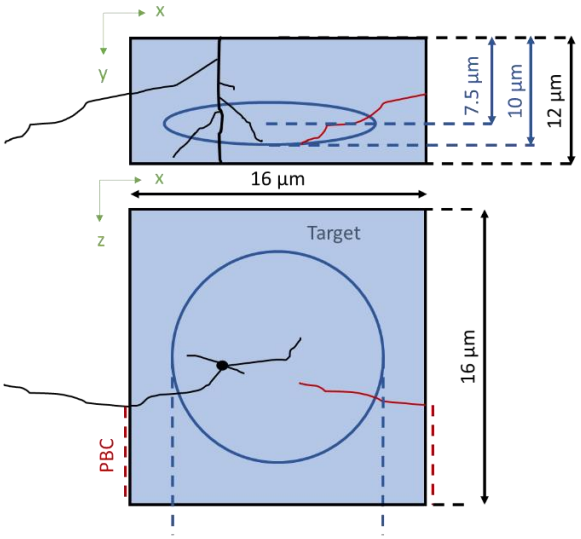

Figure 1. Simulation set-up for microdosimetry calculation. The light blue volume represents the simulated water volume, the dark blue circle the microdosimetry target, the black lines an ion track, the red line an electron that exited the volume and for which PBC were applied.

3 Results

Figure 2 shows the microdosimetry results obtained with Geant4 11.2 and RITRACKS with activated PBC for 9 different ions. Figure 3 shows the nanodosimetry results obtained with Geant4 11.2 and RITRACKS with activated PBC for 9 different ions. Excellent agreements were found for both microdosimetric and nanodosimetric spectra for all ion types and energies, with and without PBC *(without PBC are not shown)*. Microdosimetry spectra differ mainly for low-energy deposition events below 100 eV, especially for He, C and O ions, likely due to differences in electron interaction models. In the nanodosimetry spectra, slight discrepancies are observed in the 100 eV-10 keV ε range for heavy ions. These results will be presented at the conference with a deeper analysis on the comparisons.

4 Discussion and Conclusion

The present work aims at investigating the impact of DNA geometry on DNA break and CA predictions for HZE ions using the codes Geant4-DNA, RITRACKS and RITCARD. The first phase of the comparison process showed excellent agreements in microdosimetry and nanodosimetry spectra. This allows us to validate the Geant4-DNA newly released *Rudd Extended Ionisation Model* for heavy ion transport by comparing it with RITRACKS, that has been previously validated on several experimental data for HZE ions. In addition, we included changes in the Geant4 *Rudd Extended model* to also allow its use for alpha particles beyond 100 MeV/n. Finally, practical improvements were made to allow the use of PBC and registering physical data in both microstructures and nanovoxels, improvements that future Geant4 users may benefit from. The second step of code comparison between Geant4 and RITRACK/RITCARD is ongoing and will be dedicated to DNA break comparisons. It will focus on the impact of DNA geometry, compaction, and detailed direct/indirect effect consideration for DSB, and how such changes impact CA yields.

Whole-body blood circulation modeling and dose to circulating blood in intensity modulated radiation therapy

Bingqi Guo, PhD[1], Ping Xia, PhD[1]

[1]Department of Radiation Oncology, Cleveland Clinic, Cleveland, OH, USA

Abstract Dose to circulating blood is gaining interest in radiation oncology due to the potential impact of blood dose on the response of the immune system to radiation therapy. However, modeling the interplay of blood circulation with the dynamic delivery of intensity-modulated radiation therapy is challenging. In this study, a novel technique to model whole-body blood circulation was introduced. The model uses patient-specific anatomy from medical images and preserves realistic blood dynamics, distribution, and perfusion. To demonstrate the use of dynamic blood modeling in radiation oncology, the model was used to evaluate the dose to circulation blood in total body irradiation treated with multi-isocentric volumetric modulated arc therapy, one of the most complex techniques in radiation oncology.

1 Introduction

Dose to circulating blood is gaining interest in radiation oncology due to the potential impact of blood dose on the response of the immune system to radiation therapy. However, modeling the interplay of blood circulation with the dynamic delivery of intensity modulated radiation therapy is challenging. This study aims to develop a technique for realistic, patient-specific blood circulation modeling and explore its application in radiation oncology.

2 Materials and Methods

A. Creation of the whole-body blood circulation model

i. Organ, tissue and blood vessel segmentation

A whole-body CT scan with IV contrast was used for creation of the whole-body blood circulation model. Main organs of the body, heart chambers, aorta and vena cava, and pulmonary artery and veins were segmented using a commercial deep-learning based auto-segmentation software. Main arteries and veins were first segmented using an in-house algorithm which searches for tube-shaped contrast enhanced structures, then sorted into large arteries, hepatic veins, portal veins and other veins manually. Smaller vessels were assumed to distribute uniformly throughout the organs and tissues. Figure 1(a) shows the contours of the heart chambers, lungs, liver and main blood vessels.

ii. Blood dynamics

Figure 1(b) shows the blood dynamics diagram including the systole, diastole and portal circulations and the average blood concentration and perfusion values for main organs and tissues[1].

iii. Blood density map

The blood density map was created by dividing the blood concentration of each organ and tissue by its volume. Figure 1(c) shows the blood density map normalized to maximal value.

iv. Blood velocity maps

Blood velocity maps in the whole body in systole and diastole were calculated based on Table 1. In aorta, vena cava and pulmonary artery/veins, blood speed was assumed to decrease linearly as its travel distance from the heart chambers increases. For small vessels, organs and tissues, blood speed decreases linearly as the distance to the nearest large artery/vein increases. Figure 1 (d) and (e) shows the blood velocity map in systole and diastole, respectively.

Table 1. Blood speed

speed of blood [cm/s]	systole	diastole
Lt and Rt ventricals	60	28
Lt and Rt atriums		28
aorta and pul artery	20 - 60	
vena cava and pul veins		10 - 28
large arterie	20	
large veins		10
lungs, liver and smaller vessles	5 - 20	1.5 - 10
tissue	2 - 5	1.3 - 1.5

v. Time to heart/porta maps

Based on the blood velocity distributions and blood dynamics, the time to heart maps in systole and diastole were derived. For example, the systole time to heart in aorta is 0 at where aorta connects with left ventricle and increases as blood moves along the aorta. In every step of moving along the aorta, time to heart increases by delta distance divided by velocity. For portal circulation, time to porta hepatis, where the portal vein enters liver was calculated. Liver has negative time to porta hepatis values. Figure 1 (f)-(h) shows the time to heart/porta maps.

vi. Blood perfusion maps

Blood perfusion to each voxel in the whole body was calculated by dividing the blood perfusion of each organ and tissue by its volume. To create the (cumulative) perfusion maps, the path of blood flow from the heart to each voxel in systole and from each voxel to the heart in diastole was determined and the blood perfusion of the voxel was projected to the entire path. Time to heart/porta maps were used to determine the path of each voxel. Blood was assumed to move in the direction which minimizes the time to heart/porta while observing physiological limitations. The interface of aorta/vena cava/pulmonary artery/pulmonary veins with heart chambers should have the highest cumulative perfusion value of 100%. Figure 1 (i) and (j) shows the systole and diastole/portal blood perfusion maps, respectively.

vii. Simulation of blood circulation

In this study, heartbeat rate of 70 times per minute was used. One third of the heartbeat is systole and 2/3 is diastole. The blood density map, velocity maps, time to heart/porta maps, and perfusion maps were all used to simulate the blood circulation in the whole body. A blood "particle" was sampled from the whole-body blood density distribution at the beginning and its trajectory was calculated every 1/3 of heartbeat (dt). During systole, blood particle moves to a new location which satisfies the following conditions (1) it is a physiologically permitted move, e.g. from aorta to large artery; (2) the new location has a time to heart equals the current time to heart + dt; (3) the distance of the new location is no more than blood speed of current location times dt. All the voxels meeting conditions (1)-(3) were identified and the next step was sampled from the voxels using the systole perfusion map. Similar method was used to simulate trajectories in diastole and portal circulations.

Within each heartbeat, not all blood enters the circulation, some remain in the tissue/organ. For example, approximately 60% of blood exits the ventricles in each systole. The probability of a blood particle remaining in the current organ/tissue rather than continuing in the circulation is blood density / (blood perfusion + blood density).

Liver is an important organ in both diastole and portal circulations. In each diastole, the probability of a blood particle in liver continuing in portal circulation (moving away from portal veins) rather than diastole circulation (moving towards hepatic veins) equals portal perfusion / (portal perfusion + diastole perfusion).

1000 blood particles were simulated for 5 minutes. Two types of simulations were performed: assuming all blood particles exist left ventricle at the initial step, or randomly sample particles from the whole-body at the initial step.

B. Dose to circulating blood in VMAT-TBI

i. Multi-isocentric VMAT-TBI planning

Following our institutional protocol for total body irradiation (TBI), a multi-isocentric, volumetric modulated arc therapy (VMAT) plan was created to prescribe 12 Gy in 8 fractions to the whole-body while reducing doses to lungs and kidneys[2]. The VMAT-TBI plan consisted of 7 isocenters and 16 beams. 600MU/min was used for all isocenters except lung for which 200MU/min was used to reduce the mean lung dose rate.

ii. Dose to circulating blood

To calculate dose to circulating blood, segment (control point) doses of the VMAT-TBI plan were exported. Trajectories of the 1000 particles were synchronized with the VMAT-TBI delivery at each isocenter using an in-house delivery emulator. For each blood particle, doses received at every step in the trajectory during delivery were calculated and summed up. For comparison, dose to "static" blood pool was calculated by convolving the dose distribution of the VMAT-TBI plan with the blood density map.

3 Results

Figure 2 shows the trajectories of 100-1000 blood particles (a) existing the left ventricle and (b) randomly sampled from the body in 10 seconds-5 minutes. Each particle is assigned a random color. For small number of particles and/or short duration of simulation, the blood particles concentrate on large vessels and major organs (heart, lungs, and liver). With a larger number of particles and longer simulation time, trajectories of blood particles occupy the whole-body.

Figure 2(c) shows the dose distribution of the VMAT-TBI plan and the isocenters, beams, and delivery times at each isocenter. Delivery time ranges from 50s to 332s with lung isocenter having the longest delivery time. For this VMAT-TBI plan, figure 2(d) compares mean doses and cumulative dose volume histogram (DVH) to the "static" and dynamic blood pool in one fraction. The mean dose is comparable between the circulating blood and the "static" blood pool (1.50 +/- 0.35 Gy vs 1.43 +/- 0.36 Gy for the whole plan, and 0.66 +/- 0.34 Gy vs 0.75 +/- 0.60 Gy for the lung isocenter, respectively). However, dose volume histogram is very different. The mean dose to the circulating blood in VMAT-TBI equals the prescription dose (1.5 Gy in one fraction).

4 Conclusion

In this study, a novel technique to model the whole-body blood circulation was introduced. The model used patient-specific anatomy from CT images and realistic blood dynamics, distribution and perfusion. To demonstrate the application of dynamic blood modeling in radiation oncology, the model was used to calculate the dose to circulation blood in total body irradiation treated with multi-isocentric volumetric modulated arc therapy, one of the most complex techniques in radiation oncology.

Abstract
A framework is developed to include the preferred path of microscopic tumor invasion along muscle fibers in radiation target volumes. Following the novel idea that the directionality of muscle fibers inside the muscle can be represented by a flow velocity field, fluid flow simulations are performed with a computational fluid dynamics solver using the finite-elements method. The flow velocity fields are then embedded in a shortest path algorithm to model the microscopic infiltration around the gross tumor. The model assumes that the preferred path of microscopic tumor invasion is along the dominant muscle fiber direction estimated from the velocity field. The method was tested on a sacral chordoma tumor, a malignant tumor originating in the pelvis with suspected microscopic invasion of the gluteal muscles.

1 Introduction

Chondrosarcoma is a type of cancer that originates in cartilage cells and typically develops in bone structures of the pelvis, femur, upper arm, or shoulder blade [1]. One of the major uncertainties in the treatment of chondrosarcomas is how to account for microscopic tumor invasion into the surrounding musculature. It is known that tumor cells encounter greater resistance in the transverse direction of the muscle fiber than in the longitudinal direction [2]. Therefore, to maximize the therapeutic effect, one should use radiation target volumes with more generous margins in the longitudinal direction of the muscle fiber. However, defining such target volumes is a real challenge because CT images have poor soft tissue contrast and therefore cannot provide much intramuscular information. In addition, the typical clinical expansion algorithms that are used to generate radiation target volumes are unable to account for muscle-specific orientation and muscle fiber architecture. As a result, physicians are currently limited to manually delineating target volumes or using expansions along the major anatomical axes, which is an oversimplification of the complex muscle anatomy.
A promising computational approach in the field of biomechanics is the analysis of muscle force generation by representing muscle fibers as an idealized flow of a fluid within the boundaries of the muscle surface. In [3, 4], the equivalence was made between muscle fibers connecting bones through the origin and insertion with an irrotational and incompressible flow between a source and drain. It was shown that the orientation of the vector field from such fluid flow simulations can reproduce the microscopic muscle fiber orientations obtained from the patient's diffusion tensor image, which is a direct representation of the muscle microstructure.
The goal of this study is to combine recent advances in automatic expansion algorithms and fluid flow simulations to create radiation target volumes with local muscle fiber orientation into a single framework. The framework is tested for a sacral chordoma, a type of chondrosarcoma that develops in the sacrum with suspected infiltration in the surrounding gluteal muscles.

2 Materials and Methods

This section presents the framework for obtaining radiotherapy target volumes with muscle fiber information. The main goal is to generate the clinical target volume (CTV), which includes the volume of suspected microscopic tumor invasion. The CTV is obtained as a geometric expansion of the gross tumor volume (GTV), where the GTV-to-CTV expansion is spatially modulated according to the preferred mode of tumor invasion along the muscle fiber direction. The calculation is based on volume delineations of muscles and their corresponding attachment sites (muscle origins and insertions). Here we use a patient, called the *template* patient, with the complete set of delineations available, which serves as the basis for the flow calculations. The results can then be mapped to other different patients, called *target* patients, that do not have attachment delineations available. In short, the workflow consists of (a) performing fluid flow simulations in the template patient for the different gluteal muscles, (b) mapping the flow fields onto the target patient, and (c) generating radiation target volumes by including the mapped flow fields in a shortest path calculation [5]. The first step requires the use of the Finite Element Method (FEM) in a mesh-like geometry as explained below.

2.1 Flow simulation & mesh generation

The flow in a simply-connected domain can be described as a potential flow, through the use of a velocity potential ϕ. Assuming that the flow is both irrotational and incompressible, the Laplacian, ∇^2, of the velocity potential must be zero and the problem reduces to solving a Neumann boundary value

problem for the Laplace equation:

$$\begin{aligned} \nabla^2\phi &= 0, \quad \text{in muscle} \\ \nabla\phi \cdot \mathbf{n} &= 0 \quad \text{on muscle} \end{aligned} \tag{1}$$

$\mathbf{n}$ denotes the vector normal to the muscle surface, so the second equation imposes a zero flux condition at the muscle periphery. Fixed Dirichlet boundary conditions are imposed at the origin and insertion sites in order to simulate a flow between a source (origin) and drain (insertion):

$$\begin{aligned} \phi &= a \quad \text{in origin} \\ \phi &= b \quad \text{in insertion} \end{aligned} \tag{2}$$

with scalar values a and b. Since only the orientation of the potential flow is relevant to our problem, the values for a and b can be arbitrarily chosen as long as $a \neq b$. Finally, the flow velocity field $\mathbf{v}$ is obtained as $\mathbf{v} = \nabla\phi$. Fig. 1 A) gives a schematic overview of the problem statement.
All binary volumetric structures extracted from the patient dicom files were converted into volume meshes in Python. First, the *skimage* marching cubes algorithm is used to find a surface mesh from binary volumetric data. Then, the *pygalmesh* library is used to generate a volumetric tetrahedral mesh from the surface mesh [6], which is used as the domain for the FEM computation (see Fig. 1 B). Eq. (1) is solved using the open-source FEM computing platform FEniCS [7].

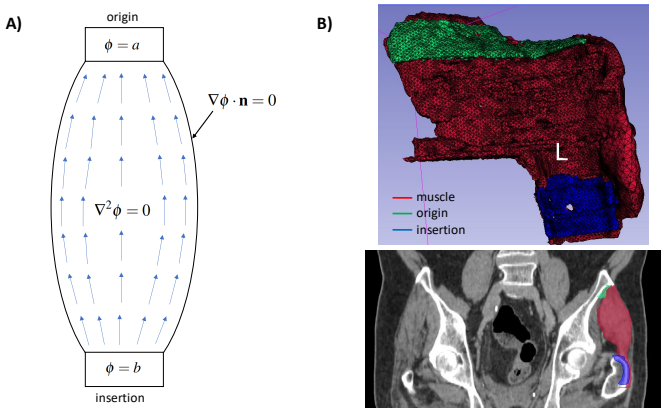

Figure 1: A) Schematic drawing of the Laplacian flow simulation problem. B) Example of the template gluteus medius mesh structures showing the muscle, origin and insertions (top), and associated CT image with structure segmentations (bottom).

2.2 Shortest path calculation & volume generation

A GTV-to-CTV margin can be obtained by using a shortest path calculation with GTV at the origin. Within this framework, the CTV is defined as an iso-distance contour in the 3D shortest distance map. The shortest distance S can be found as a solution to the Eikonal equation [5, 8]:

$$\nabla^{\mathsf{T}} S \cdot \mathbf{G}^{-1} \cdot \nabla S = 1, \tag{3}$$

where $\mathbf{G}$ is a positive semidefinite tensor of second order, called the Riemann metric tensor, or simply the metric. The metric plays an important role because it models the suspected tumor infiltration distance in a tissue. The relationship between the metric and the velocity field can be established by identifying the orientation of the velocity field as the orientation of greatest distance increase in the space defined by the metric. One way to formalize this relationship between $\mathbf{G}^{-1}$ and $\mathbf{v}$ is by first, creating a 3×3 tensor as the outer product, $\otimes$, of $\mathbf{v}$ with itself and performing a spectral decomposition:

$$\mathbf{v} \otimes \mathbf{v} = Q \cdot \Lambda \cdot Q^{-1}, \tag{4}$$

with Q and Λ the matrices of eigenvectors and eigenvalues, respectively. Second, replacing Λ by a parameterized diagonal matrix $diag(\alpha, 1, 1)$ and defining:

$$\mathbf{G}^{-1} \equiv Q \cdot diag(\alpha, 1, 1) \cdot Q^{-1}. \tag{5}$$

α is a dimensionless free parameter that controls the relative distance increase along the principal eigenvector which, in this context, corresponds to the preference for tumor invasion along the dominant muscle fiber direction.
The shortest path equation was solved using the Python-based fast marching solver HamiltonFastMarching [9].

2.3 Image registration & velocity field transformation

Image registration is used to transform the flow velocity fields from the template patient to the target patient for insertion in (3). Let $\mathbf{v}_1, ..., \mathbf{v}_n$ be the flow velocity fields for a set of n muscle compartments in the template patient. n separate displacement vector fields between the muscle compartment pairs. The transformed flow velocity fields in the target patient are then obtained by multiplying each velocity field by the *inverse* Jacobian matrix J of its associated displacement vector field, $\tilde{\mathbf{v}} = J^{-1} \cdot \mathbf{v}$ [10]. Similarly, the $\mathbf{G}^{-1}$ can be transformed directly according to the tensor transformation rule:

$$\tilde{\mathbf{G}}^{-1} = J^{-1} \cdot \mathbf{G}^{-1} \cdot J^{-\mathsf{T}}. \tag{6}$$

Eq. 6 allows the mapping of velocity fields between different patients by accounting for geometric differences such as differences in size and shape of muscles. Therefore, replacing $\mathbf{G}^{-1}$ by $\tilde{\mathbf{G}}^{-1}$ in (3) enables the calculation of a 3D shortest distance map in the target patient image.
Deformable image registrations between muscles was performed using DIPY (version 1.6.0) [11].

2.4 Patient data

A sacral chordoma patient, with manual delineations of the gluteus maximus, gluteus minimus and gluteus medius is used as a template image for obtaining muscle fiber information. The origin and insertion sites for all muscles of the template patient were delineated by an experienced radiation oncologist in our institution. Another sacral chordoma patient without origins/insertions available was used as a target image to generate the CTV. The hip bones, which act as

an impermeable barrier to tumor infiltration, were autosegmented on the CT image using TotalSegmentator (version 2.0.5) [12].

3 Results

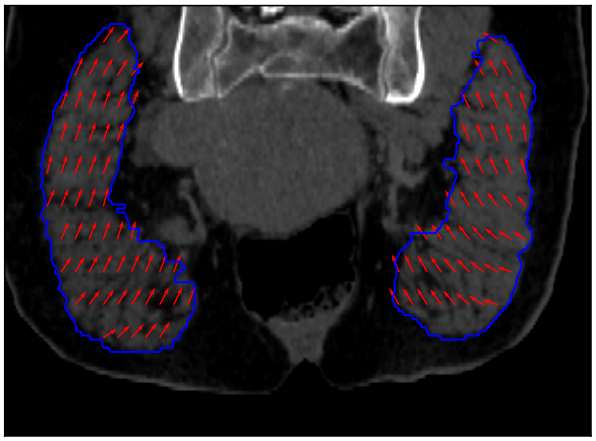
This section presents the results of the flow simulation in the template patient, followed by a comparison of the CTVs in the target patient with and without the inclusion of preferential models of tumor invasion.

3.1 Flow simulations

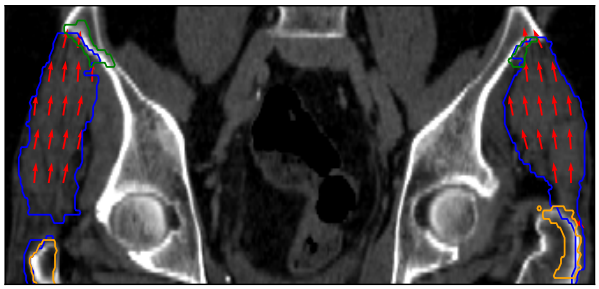
Fig. 2 shows the flow velocity fields in the template patient, overlayed on the CT image for the various gluteal muscles. As displayed, the FEM obtained smooth vector fields that can be mapped to the target patient.

3.2 CTVs

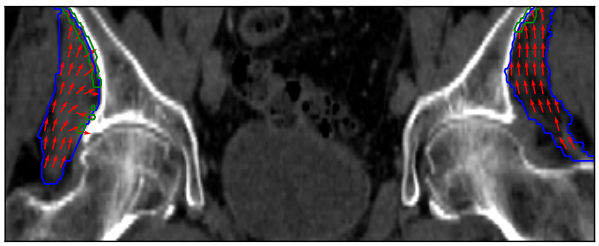
Fig. 3 compares the CTVs in the patients with and without muscle fiber orientation. The reference CTVs are defined as volumes with a 10 mm margin around the GTV in non-muscle tissue and larger margins of 20 mm and 30 mm in the gluteal muscles. The fiber-specific CTVs were generated by specifying a value of $\alpha > 1$ in the gluteal muscles and $\alpha = 1$ in the other tissues. As α increases, the model increases its preference for muscle invasion along the muscle fiber direction. We choose values for α equal to 4.0, and 9.1 because these specific values for α correspond to the standard CTV ranges mentioned earlier.
Significant differences in the shape of the CTVs are observed, especially as the CTV margins become more anisotropic. The difference between the reference CTV and the muscle fiber CTV was quantified using the 95% Hausdorff distance (HD95). The HD95 was 7.6 mm, and 13.9 mm for the (10 / 20) mm and (10 / 30) mm CTVs, respectively. This means that our proposed method has the potential to significantly impact current CTV delineation standards.



(a) Gluteus maximus



(b) Gluteus medius

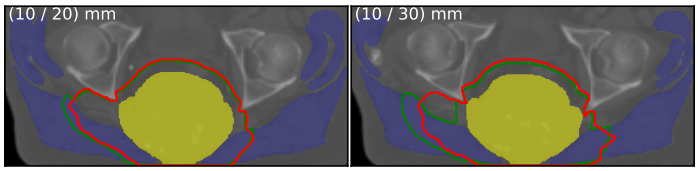


(c) Gluteus minimus

Figure 2: The flow velocity field obtained through Laplacian flow simulations are depicted by the red arrows within the (a) gluteus maximus, (b) gluteus medius and (c) gluteus minimus muscles. The flow vectors are assumed to be representative of the muscle fiber direction.

4 Discussion

In radiation therapy, the goal is to deliver a therapeutic dose to the CTV so that all tissues suspected of harboring tumor cells are treated. Currently, for chondrosarcoma treatments, the CTV is defined as a geometric expansion of the GTV by specifying a uniform margin in the muscle compartment. However, such an oversimplified approach does not take into account the mode of tumor invasion along the muscle fibers. As a result, tumorous tissue may be undertreated or radiation may be delivered to areas that are potentially tumor-free.
This study develops a computational method to improve the target volume definition for tumors with spread patterns along certain predefined structures such as skeletal muscles. Spread patterns were derived from Laplacian flow simulations to obtain patient-specific muscle fiber information. The Laplace equation is a fundamental equation in physics as it arises in a number of phenomena such as gravitational theory, electrostatics, fluid mechanics, and the heat equation. In this context, Laplace's equation is used to simulate a laminar flow that is representative of the directionality of the muscle fibers inside the muscle. Formally, potential flows governed by Laplace's equation are solutions to the time-independent Navier–Stokes equations for viscous (low Reynolds numbers), incompressible and irrotational fluids [4]. Realistic muscle fiber trajectories can be obtained by imposing different types of boundary conditions. First, a constant inflow and outflow was assumed at the origin and insertion sites, and second, a zero flux condition at the muscle periphery prevented muscle fibers from leaking through the outer muscle



(a) Axial slice.

surface .

Once the flow fields have been computed with the FEM, insertion into the shortest path algorithm enables the generation of radiation target volumes. The shortest path map models the preferential invasion for miscroscopic tumor invasion in the tissues surrounding the gross tumor. Here, the flow velocity is equivalent to the presumed tumor infiltration distance along its principal direction.

A limitation of the current implementation is that muscle insertions are not currently delineated in clinical routine. Therefore, the decision was made to manually delineate origins and insertions in a single patient CT image, which served as a template to provide muscle fiber information. Automatic segmentation of insertion sites may be an interesting avenue for future research to further personalize the model.

Future research will focus on validating the model, and introducing tumor-specific effects such as the displacement of origin and insertion sites by the gross disease and disruptions of muscle fibers. In prospective setting, model validation requires the use of DTI. Alternatively, retrospectively, the orientation and magnitude of the flow velocity fields can be informed by areas of recurrence after treatment.

5 Conclusion

This study presents a novel framework for incorporating the preferred path of tumor invasion into the clinical target volume for radiotherapy treatments. The directionality of tumor invasion was estimated using fluid flow simulations to obtain realistic muscle fiber trajectories. The method has the potential to improve the consistency and accuracy of the clinical target volume, thereby reducing the physician's time burden.

Abstract: The ability to better discern tumor from normal tissue has the potential to improve treatment efficacy. This study uses dynamic contrast enhanced (DCE)-based pathophysiological nested model-selection (NMS) technique along with wavelet-based spatiotemporal modeling of DCE-MRI information to characterize the RT response of tumor and normal brain in an animal model. Twenty-three immune-compromised-RNU rats were implanted orthotopically with human U251N glioma cells. 28 days after brain implantation, two DCE-MRI studies were performed 24hr apart. 20 Gy stereotactic radiation was delivered before the second MRI. NMS based DCE-MRI analysis was performed to distinguish different tissue regions. Time-traces of DCE-MRI information for different models were analyzed using a wavelet-based coherence analysis method to characterize and rank their RT-induced effects. Compared to the peritumoral tissues ($r=0.622$, $p<0.0001$), normal and highly permeable tissues ($r=0.650$ with $p<0.0001$ and $r=0.809$ with $p<0.0001$, respectively) are less impacted by RT. This study demonstrates a novel approach to discern peritumoral tissue from normal brain using acute changes in physiology in response to radiation therapy that has the potential to improve treatment planning and RT efficacy.

1 Introduction

An important issue affecting treatment efficacy in oncology is the ability to distinguish tumor from normal tissue. Recent studies [1-6] have shown that tumor and normal tissue vascular networks are characterized by different permeability and other physiological parameters. Furthermore, differential acute responses to treatment between tumor and normal tissue have potential to be exploited using decoded spatial and temporal signatures to facilitate and improve treatment planning.

In animal models, dynamic contrast enhanced (DCE)-MRI pharmacokinetic (PK) analysis shows promise as a stable descriptor of tumor physiology [1, 2], and of physiological reaction to treatments [1-6]. Our group has taken an important step toward the improvement of the image-based estimation of vascular permeability parameters by introducing a nested model selection (NMS) technique [7, 8].

This study combines a physiological NMS technique with a novel spatiotemporal modeling of wavelet-based information of DCE-MRI data, enabling evaluation of the RT-affected regions in an animal model of cerebral U251N tumors as well as the time-varying information content of the DCE-MR raw data on a voxel-by-voxel basis.

2 Materials and Methods

2.1 Animal Population, DCE-MR Studies, and Brain Irradiation: Twenty-three immune-compromised-RNU/RNU rats were stereotactically and orthotopically implanted with 5×10^5 U251N cancer cells (The U251N cells [9]were contributed by Dr. Tom Mikkelsen from Department of Neurosurgery, Henry Ford Health) in 10 µl of phosphate buffered saline (PBS) that formed a 3-4 mm diameter orthotopic glioma in two weeks post-implantation[10]. For each rat, two DCE-MRI studies (multi-slice, multi-echo gradient-echo sequence, with three 2.0 mm slices, no gap, matrix:128×64, FOV:32×32mm^2, $T_R/T_{E1}/T_{E2}$ = 24ms/2ms/4ms, flip-angle=18º, SW=150 kHz) were performed 24 hours apart using a 7T Varian (Agilent, 20cm bore system with Bruker console) scanner. Four-hundred slice packages at ~ 1.55s intervals (total experiment duration: ~10min) were acquired. A bolus of MR contrast-agent (MR CA-Magnevist) was injected (tail-vein) by hand push at acquisition 15. For each DCE-MRI experiment, two T1 mapping (TOMROP, T One by Multiple Read Out Pulses, or Look-Locker, LL) sequences [11, 12] were run to produce voxel-by-voxel maps of tissue T_1 prior to, and immediately after the Dual Gradient Echo (DGE) DCE-MRI study. All experiments in this study were performed in accordance with institutional regulations (IACUC#1509). A single 20Gy stereotactic-radiation exposure was delivered to rat brains before the second MRI which was acquired 1-6.5 hours after radiation.

2.2 Pharmacokinetic Analysis: We used the Standard Model (SM) for evaluating cerebral physiology [7, 8, 13] following measurement of contrast tracers using DCE-MRI experiment. A Tofts model [14, 15] was used to model the leakage of contrast agent (CA) in the vasculature system. After intravenous administration of CA, the CA concentration in tissue is given by:

$$C_t(t) = K^{trans} \int_0^t e^{-K_{ep}(t-\lambda)} C_p(\lambda) d\lambda + v_p C_p(t) \quad (1)$$

where: C_p and C_t are the plasma and tissue concentrations of the CA, K^{trans} is the volumetric forward transfer rate of the contrast agent into the interstitial space. The k_{ep} is the transfer rate from interstitial compartment to the vascular compartment, t and λ denote the experiment time, and v_p is the fractional volume of the vascular distribution space or plasma distribution space. We assumed that CA concentration, [Gd], is proportional to the change in the longitudinal relaxation rate (R_1) after CA administration:

[Gd] = CA(t) ~ $\Delta R_1(t)$, where $R_1 = 1/T_1$ (T_1 is the longitudinal relaxation time).

2.3 Nested Model Selection Technique: As shown in Figure 1, we have shown[7, 8] that three physiologically nested models (models 1, 2 and 3) can be derived from the standard Toft's model to describe possible pathophysiological conditions of underlying tissue pathology. We have generated a series of stable processing pipelines accordingly, for producing vascular parametric maps based on the NMS[7, 8]. As shown in this figure, NMS technique generated [16] three maps of brain regions labeled with the number of parameters used to describe the data: ***a)*** Model 1 region: normal vasculature with no leakage, the only parameter estimated is plasma volume, v_p; ***b)*** Model 2 region: leaky tissues with CA leakage without measurable back-flux to the vasculature, in which case, v_p and, K^{trans} can be estimated; or ***c)*** Model 3 region: leaky vessels with CA leakage and measurable back-flux and, thus, v_p, K^{trans}, and k_{ep}, or extracellular extra-vascular volume, v_e (ratio of K^{trans} and K_{ep}) can be estimated.

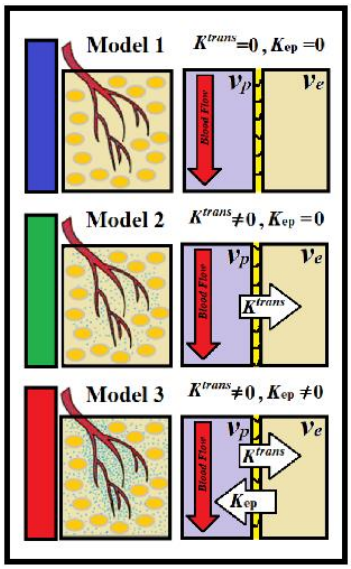

Figure-1: Three physiological Nested Models.

2.3 Nonstationary Time-Frequency Analysis: Normalized time-traces of DCE-MRI information (1st and 2nd echoes for pre, and post-RT cohorts) for three model regions extracted from all the rat brains were analyzed using a magnitude-squared wavelet-based coherence (MSWC) technique to characterize their time-frequency information before and after radiation. The MSWC technique is useful for analyzing nonstationary signals and recruits an analytic Morlet wavelet [17-19] to estimate the measures of the magnitude and phase correlations between two signals (reference and observation signals) in the time-frequency space. The wavelet cross-spectrum (WC) is a measure of the distribution of power of two signals (reference versus observation) [17-19] and for two time series time series, *R* and *O*, can be written as:

$$WC_{RO}(\Omega,\beta) = \vec{\varphi}(C_R^*(\Omega,\beta).C_O(\Omega,\beta)) \quad (2)$$

$C_R(\Omega, \beta)$ and $C_O(\Omega, \beta)$ denote the continuous wavelet transforms of signals R and O at scales Ω and positions β. The superscript * is the complex conjugate, and φ is a smoothing operator in time and scale domains. Therefore, the Wavelet coherence [17-19] is defined as the measure of the correlation between the two signals R, and O in the time domain as follows:

$$\frac{|\vec{\varphi}(C_R^*(\Omega,\beta).C_O(\Omega,\beta))|^2}{\vec{\varphi}(|C_R(\Omega,\beta)|^2).\vec{\varphi}(|C_O(\Omega,\beta)|^2)} \quad (3)$$

For each pathophysiological model, the pre- and post-RT signal coherence level was estimated using Equation 3. The coherence level of the time-frequency information (in the z space) was used to compare and rank the effect of radiation on different model regions corresponding to two different time-varying DCE-MRI raw signals (1st and 2nd echoes).

3 Results

An example of model selection map and its corresponding DGE (1st and 2nd echoes) images for a slice of a rat brain are shown in Figure-2. Figure 3A-F demonstrate amplitude and phase (black arrows) information changes within the cone of influence (certain area delineated by white dashed-line) of the two raw DCE-MRI signals (1st and 2nd echoes) due to the RT for different model regions (Subfigures 3A, 3B, and 3C for the 1st echo and 3D, 3E, and 3F, for the 2nd echoes) at different time points (10 sec/sample). Subfigures 4A-B illustrate the variation of the coherence level between the pre and post RT for the two raw-DCE-MRI signals (subfigures A and B for the 1st and 2nd echoes, respectively) for three different model regions (blue, green, and red for Models 1, 2, and 3 respectively).Figure 3A-F along with subfigures 4A-B demonstrate the magnitude-squared of coherence (RT affected coherence level) for normalized frequency at different timepoints for the two raw-DCE-MRI signals for three different model regions. These figures illustrate that the higher loss of coherence (RT-induced signal changes, r=0.622 with p<0.0001) belongs to the Model 2 regions compared to Models 1 and 3 (r=0.650 with p<0.0001 and r=0.809 with p<0.0001 for Models 1 and 3, respectively).

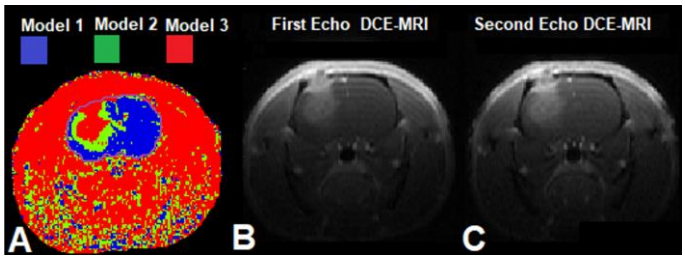

Figure-2: Subfigure 2A-C show model choice map, the 1st and 2nd echo images for a slice of a rat brain. The smooth muscles outside of the rat brain are classified as highly permeable tissues (Model 3, in red color).

4 Discussion

In this study, we assumed that CA concentration, [Gd], is proportional to the change in the longitudinal relaxation rate (R_1) after CA administration: [Gd] = CA(t) ~ $\Delta R_1(t)$, where $R_1 = 1/T_1$ (T_1 is the longitudinal relaxation time). This assumption is supported in most DCE-MRI studies because they are carried out under the conditions of rapid repetition time and Ernst tip-angle adjusted for a mean decrease in R_1. Under these conditions, studies in multicompartmental systems demonstrate little effect of exchange mechanisms [20, 21].

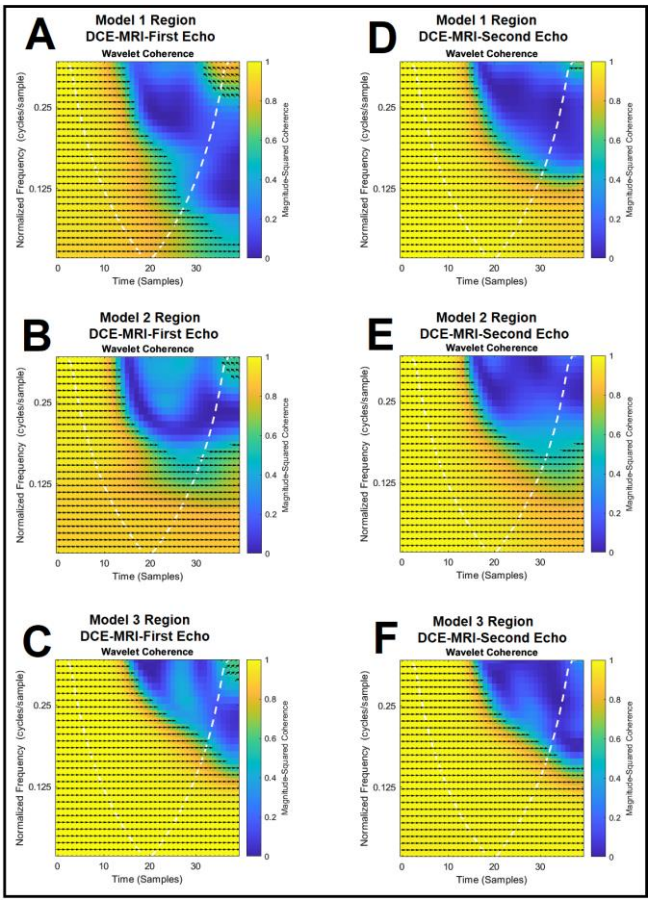

Figure-3: This figure shows the Magnitude-Squared of Coherence for normalized frequency at different timepoints (10 sec/sample) for the two raw-DCE-MRI signals for three different model regions: Subfigures 3A, 3B, and 3C for the 1st echo and 3D, 3E, and 3F, for the 2nd echoes.

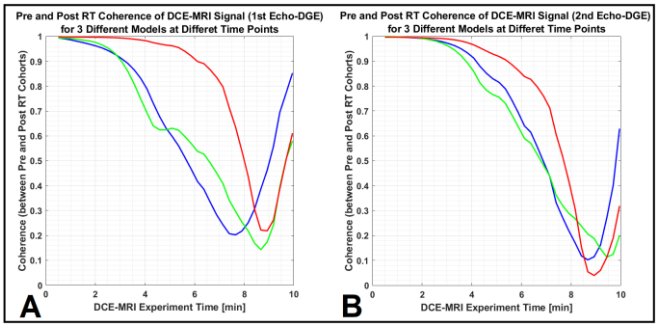

Figure-4: This figure shows the variation of the coherence level between the pre and post RT for the two raw-DCE-MRI signals (1st and 2nd echo signals) for three different model regions (blue, green, and red for Models 1, 2, and 3 respectively).

Figure 4A-B also illustrates that the highest RT-induced signal changes for all models occur during the 8 to 9 minutes of the DCE-MRI experiment (low-frequency components). As shown in Figure-4, compared to the 1st echo, the 2nd echo of the DCE-MRI information for all the three pathophysiological regions shows higher RT-induced changes at a later time (~ 9 min) of the DCE-MRI experiment. This is because that the 2nd echo signal is associated with the T_2* dephasing effect and directly affects the uncertainty level and heterogeneity content of the raw signal due to the local and static magnetic field inhomogeneity. Many studies have already shown that the DCE-MRI features of the U251N animal model tumors correlate with human Glioblastoma, including a necrotic center, poorly demarcated, infiltrative tumor borders, and an enhanced rim on T_2-weighted imaging (2nd echo in DGE exam). Our group is one of the few studying animal tumors using the DGE pulse sequences. In the paradigm, vascular permeability, and parametric maps, allow separation of T_1 and T_2* effects. Further, the raw information of these two components can be used to model the extravascular space of the tumor, which plays an important role in response to therapy. The cerebral physiology and mechanical characteristics exhibit a high degree of uniformity across various species, as established by previous research [22-24]. This study's analysis offers insightful revelations about the specific components and regions influenced by radiation within the context of DCE-MR imaging. Moreover, it underscores the significance of these findings in delineating the microenvironment of human tumors. The acquired data holds considerable promise for enhancing the evaluation and treatment strategies of lethal human tumors. It is imperative for the clinical research community to integrate this knowledge to deepen their understanding of the fundamental physiology of solid tumors. Consequently, replicating and refining this research using clinical pulse sequences (such as Spoiled Gradient-Recalled Echo, SPGRE with single echo) at varied temporal resolutions could greatly benefit clinical studies in radiation oncology, offering substantial translational potential.

5 Conclusion

This pilot study shows for the first time that wavelet-based radiomic analysis combined with an NMS technique can effectively decompose DCE-MRI information to rank the irradiated tumor regions and its surrounding normal tissues by their temporal MR signal changes. This is an important first step toward characterizing RT-affected brain regions and the RT-induced temporal changes in raw DCE-MR experiment which both are fundamental in treatment planning of cancer patients, design and optimization of DCE-MR imaging, and pharmacokinetic modeling.

Abstract Treatment planning systems (TPS) are an essential component for simulating and optimizing a radiation therapy treatment before administering it to the patient. However, TPS commercialized by private companies are often black-boxes when it comes to the implementation of most of their features (i.e. image registration, dose calculation and optimization algorithms). This hampers and delay researchers when working with these TPS for implementing and testing new ideas. We have developed OpenTPS, a new open-source software platform (opentps.org), to foster high quality research involving treatment planning for external beam radiotherapy, and, in particular, for proton therapy. It is designed to be a flexible and user-friendly platform for medical physicists, radiation oncologists, and other members of the radiation therapy and research community. It serves to create customized treatment plans for educational and research purposes, particularly for emerging delivery and optimization techniques such as FLASH, arc proton therapy, or beamlet free optimization, among others.

1 Introduction

Planning a radiotherapy treatment is a complex task, which requires the acquisition of advanced medical images and the use of sophisticated algorithms to analyze these images, simulate the effect of radiation on the patient (i.e. dose calculation) and optimize the radiation dose distribution. Today, the main treatment planning systems (TPS) are marketed by big companies, which charge up to several hundred thousand euros for a license of such software. They come with multiple features and a user-friendly GUI, but their big drawback is their low modularity, lack of transparency accessibility to the code. This difficulties their use in research environments, sometimes delaying or hampering research projects. This is the case, for example, of projects that attempt to study treatment planning for new dose delivery modalities, faster optimization algorithms, more precise treatments, etc. Additionally, small research groups and clinics that do not have access to these expensive TPS experience a greater difficulty in conducting relevant research in the field, further slowing scientific progress in the field.

To address this issue, multiple groups have contributed to the development of open-source tools for treatment planning over the past decades. Well-known platforms are matRad [1], FoCa [2], CERR [3], or some modules embedded in 3DSlicer [4]. Our group has also a long experience in open-source tools, with the development of REGGUI [5] for image-processing, MCSquare [6] for Monte Carlo dose calculation in proton therapy, and MIROpt [7] for robust optimization in proton therapy. While these tools were entirely developed in Matlab and/or C++, in 2020 we embarked on a project to merge these existing tools and develop our own open-source platform, OpenTPS, using the state-of-the-art and widely-available Python programming language. OpenTPS (opentps.org) is designed to serve as a flexible framework for both personal and collective research efforts. Its open-source code is publicly available under the Apache-2.0 license. The code is designed to be easily extended and customized. The software is organized into two packages: the Core package, which is a library that defines data classes, data processing methods, and IO methods, and the GUI package, which offers a graphical interface for viewing and interacting with the data. In the current release, the Core package includes a range of features that are essential for proton therapy treatment planning, but extension to conventional radiotherapy treatments is being addressed and will be included in the next release. Some of the key features available in the current Core package of OpenTPS include:

- Data management and processing: DICOM importing, exporting and processing patient data.
- Dose computation: computing the dose from proton therapy treatment plans using fast Monte Carlo simulations with MCsquare.
- Treatment planning: creating treatment plans for individual patients, including the ability to define beam angles, energy levels, spot spacing, etc.
- Treatment evaluation: performing quality assurance checks on treatment plans, including the ability to evaluate robustness, compare doses, and assess the conformity of the treatment plan to the patient's anatomy.
- Data augmentation: creating artificial variations of patient data for robustness evaluation and for machine learning applications.

In the next section, we detail these tools and give an example of their use for two use cases: 1) implementation and evaluation of advanced optimization techniques of arc proton therapy, and 2) generation of synthetic data to simulate and evaluate different scenarios of tumor motion.

2 Materials and Methods

2. 1. GUI

OpenTPS comes with an optional graphical user interface (GUI) for visualization of 3D images, dose maps, contours

and dynamic images. Several other interactive tools are available: profile plots, visualization of DVH, segmentation, etc. The implementation is based on the PyQt, VTK, and PyQtGraph libraries, which are widely recognized for their capabilities in data visualization and analysis in scientific and medical applications. Figure 1 shows a screenshot of the GUI loaded with a head-and-neck patient geometry and the optimized treatment dose associated to the case. In addition, graphical modules have been implemented to design and optimize a treatment plan. The entire GUI is extensible and modifiable by the user. Examples of extensions can be found in the OpenTPS documentation.

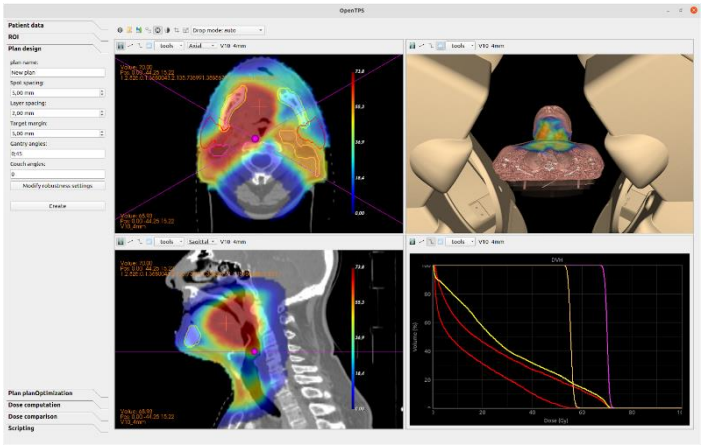

Figure 1. GUI with a head-and-neck cancer patient and an intensity-modulated-proton-therapy dose distribution.

2. 2. Core package

Data management and processing

The current version of OpenTPS supports the import patient data in DICOM format (CT, RT structures, RT dose, RT ion plan and vector field), MHD format (3D images), and OpenTPS-specific serialized object format. DICOM and MHD export is also supported.

The core library of OpenTPS includes a range of common image processing methods: resampling, coordinate sys- tem conversion, affine transformations, and filtering. Additionally, it has segmentation options such as automatic segmentation for body, lung and bones in CT images.

Rigid and deformable image registration methods are available, including the diffeomorphic Morphons algorithm [8]. The morphons registration is also used to create motion models. Deformation fields between the 4DCT phases are computed. Then with the deformations from all 4DCT phases, the midposition (MidP) image [9] can be computed. A motion model, called Dynamic3DModels in OpenTPS, is composed of the MidP image and the various deformation fields from the MidP image to each of the 4DCT phases.

Digitaly reconstructed radiographs (DRR) can also be computed using a 3DCT to simulate in room x-ray devices.

Dose calculation

A stable release of the fast Monte Carlo for proton therapy, MCsquare, is included in OpenTPS. However, OpenTPS is designed with the flexibility to support multiple dose engines and we are currently working on the implementation of photon dose calculation algorithms, both Monte Carlo and analytical.

MCSquare is available via the class MCsquareDoseCalculator and can be used to compute dose distributions, dose influence matrices, and LET distributions. Input paramaters such as the number of primaries, the beam model and the CT calibration are required to compute a dose based on CT and a treatment plan. From those inputs, MCsquareDoseCalculator generates the files required by MCsquare. Then, MCsquare simulates the interaction of each particle in batches until it reaches a user-defined minimal statistical uncertainty, or it simulates all the primaries.

Plan optimization

The treatment planning module of OpenTPS provides a set of tools and functions that are used to create and optimize a treatment plan based on several inputs. In general, the method followed depends on the treatment delivery modality chosen. As OpenTPS is initially built for research in proton therapy, the implementation of the treatment planning module conform to IMPT delivery, but implementation of IMRT and VMAT is being investigated. In proton pencil beam scanning (PBS), the dose is painted using scanning magnets that steer each pencil beam to a specific location in the target volume, namely a spot. Dividing the tumor into iso-energy layers, the treatment is therefore delivered by irradiating the volume spot-by-spot and layer-by-layer. This process is repeated for each irradiation direction. The modulation of the spot intensity is the aim of plan optimization. The optimal spot intensities result from solving a optimization problem where the user has built a cost function based on dose-volume objectives for the target volume and organs at risk (Figure 2).

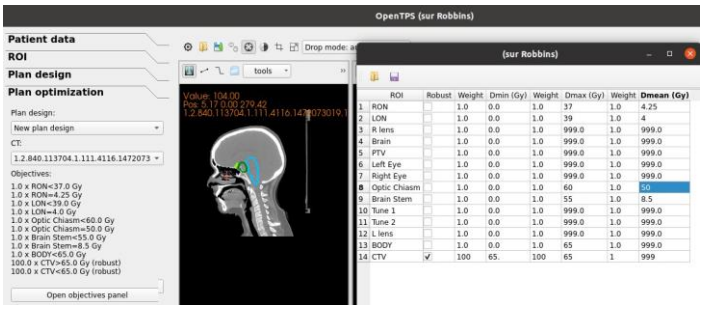

Figure 2. Objectives panel of the OpenTPS GUI.

OpenTPS comes with several built-in optimizers that solve the above problem. It is also designed so that other optimizers may be easily implemented. A variety of iterative solvers are provided: quasi-Newton's methods from Scipy, in-house implementation of LBFGS algorithms [10], gradient-based methods such as the classical gradient descent and the FISTA algorithm [11] from PyUNLockBox [12]. FISTA solves non-differentiable convex optimization problems by proximal splitting. For example, it can be of particular interest for ArcPT treatment plan optimization where one wants to maximize the spot sparsity by adding a l1-

norm penalty to the total objective function. Linear programming [13] methods are also available and can be used to solve the optimization problem. Based on the list of objectives in the plan design, a model is built with linear equations instead of the typical quadratic version. The model and the solver are built on the Gurobipy package [14], a Python interface to the powerful Gurobi solver, which requires a specific license. Gurobi includes a variety of algorithms to solve linear programming problems.

Treatment evaluation
In OpenTPS, a dose-volume histogram (DVH) evaluation is performed to assess the quality of the treatment plan. For proton therapy, it is important to assess the robustness of the plan to treatment uncertainties, thus robustness evaluation must also be performed on different uncertainty scenarios and not only on the nominal case, leading to a DVH-band instead. Two strategies are available depending on the scenarios definition. The first method, which is based on good practice rules and is commonly used in clinical routine, involves verifying the dose in the error space for a small number of extreme scenarios [15]. In OpenTPS, the dose is re-computed with MCsquare for 81 scenarios resulting from a combination of the setup and proton range erros. The second strategy generates a confidence interval in the so-called dosimetric space. It refers to all possible realizations of the treatment plan, or the different dose distributions that could be achieved. Described in [16], the scenarios are randomly sampled by MCsquare. The analysis in the dosimetric space reports the percentage of evaluation scenarios that meet a certain criterion such as minimum dose coverage for a target percentage (e.g., 95% coverage for 90% of scenarios).

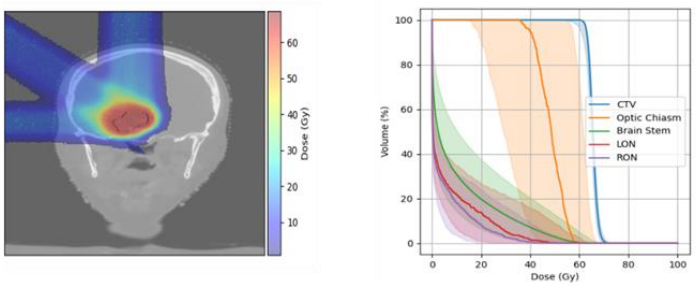

Figure 3. Example of a brain patient optimized in OpenTPS and robust evaluation of the plan (right) with the DVH-bands encompassing all uncertainty scenarios.

3 Results

Use case 1) Optimization in arc proton therapy.
Several solvers were implemented in OpenTPS to optimize arc proton therapy plans. Here, the arc proton problem is formulated as a MIP program and generates the best plan for a brain patient with only five upward energy switching (Figure 4). Details of the implementation and results can be found elsewhere [17].

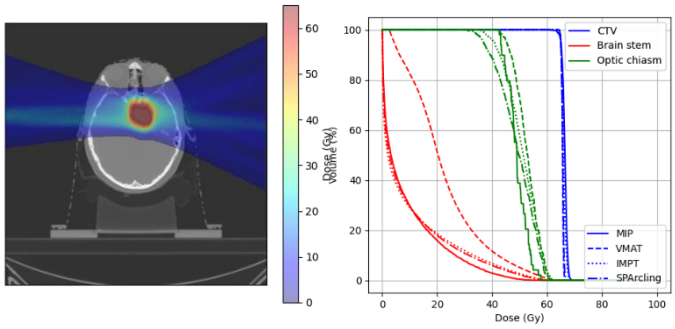

Figure 4. Left: Arc proton therapy dose distribution optimized in OpenTPS with Mixed-Integer Programming (MIP). Right: DVH comparison for Arc proton plans (in-house MIP optimizer, solid line and SPArc [18] technique re-implemented in OpenTPS, dashdot line), VMAT plan (dashed line) and conventional 2 lateral beam IMPT plan (dotted line).

Use case 2) Simulation of different tumor motion scenarios
Using a 4DCT based patient-specific breathing motion model, we can create sequences of variable length containing any desired variation of breathing pattern [19], as well as inter-fraction changes such as setup error simulations or target shrinks and baseline shifts. This way, the delivery of treatment plans can be simulated on these image sequences to assess the plan robustness against the chosen variation. This method of data augmentation is also used to train AI models [20].

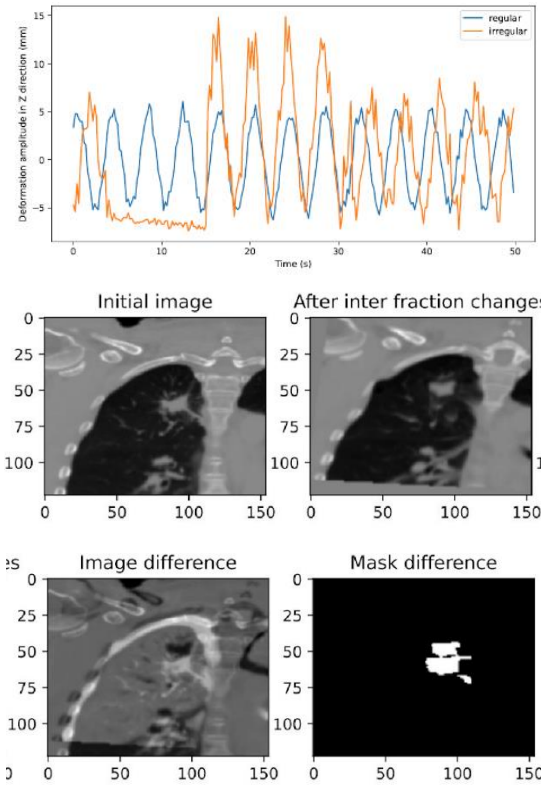

Figure 3. Example of synthetic breathing signals (regular and irregular), generated with OpenTPS tools (top), and example of synthetic inter-fraction deformations applied to and lung CT (bottom).

4 Discussion

OpenTPS is a unique platform for research in radiotherapy treatment planning, and particularly for proton therapy planning, in its current state. It is an open-source tool written in a user-friendly programming language. This allows for both internal contributions and international collaboration to enhance the platform quickly, making it increasingly sophisticated over time. Our research group is currently focusing on several exciting areas within OpenTPS, including arc proton therapy treatment planning and FLASH proton therapy. Depending on the needs of the users, new features might be added in the future such as (but not limited to) other treatment or image modalities, objects tracking or position prediction in dynamic sequences. Additionally, the platform has potential for real-time treatment delivery visualization and 2D to 3D image reconstruction.
The information to get started are available on our website (opentps.org) or on gitlab.

5 Conclusion

OpenTPS offers a flexible and dynamic platform for exploring new possibilities and pushing the boundaries of what is possible in radiation therapy and in proton therapy particularly.

Abstract In this contribution, we present GATE 10, the new version of the long-standing Geant4 application GATE, dedicated to medical physics, e.g. radiation imaging and radiation therapy systems. It features a Python-based user interface and integration of artificial intelligence methods. Moreover, being a Python package, GATE 10 can be easily integrated into external software, e.g. as a Monte Carlo dose engine. The user interface is easy to use, yet provides access to the rich functionality of Geant4 and preconfigured components of GATE (e.g. actors, sources).
GATE 10 is currently under rapid development and a first non-beta release is planned for May 2024. The software is open-source and available via the GitHub platform. Installation is performed via the Python package manager (`pip`). In this contribution, we present an overview of GATE 10 and a selection of new features and improvements.

1 Introduction

Since the beginning of GATE almost 20 years ago, users configure a simulation via macro commands grouped in text files [1, 2] similar to those in Geant4 [3]. Since then, the rise of high-level programming languages such as Python and new machine learning approaches have revolutionized scientific computing. The new version GATE 10 features a Python-based user interface and integration of artificial intelligence methods. Moreover, GATE 10 can be easily integrated as Python package into external software, e.g. as a Monte Carlo dose engine.

We have designed and implemented GATE 10 completely from scratch building onto the legacy of previous versions. On the one hand, it retains most of the features contributed to the code over time. This includes actors as well as preconfigured particle sources. Actors are collections of user actions to hook into Geant4's particle tracking to extract physics quantities, e.g. particle distributions, energy deposit, etc. GATE's particles sources are preconfigured primary particle generators including spatially distributed sources inside a patient for the use in nuclear medicine and imaging. On top of that, GATE 10 includes numerous new features and improvements, of which we will present a selection in this contribution.

2 Design principle of GATE 10

We have been developing GATE 10 with the following goals in mind:

1. Ease of use: The user should be able to concentrate on configuring the simulation rather than worrying about technical aspects of the software.
2. The Python script through which the simulation is set up should appear like an input file with the advantage of having access to all the computational tools available in Python and Python libraries (e.g. `numpy` [4]).
3. Give the user access to the rich Geant4-functionality, with a focus on applications in medical physics and medical imaging.
4. Provide an inner code structure with interfaces within which contributors can implement new features.
5. Keep a reasonable resemblance to the logic of older versions of GATE, i.e. version 9 and older.
6. Support a multitude of platforms including Linux, MacOS, and Windows.
7. Provide functionality to facilitate the logistics of running GATE simulations.
8. Do not compromise the simulation speed or even improve simulation speed compared to older versions of GATE.

3 Code structure

GATE 10 is composed of a part implemented in C++ and a part implemented in Python. The C++ library includes functionality that has a relevant impact on computational speed, i.e. mainly functions frequently called during particle tracking, e.g. after each step or at the beginning of each new track. This mainly concerns scoring (actors) and primary particle generation (sources). By implementing this part of GATE 10 in C++, Geant4 does not need to execute callbacks into Python code which would be associated with a computational overhead. Together with Geant4 classes and

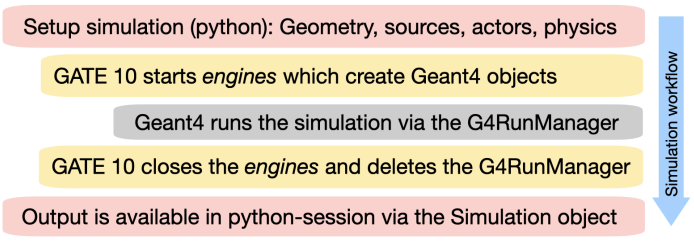

Figure 1: Workflow of a GATE 10 simulation from set-up to simulation run.

functions, the C++-portion of GATE 10 is exposed to Python via *pybind11* [5].

The pure Python part of GATE 10 provides a user interface to build simulations and an internal interface to Geant4. In particular, GATE 10 has two distinct kinds of classes which handle a simulation. *Managers* provide an interface to the user to set-up and configure a simulation and collect and organize user parameters in a structured way. *Engines* provide the interface to Geant4 and are responsible for creating all Geant4 objects. Managers and engines are divided into sub-managers and sub-engines responsible for certain logical parts of a simulation, such as geometry, physics, primary particle generation (sources), and scoring (actions, actors). Additionally, many components in GATE are implemented as classes which provide interfaces to the managers and engines. Figure 1 shows a scheme of the simulation workflow. The user sets up a simulation starting with the `Simulation` class, the main manager. It collects general parameters, e.g. about verbosity and visualization, and it manages the way the simulation is run (e.g., in a subprocess or not). Sub-managers are: `VolumeManager`, `PhysicsManager`, `ActorManager`, `SourceManager`. These managers can be thought of as bookkeepers. For example, the VolumeManager keeps a dictionary of all the volumes added to a simulation, a dictionary of all the parallel world volumes, etc. Furthermore, it also provides the user with methods to perform certain tasks, e.g. `VolumeManager.add_parallel_world()`.

The `SimulationEngine` is the main driver of the Geant4 simulation. Given a simulation object `sim`, it creates a new `SimulationEngine` every time the user calls `sim.run()`, which in turn creates all the sub-engines: `VolumeEngine`, `PhysicsEngine`, `SourceEngine`, `ActorEngine`, `ActionEngine`. The method `SimulationEngine.run_engine()` actually triggers the construction and run of the Geant4 simulation. It takes the role of the `main.cc` file in a pure Geant4 simulation. When the Geant4 simulation has terminated, `SimulationEngine.run_engine()` returns the simulation output which is then collected by the `Simulation` object.

GATE classes representing a Geant4 object (or multiple Geant4 objects combined as, e.g., in the Volume classes) are designed to do multiple things:

- Store user parameters. Example: the `Region` class holds the user parameters `user_limits`, `production_cuts`, and `em_switches`.
- Provide interface functions to the user and to manager classes to configure the object or inquire about it. Examples: `Region.associate_volume()`, `Region.need_step_limiter()`
- Provide interface functions to the engines to handle the Geant4 objects, such as `initialize()` and `close()`.
- Provide convenience functionality such as yielding the object's configuration as a dictionary (`to_dictionary()`), reloading it from a dictionary (`from_dictionary()`), dumping info about the object (e.g. `Region.dump_production_cuts()`), and copying the configuration from another object (`volume2.copy_user_info(volume1)`).
- Handle technical aspects such as serialization via pickling (e.g. for subprocesses dispatching) in a unified way.

4 Example: Dose calculation

In this section, we present a simple example to illustrate the use of GATE 10. The simulation consists of a patient parametrised via a CT image and a conversion table from CT numbers (in Hounsfield units) to material, a proton beam source, and a dose actor which scores dose on a voxel grid attached to the patient geometry. Secondary electrons are only produced inside the patient if their range is greater than 3 mm. The option `start_new_process=True` lets GATE 10 run the Geant4 simulation in a separate process. In this way, the simulation can be run multiple times in a loop, each time with a different beam energy. Dispatching to a subprocess also allows the user to run the same simulation multiple times in an interactive Python session, such as *ipython* or *jupyter*.

```
import opengate as gate
sim = gate.Simulation()
mm = gate.g4_units.mm
MeV = gate.g4_units.MeV
patient = sim.add_volume("Image", name="patient")
patient.image = "patient-4mm.mhd"
patient.mother = "world"
patient.voxel_materials = [
    [-2000, -900, "G4_AIR"],
    [-900, -100, "Lung"],
    [-100, 0, "G4_ADIPOSE_TISSUE_ICRP"],
    [0, 300, "G4_TISSUE_SOFT_ICRP"],
    [300, 800, "G4_B-100_BONE"],
    [800, 6000, "G4_BONE_COMPACT_ICRU"]]
patient.set_production_cut(
    particle_name="electron",
    value=3 * mm)
src = sim.add_source("GenericSource", name="p_src")
src.particle = "proton"
src.position.type = "sphere"
src.position.radius = 10 * mm
src.position.translation = [0, 0, -140 * mm]
src.n = 1e4 # number of primaries
src.direction.type = "momentum"
src.direction.momentum = [0, 0, 1]
dose = sim.add_actor("DoseActor", "dose")
```

```
dose.mother = "patient"
dose.size = [99, 99, 99]
dose.spacing = [2 * mm, 2 * mm, 2 * mm]
dose.img_coord_system = True
dose.translation = [2 * mm, 3 * mm, -2 * mm]
for en in [130, 140, 150, 160]:
    src.energy.mono = en * MeV
    dose.output = f"patient_dose_energy_{en}.mhd"
    sim.run(start_new_process=True)
```

5 Memory management between Python and Geant4

In this section, we describe a rather technical detail about the combination of Geant4 and Python which is, however, crucial to make simulations work correctly. GATE 10 creates certain kinds of Geant4 objects within code on the Python-side while other Geant4 objects are created on the C++-side, in particular by Geant4 itself. To avoid memory leakage, Geant4 objects need to be deleted at the end of a simulation, either by the C++-side, usually meaning Geant4, or by the garbage collector on the Python-side. This requires some understanding of how lifetime is managed in Geant4. GATE 10 uses the `G4RunManager` to initialize, run, and deconstruct a simulation. The `G4RunManager`'s destructor triggers a nested sequence of calls to the destructors of many objects handled by the run manager, e.g. geometry and physics. Volumes, for example, are created through code on the Python-side, but they should never be deleted on the Python-side because the `G4RunManager` is responsible for deletion. Segmentation faults occur if the objects no longer exist at the time of supposed destruction triggered by the `G4RunManager`. This is achieved by correct configuration of the wrapping in *pybind11*.

There is also an important aspect on the Python-side concerning Geant4 objects that are deleted by the `G4RunManager`: Python usually stores a reference to the Geant4 objects whose creation is implemented on the Python-side. This reference will not find the object anymore once the `G4RunManager` has deleted it upon its own destruction. Therefore, we have implemented a mechanism that makes sure that references to Geant4 objects are unset before the `G4RunManager` is garbage collected (and thus its destructor is called).

GATE 10 is now very robust in terms of memory handling and segmentation faults.

6 Novel features

GATE 10 includes several novel features compared to previous versions. We briefly describe a selection of them in this section.

6.1 Native Geant4 multithreading

As a new feature in GATE 10, native Geant4 multithreading capability is available (for most of the functionalty so far). The user simply sets the number of threads, e.g. `sim.number_of_threads=4` and the `SimulationEngine` automatically sets up the `G4MTRunManager` appropriately.

6.2 Export to structured file, e.g. JSON

A simulation can be exported as a structured plain-text file in JSON format. This JSON file can be reloaded at a later stage to re-create the simulation. The user can choose, via an option, whether such as JSON file is automatically created and stored alongside the simulation output:

```
import opengate as gate
sim = gate.Simulation()
sim.store_json_archive = True
sim.store_input_files = True
sim.json_archive_filename = "simu_iccr.json"
sim.output_dir = "output"
...
sim.run()
```

The above example creates a JSON file in a folder called *output*, and alongside with it also stores a copy of all potential input files (images, material descriptions, etc.). The JSON file is structured, human-readable, and compact in size. The simulation can be re-run later by:

```
import opengate as gate
sim = gate.Simulation()
sim.from_json_file("output/simu_iccr.json")
sim.run()
```

This feature helps a lot in data analysis and is particularly interesting in applications where simulation output needs to be archived, such as clinical dose calculation. It can also be helpful for dispatching simulations in a cluster environment and for debugging. The functionality could be easily extended to other file formats such as XML.

6.3 Generative Adversarial Networks for phase-space generation

GATE 10 gives the user the possibility to generate particles via a generative adversarial network (GAN) instead of using, e.g., a conventional phase space file. The idea behind this approach is that particles are not tracked from the sources on, but generated at a later stage, thereby skipping part of the simulation geometry [6–8]. The GAN is also more convenient to store than typically huge phase space files. GATE 10 relies on the `torch` library and provides functionalities to train and apply the neural network.

6.4 User-friendly repeated volumes

Many simulations in medical imaging require geometries which contain many repetitions of the same kind of volume in space. For example, a detector head could consist of a grid of crystal segments where all segments share the same shape, size, and physical properties. Geant4 allows volumes to be

present in multiple locations in space by associating multiple G4PhysicalVolumes to the same G4LogicalVolume. Previous versions of GATE already allowed the user to repeat volumes, but GATE 10 now exposes this feature in a simple manner to the user, as can be seen in the following example snippet:

```
crystal = sim.add_volume("Box", "crystal")
crystal.size = [1 * cm, 1 * cm, 1 * cm]
crystal.translation = [
    [1 * cm, 0 * cm, 0],
    [0.2 * cm, 2 * cm, 0],
    [-0.2 * cm, 4 * cm, 0],
    [0, 6 * cm, 0]]
crystal.material = "LYSO"
```

Instead of setting translation to a single vector to define the placement of the crystal volume, we provide a list of translation vectors. GATE 10 automatically creates the correct set of G4PhysicalVolumes, thereby effectively replicating the volume 4 times in space. Similarly, a list of rotation matrices can be set instead of a single matrix, to inform GATE 10 how each copy of the volume should be rotated.
Multiple utility functions are available to automatically generated sets of translation vectors and/or rotation matrices for common geometric dispositions, such as cartesian grids and circular arrangements, e.g. for PET simulation.

6.5 Voxelized representation of the geometry

The user can generate a voxelized representation of the simulation geometry or a portion thereof. The output is a label image and a lookup table where each voxel contains a label which corresponds to a volume name in the lookup table. Slices of such an image can be easily visualised with common Python libraries such as matplotlib [9]. Such an image helps checking and verifying a geometry or can be used in post-processing simulation data. The user can specify the spatial binning and the extent of the geometry to be voxelized. For the latter, it is possible to provide a list of volumes and GATE 10 will automatically determine the suitable extent which encompasses all volumes.

7 Discussion

GATE 10 is currently under fast development, with new features being added at least at a monthly frequency. The current version as of writing this is beta7, which is stable, fully usable, and which includes more than 80% of functionality offered by previous GATE versions. A first non-beta release is planned for May 2024 and will be presented at the ICCR conference.
Until then, we will refactor the actors and sources to make the code more efficient and the user experience more intuitive. We are also working on improving computation speed of the dose actor (and derived variants) in multithreading mode. Special physics such as optical surfaces are currently being implemented as well as tesselated volumes. Several institutions are already using GATE 10 for their software projects. For example, it is currently being integrated into the IDEAL 1.2 platform for independent dose calculation in light ion beam therapy [10].
Part of our development strategy is that every feature in GATE 10 must have a test case to ensure code integrity over time. Currently, more than 140 test simulations are run automatically each time the code is modified. These tests also serve as examples for users.

8 Conclusion

GATE 10 is open-source and available via the GitHub platform [11]. Installation is performed via the Python package manager (pip), which allows for a simple installation process with one single command. All major platforms, i.e. Linux, MacOS, and Windows are supported. The user is not required to manually install Geant4 as it ships pre-compiled with GATE 10. GATE 10 can be easily used by other software as an external library.

[3]Department of Clinical Medicine - Danish Center for Particle Therapy, Aarhus University Hospital, Denmark
[4]Varian Medical Systems Inc, CA, USA

Abstract We have developed PortPy (Planning and Optimization for Radiation Therapy in Python), an innovative open-source software package designed to expedite the research and clinical translation of novel treatment planning techniques in radiation therapy. PortPy addresses the limitations of existing packages by offering several key features: 1) Interoperability with Commercial Systems: PortPy is designed to work seamlessly with a commercial treatment planning system, Eclipse. This interoperability allows for the objective evaluation of new techniques in comparison to the current best clinical practices. 2) Inclusion of Benchmark Dataset: The package includes a benchmark dataset, currently 50 lung patients, complete with clinical plans and all necessary data for treatment planning optimization, such as voxels, beamlets, and the dose influence matrix. This data is extracted from Eclipse using its API, facilitating comprehensive and realistic testing scenarios. 3) Advanced Benchmark Algorithms: PortPy encompasses benchmark algorithms capable of identifying "global" optimal solutions, using computationally intensive mixed integer programming, for various non-convex optimization problems encountered in treatment planning. This includes challenges such as Dose Volume Histogram (DVH) constraints, direct machine parameter optimization for Volumetric Modulated Arc Therapy (VMAT), and beam orientation optimization for Intensity Modulated Radiation Therapy (IMRT). PortPy enables the design, testing, and clinical validation of both classical optimization-based and cutting-edge AI-based treatment planning techniques. It promotes transparency, reproducibility, and community-driven development in the field of radiation therapy treatment planning.

1 Introduction

The importance of open-source packages in advancing research, promoting transparency, and encouraging community-driven development cannot be overstated. In the field of radiotherapy treatment planning, existing Matlab-based open-source packages like CERR [1] and MatRad [2] have made significant contributions. The rising popularity of Python as a free, open-source programming language has inspired the development of Python-based packages such as OpenTPS, focusing on proton treatment planning, and PyMedPhys, mainly aimed at machine and plan quality assurance (QA). However, a key limitation of these existing packages is their inability to objectively evaluate new treatment planning techniques against current clinical practices. This limitation stems from the difficulty in fully replicating clinical environments, such as detailed linear accelerator configurations and commercial dose calculation engines. Consequently, plans generated using novel techniques, such as AI-based automated treatment planning, cannot be objectively compared with clinical plans used in patient treatment. We seek to overcome this barrier with the development of PortPy (Planning and Optimization for Radiation Therapy in Python), a new Python-based open-source package. PortPy is currently compatible with the Varian Eclipse treatment planning system (TPS), and future expansions to other TPSs are planned. It is important to emphasize that PortPy can be utilized without access to any TPS. However, access to a TPS is necessary if a final evaluation within the TPS is desired. Furthermore, PortPy addresses the absence of a benchmark dataset and algorithms in current packages, providing a crucial tool for researchers to evaluate novel techniques.

Figure 1 illustrates the inspiration behind PortPy's development, drawing from successful open-source practices in the AI and computer science community. Open-source tools such as PyTorch and TensorFlow, alongside benchmark datasets like ImageNet, and benchmark algorithms like AlexNet, have revolutionized AI and data science. Our goal is to replicate this successful model, equipping researchers with comprehensive tools (PortPy integrated with commercial TPS and the popular 3DSlicer imaging package), a benchmark dataset (currently 50 curated lung patients with expert-selected beams, all necessary optimization data, and benchmark IMRT plans generated using our in-house automated planning system, ECHO), and benchmark algorithms (including Mixed Integer Programming [MIP] algorithms for global optimal solutions).

2 Materials and Methods

Figure 2 illustrates the PortPy design and its three main modules: "Data Management", "Plan Generation", and "Plan Evaluation", which are discussed in the next sections.

2.1 Data Management

This module provides access to the curated benchmark PortPy dataset, which currently comprises data from 50 lung patients.

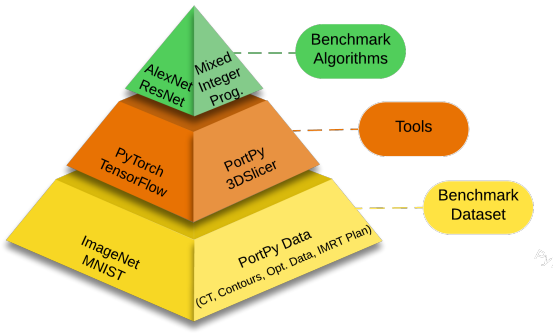

Figure 1: The development of PortPy has been inspired by the recent advancements in AI, facilitated by new tools, benchmark datasets, and algorithms. This analogy is depicted in this figure.

It allows researchers to test and develop their algorithms using the same dataset. The available data includes: 1) CT images and contours, 2) all necessary data for optimization for 72 uniformly selected beams (e.g., beamlets, voxels, dose influence matrix) extracted from Eclipse (version 16.1), 3) expert-selected beams for each patient, 4) an IMRT plan for each patient, generated using our in-house automated planning system, ECHO [3] (Expedited Constrained Hierarchical Optimization). ECHO is integrated with the Eclipse system and is currently in routine use in our clinic, having treated over 10,000 patients to date. It is important to note that the plans included in our dataset are not the clinical plans used for actual patient treatment, and therefore have not undergone the routine clinical scrutiny. However, they serve as valuable benchmark plans for research purposes.

2.2 Plan Generation

This module facilitates the generation of treatment plans using either classical optimization methods or emerging AI-based techniques. For optimization tasks, PortPy has been integrated with CVXPy [4], a widely-used open-source package. CVXPy enables the high-level formulation of optimization problems and offers out-of-the-box access to a range of of free (e.g., SCIP, SCIPY) and commercial (e.g., MOSEK, CPLEX) optimization engines (available for free for research purposes). Additionally, the PortPy.AI module is equipped with essential functionalities for AI-based planning. These include data access, data pre-processing, model training and testing, and patient-specific 3D dose prediction. The availability of both optimization and AI-based planning modules within PortPy allows researchers to not only compare these techniques but also explore their complementary aspects (Use Case 3, Section 3.3).

2.3 Plan Visualization and Evaluation

PortPy is equipped with basic built-in visualization tools, such as Dose-Volume Histograms (DVH) and dose distribution maps, as depicted in Figures 3, 4, 5. For more advanced visualizations, it integrates seamlessly with the popular open-source 3DSlicer package. When it comes to plan evaluation, PortPy provides a suite of methods to quantify optimized plans using clinically relevant metrics (for example, mean, maximum, DVH) and to compare these plans against established clinical criteria, as shown in Figure 4. Additionally, PortPy enables the export of plans in the DICOM RT plan format, allowing users to import these plans into any commercial TPS for final dose calculation and assessment. Figure5 illustrates how the results from PortPy align closely with Eclipse after importing the plan in Eclipse and running final dose calculation. It should be highlighted that although DICOM RT plan can be imported into various TPS, discrepancies are anticipated with TPSs other than Eclipse, due to the fact that our current data are derived from Eclipse, and there may exist variations in dose calculation methods between Eclipse and other TPSs. For IMRT, PortPy also supports exporting the optimal fluence map in a format compatible with Eclipse, facilitating the import into Eclipse for final leaf sequencing and dose calculation.
Furthermore, PortPy includes a collection of benchmark algorithms, useful for evaluating novel treatment planning optimization algorithms. These algorithms employ mixed integer programming (MIP) and are able to identify the best global optimal solutions for non-convex problems, including DVH constraints, VMAT, and beam angle orientations. While these algorithms are highly computationally demanding (typically taking days or weeks to solve) and not suited for real clinical application, they can be run on powerful computers and in the absence of time constraints to find global optimal solutions. These solutions then serve as benchmarks to validate new, computationally efficient algorithms (see Use Case 2, Section 3).

3 Results

In this section, we present three use cases to demonstrate the capabilities of PortPy. Additional examples are available on our GitHub page, provided in user-friendly Jupyter Notebook formats for ease of access and experimentation.

3.1 Use case 1: Developing and validating new treatment planning algorithms

The details of this simple and educational use case are provided in a Jupyter Notebook available on our GitHub page. To illustrate how researchers can develop new treatment planning techniques and validate them using PortPy, we performed the following tasks:

1. Utilizing the "Data Management" module, we loaded a lung patient case from the PortPy dataset, using the expert selected beams, which are also included in the dataset. We then employed the "Plan Generation" module and "Optimization" class to create a new IMRT plan using constraint optimization. We applied max/mean

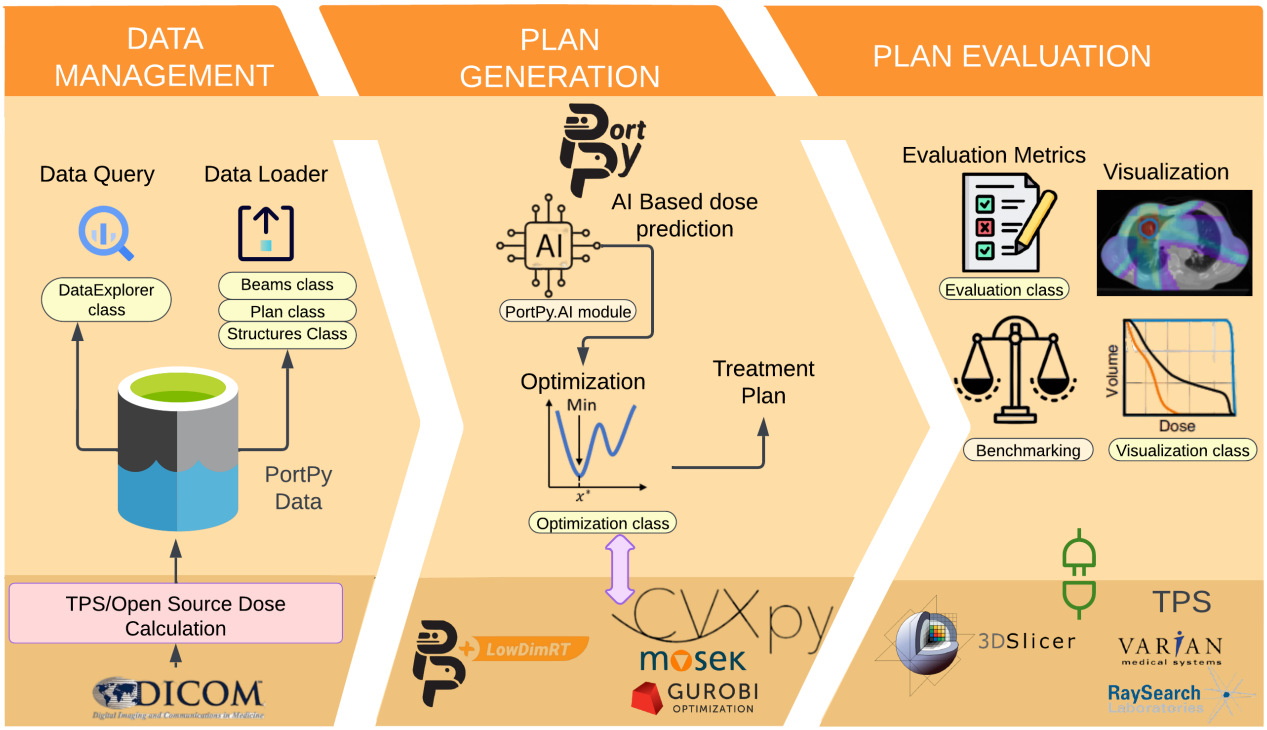

Figure 2: (PortPy workflow) PortPy comprises three primary modules: 1) "Data Management" for accessing the benchmark dataset, 2) "Plan Generation" for creating treatment plans using either classical optimization techniques or AI-based planning, and 3) "Plan Evaluation" for visualizing and assessing the generated plans.

hard constraints in line with our clinical criteria and developed a composite quadratic objective function, adjusting the weights manually. The integration with CVXPy facilitated the formulation of this optimization problem. Subsequently, we asked CVXPy to use the commercial optimization engine MOSEK (for which we obtained a free academic license) for solving the problem. Following this, we utilized PortPy's leaf sequencing algorithm to segment the resulting optimal fluence. Alternatively, the optimal fluence can be used without leaf sequencing.

2. The "Plan Evaluation" module and "Visualization" class were used to display the dose distribution and fluence profile of a beam in PortPy (see Figure 3). We then utilized the "Evaluation" class for a quantifiable assessment of the plan against our clinical criteria (refer to Figure 4).

3. We imported the DICOM RT plan file generated by PortPy, including the optimal control points, into Eclipse for the final dose calculation. Figure 5 shows that the results in Eclipse and PortPy are aligned, with minor discrepancies attributable to sampling inaccuracies and specific details regarding scattering and leaf transmissions.

4. We conducted a comparison of the plan with the PortPy IMRT benchmark plan (shown in Figure 6), which was generated using our in-house automated planning system, ECHO.

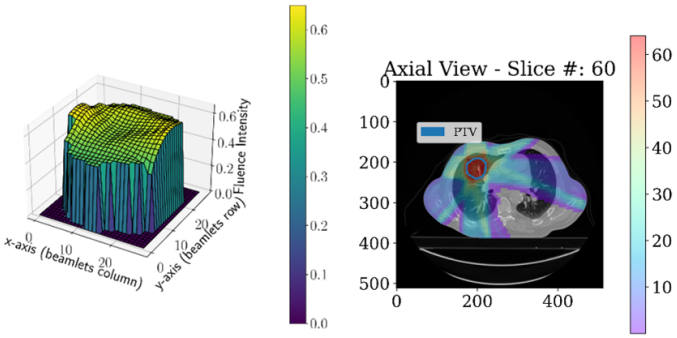

Figure 3: PortPy enables visualization of the generated plans, and for advanced visualizations, it offers integration with 3DSlicer and commercial treatment planning systems.

	constraint	structure_name	Limit	Goal	Plan Value
0	max_dose	GTV	69Gy	66Gy	65.88
1	max_dose	PTV	69Gy	66Gy	65.88
5	max_dose	HEART	66Gy		57.47
6	mean_dose	HEART	27Gy	20Gy	4.64
7	V(30Gy)	HEART	50%		1.00
8	V(30Gy)	HEART		48%	1.00
9	max_dose	LUNG_L	66Gy		65.88
10	max_dose	LUNG_R	66Gy		20.92
11	max_dose	CORD	50Gy	48Gy	10.50

Figure 4: PortPy allows for the evaluation of generated plans through quantifiable metrics, enabling comparisons with established clinical criteria. The color green is used to indicate areas where limits and goals are met.

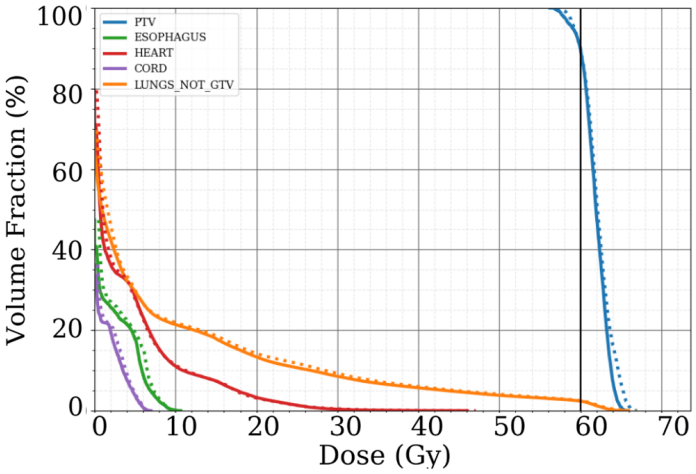

Figure 5: The DVH curves generated in PortPy (solid lines) for the optimized plan closely align with the DVH curves generated in Eclipse (dotted lines) following the final dose calculation

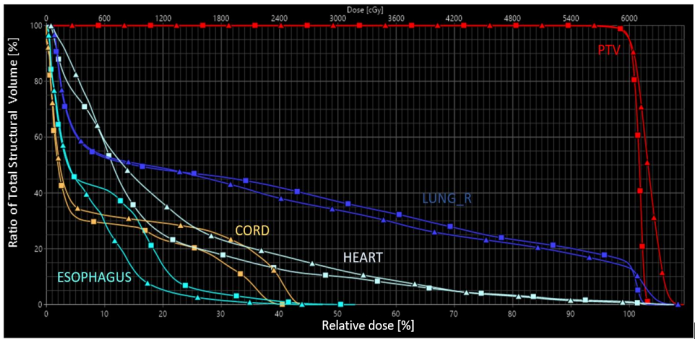

Figure 6: The plan generated in PortPy (lines with square marks) is imported into Eclipse and compared against the benchmark IMRT plan that is available in the PortPy dataset (lines with triangle marks). The benchmark plan in the dataset was generated using our in-house automated planning system, ECHO.

3.2 Use case 2: Bench-marking novel algorithms against the global optimal solutions

Certain non-convex optimization problems common in this field can be solved to global optimality through proper formulation using Mixed Integer Programming (MIP), which is notably computationally intensive. Figure 7 displays plans generated using both expert-selected beams, as provided in the dataset, and globally optimal beams. The global optimal beams were determined by solving the MIP-based problem, a process that required over four days of computation on our system. These plans can act as benchmarks for validating new, more computationally efficient algorithms for beam orientation optimization. Additionally, PortPy includes global optimal solutions for both VMAT and DVH constraints.

3.3 Use case 3: AI-based automated planning

The PortPy.AI module facilitates the end-to-end development and validation of innovative AI-based planning techniques. For instance, it enables the training of deep learning models using the PortPy benchmark dataset and benchmark IMRT

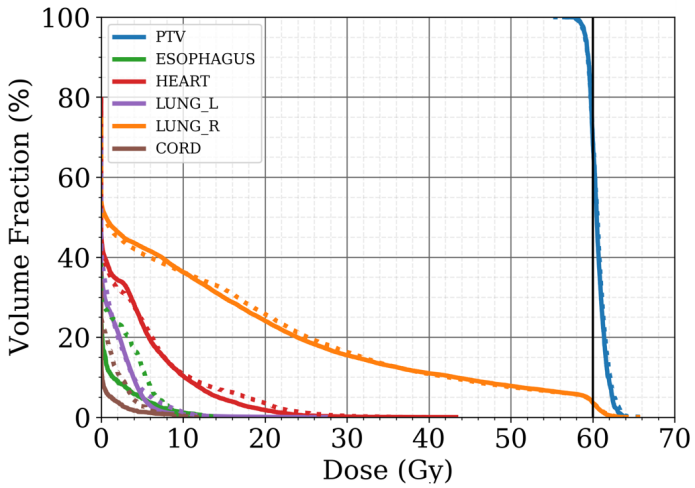

Figure 7: DVH curves generated with expert-selected beams (solid lines) are compared to those from globally optimal beams (dashed lines), the latter obtained by solving a mixed integer programming problem (> 4 days to solve).

plans. Subsequently, these models can predict the 3D dose distribution for a new patient. Following this prediction, the "Optimization" module can be employed for dose mimicking optimization, and the optimal control points (or fluence map) can be imported into a TPS for final evaluation. Illustrative workflows and examples are provided in our GitHub repository's Jupyter Notebooks.

4 Discussion and Conclusion

PortPy has been developed to address the limitations of the current packages, with a primary aim to advocate transparency, reproducibility, and foster community-driven development within the realm of radiotherapy treatment planning. PortPy stands as an open-source community project, under continuous enhancement, and we invite contributions and involvement from the broader scientific community. PortPy has been downloaded over 7,000 times in the past four months, a testament to its adoption within the scientific community.

Pylinac: An open-source quality assurance image analysis engine

James Kerns[1]

[1]Radformation, New York, NY, United States of America

Abstract Pylinac is an open-source image analysis library written in Python that can analyze routine quality assurance images and datasets for medical physicists in radiotherapy. The library is concise and usually implemented in a few lines of code. The engine is used in a commercial application and receives regular updates. Several modules are available for complete analysis of starshots, CatPhan phantom, and planar (2D) phantoms from numerous commercial manufacturers.

1 Introduction

The use of software to automate quality assurance (QA) analysis has been well established in medical physics [1–3]. Its use can assist or automate procedures or analysis of images or data. Although publishing studies of in-house software is common, these studies rarely publish the code itself for use by other researchers. As well, the American Association of Physicists in Medicine (AAPM) TG-142 [4] and TG-198 [5] has added more tests for a physicist to be responsible for; thus quick, accurate, and automatic test analysis can reduce the physicist's time spent on routine QA items.

The goal of this work is to showcase one part of a QA software analysis programming library that is robust, automatic, extensible, and open-source. The library can be integrated into a QA workflow to automate image analysis and data exploration. Currently, the library has numerous modules that each address a common QA test. Examples include volumetric-modulated arc therapy (VMAT) QA, starshots, cone-beam CT (CBCT)/CT, machine logs, Winston-Lutz isocenter size [6], and picket fences.

Several commercial options are available to automate or assist in completing TG-142 items, however they are proprietary. This library is open-source and thus all code and algorithms can be inspected by users for robustness. The library is also vendor-agnostic; several manufacturers are supported and is largely driven by user requests. The library can be integrated with other libraries to provide more features, such as a graphical user interface or web server interface. Given its open-source nature and liberal licensing, it can be extended and used by the community to conform to the needs of individual clinics.

The aim of the library is to provide an easy-to-use programming interface for doing complex but routine QA tasks or data exploration that is tedious or error-prone to do manually. The library automates as much of the analysis as possible, including data filtering and image localization; only input that is necessary should be given by the physicist. Output includes raw values, figures, and PDF reports. It is object-oriented in nature, allowing for code reuse and extension, and most algorithms can be utilized with fewer than 10 lines of code. The library is available on Github [7].

2 Materials and Methods

For the sake of space, only the CatPhan analysis is addressed here.

2.1 Data Collection

All data was collected on a TrueBeam accelerator, equipped with an on-board kV imager. Results were measured manually to benchmark the library.

2.2 Data Analysis

The library is written in the general programming language Python [8]. Although MATLAB is a very common language for numerical data analysis, including uses in medical physics, the extensibility beyond numerical analysis is limited compared to general programming languages. The library uses several open-source Python packages for reading, processing, and plotting data.

Cone-beam CT and CT QA commonly use the CatPhan phantom to measure several image quality metrics. The analysis software can automatically register CatPhan 503, 504, 600, and 604 phantoms, correct for position offsets in all three Cartesian directions, and correct for modest phantom roll, pitch, and yaw. The library can analyze the CTP404 (HU linearity & geometric scaling), CTP528 (high-contrast line pair resolution), CTP486 (HU uniformity), and CTP515 (low-contrast detectability) modules. Where applicable, the analysis procedure follows the CatPhan manual procedures for each phantom. The analysis procedure is as follows:

Register the phantom z-location. Upon loading, all the images are scanned to determine where the houndsfield units (HU) linearity module (CTP404) is located. This is accomplished by examining each image slice and looking for 1) a disk the size of the CatPhan and 2) a circular profile at the locations of the HU linearity regions of interest (ROIs) that has characteristics like the CTP404 module. If the profile contains low, high, and mostly medium values then it is thought to be the HU linearity module. All such slices are found and the median slice is set as the HU linearity module location. All other CatPhan modules are at known offsets from this position.

Determine phantom roll. Although there is often little axial roll in the CatPhan, even small rotations can misalign the ROIs and lead to inaccurate results. The roll of the phantom is determined by converting the HU linearity slice to a binary image based on a threshold. The air-filled ROIs, which are below the threshold, are then located and the angle made by the two holes determines the phantom roll.

Determine HU linearity. The HU module (CTP404) contains several materials with different HU values. Using angle positions corrected for roll and the radius from the center of the phantom, circular ROIs are sampled which correspond to the HU material regions. The mean pixel value of the ROI is the determined HU value.

Determine HU uniformity. HU uniformity (CTP486) is calculated in a similar manner to HU linearity, but within the CTP486 module/slice looking at a top, bottom, left, right, and central ROI.

Calculate Geometry/Scaling. The HU module (CTP404) also contains several "nodes" which have a known spacing. Using corrected angles, the area around the 4 nodes are sampled and then a threshold is applied which identifies the node within the ROI sample. The center of mass of the node is determined and then the distance between nodes is calculated and averaged.

Calculate Spatial Resolution/MTF. The Spatial Resolution module (CTP528) contains 21 pairs of aluminum bars having varying thicknesses. One unique advantage of these bars is that they are all focused on and equidistant to the phantom center. Thus, a circular profile is taken at the radius of the line pairs. The peaks and valleys of the profile are located; peaks and valleys of each line pair are used to calculated the modulation transfer function (MTF). The relative MTF (rMTF), i.e. normalized to the first line pair, is then calculated from these values. Up to the first eight line pairs are analyzed; however, each line pair region is analyzed sequentially and if the MTF falls below a detectable level the analysis stops at the last reasonable line pair region.

Calculate Low Contrast Resolution. Low contrast is difficult to determine quantitatively since visual acuity has several factors. The library uses both the contrast value of the ROI as well as the ROI size to compute a "detectability" score (equation 1), which is based on the contrast-to-noise equation. ROIs above the score are said to be "seen", while those below are not seen. Only the 1.0% supra-slice ROIs are examined. Two background ROIs are sampled on either side of each ROI and averaged. The score for a given ROI is calculated using equation 1:

$$Visibility(I) = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} \times \frac{\sqrt{\pi r^2}}{\sigma_I} \quad (1)$$

where I is the region of interest and r is the radius of the ROI, and σ_I is the standard deviation of the ROI.

Calculate Slice Thickness. Slice thickness is measured by determining the full-width half-max (FWHM) of the wire ramps in the CTP404 module. A profile of the area around each wire ramp is taken, and the FWHM is determined from the profile. The profiles are averaged and the value is converted from pixels to mm and multiplied by 0.42 as per the CatPhan manual. Measurements of the image quality metrics were also determined by hand according to the CatPhan 504 manual at the treatment console at the time of measurement and compared to algorithm analysis results where applicable.

3 Results

CBCT results for a small field of view (FOV) protocol scan can be visualized in Figure 1, which shows a summary of results. The figure shows the slices where the analyses were done, markers to show the ROIs of each test, and plots of the HU, rMTF, and uniformity slice. The acquired values were compared to the manual ones taken at the time of measurement and are presented in Table 1.

The difference between the manual measurements and those of the algorithm are quite small for all measurements taken. On average, the HU analysis had a difference of 1.6 and 2.8 HU for the head and thorax acquisition modes, respectively. HU differences between manual and algorithm values was never more than 10, indicating good agreement. Geometric scaling showed agreement to within 0.2mm. The slice thickness measurements showed the largest relative difference in measurement. Given that the nominal slice thickness was 2 mm however, the automatic analysis showed better agreement to the nominal value on average, being within 0.2 mm for both scans. It should be noted that slice thickness accuracy degrades with lower image quality since the wire ramps become more difficult to delineate from the noise; this may explain the higher thorax scan manual value.

4 Discussion

The results of the benchmark tests all agreed well with the manual measurements taken. The library has been shown to have algorithms that can analyze routine QA test files with a high level of accuracy. The library is also well documented for easy setup and use, creating a low barrier to entry, especially for users without a deep knowledge of programming.

Robustness of the algorithms are ensured by continuous code testing. Each improvement or new feature is backed by corresponding code tests to ensure that changes have not introduced unintentional errors to existing features and that the new code works properly. The library has a large and growing test data suite of hundreds of images and datasets to ensure data from different machines, different acquisition conditions, and different data qualities give consistent results. These images have been contributed from a variety of clinics, ensuring a range of procedures and results and equipment performance. Users are encouraged to donate images to the test suite. Also, because of the transparency by being open-source, users can examine the algorithms for accuracy,

Table 1: CBCT measurement values comparing manual measurements of HU linearity, HU uniformity, geometric scaling, and slice thickness with the automatic algorithm analysis and difference between them for the “Head” and “Thorax” scan protocols.

implementation, and can contribute to improvements and enhancements, all of which adds to the robustness of the library.

The library is also extensible because of its modular and object-oriented design. As an example, several of the library's modules use digital imaging and communications in medicine (DICOM) images in their analysis. These modules all use a DICOM image class that itself can perform various data manipulations. Users can directly extend this class to do a specialized manipulation of their own DICOM images. As well, because Python has frameworks for web applications and databases, it is easy to use such libraries as this one for local or cloud-based web services.

Several investigators have also used and validated Pylinac within their own studies [2, 9, 10].

5 Conclusion

An open-source library has been built which allows users to easily analyze images and data for routine QA procedures. The CatPhan routine was validated in this study. The library has been benchmarked, agrees well with manual measurements, and has been tested using hundreds of image sets. The library can be used standalone or integrated with other services to provide any level of QA support for a clinic.

Abstract ***Objective*:** To present a long short-term memory (LSTM) network-based dose calculation method for magnetic resonance (MR)-guided proton therapy. ***Approach*:** 30 deformed planning computed tomography (CT) images of prostate cancer patients were collected for Monte Carlo (MC) dose calculation under a 1.5 T magnetic field. Proton pencil beams (PB) at 150, 175, and 200 MeV energies were simulated (6480 PBs at each energy). A 3D relative stopping power (RSP) cuboid covering the extent of the PB dose was extracted and flattened into the LSTM model, yielding a 3D predicted PB dose. Training and validation involved 25 patients; 5 patients were reserved for testing. ***Results*:** Test results of all PBs showed a mean gamma passing rate (2%/2 mm) of 99.89%, with an average center-of-mass discrepancy of 0.36 mm between predicted and simulated trajectories. The model inference time was 10 ms per beam. ***Conclusion*:** LSTM models for proton dose calculation in a magnetic field were developed and showed promising accuracy and efficiency for prostate cancer patients.

1 Introduction

Proton therapy has limitations in achieving high-precision dose delivery due to its inherent range uncertainty [1], which drives the need for online image guidance during proton dose delivery. Magnetic resonance imaging (MRI) has the advantages of high soft tissue contrast and non-ionizing radiation, and offers the potential for real-time anatomical imaging [2]. With the combination of real-time MRI and proton therapy, the treatment plan could be adapted or re-optimized based on the latest patient geometry before dose delivery, which would improve the target dose coverage and reduce the dose to surrounding normal tissues [3]. To make this online adaptive mode a reality, the plan adaptation and re-optimization require an accurate and fast proton dose calculation engine.
For proton dose calculation in magnetic fields, the Lorentz force causes protons to be deflected as they travel [4]. Monte Carlo (MC) methods, which compute the trajectories of individual particles by simulating particle transport physics, can consider the impact of magnetic fields on dose distributions but also require high computation times. To offer a trade-off between speed and accuracy, several analytical methods have been proposed to estimate the proton beam deflection and achieve accuracy close to MC methods in homogeneous tissues. Although the calculation time of recent MC and analytical methods can be accelerated by graphics processing units (GPUs) from several hours to several seconds [5, 6], the ultimate need for future real-time plan adaptation and re-optimization is still unmet, which requires dose engines to produce MC accuracy at millisecond speeds in the online iterative process.
Recently, several studies have shown the feasibility of deep learning techniques to realize millisecond proton dose calculations with MC accuracy. Some methods use computationally cheap physical inputs and computed tomography (CT) scans as inputs to U-Net convolutional models, which learn the correlation between physical inputs, CT scans and MC label dose [7, 8]; some other methods use long short term memory (LSTM) and transformer models, which are suitable for processing sequences with long dependencies, to learn the mapping of CT sequences to dose sequences in the beam's eye view (BEV) coordinate system [9, 10]. Although the two kinds of methods achieved good accuracy and high speed, to the best of our knowledge, they have not been applied to proton dose calculation scenarios under magnetic fields.
In this work, we applied a previously published LSTM proton dose calculation model [9] to dose calculation in a 1.5 T magnetic field, and confirmed its accuracy in patient cases with prostate cancer.

2 Materials and Methods

2.1 Proposed framework

The framework of this study is shown in Figure 1. First, based on the given initial energy and beam direction, a 3D relative stopping power (RSP) cuboid of interest containing the proton beam dose region is resampled from the patient's CT-derived RSP. Then, in the BEV coordinate system, the 3D cuboid of interest is treated as a sequence of 2D slices traveling from upstream to downstream. By flattening these

2D slices into 1D sequences, the directional LSTM unit can process the RSP sequences and generate the internal hidden states and outputs, where the former can be used as the input information for the subsequent slices. The outputs are passed to a fully-connected neural network to generate the predicted dose slices. Finally, the dose slices from our model are spliced back to the original 3D dose size and compared with the ground truth MC dose.

2.2 Dataset processing

We used a patient dataset which included deformed planning CT images after registration with MRI from 30 prostate cancer patients treated with a 0.35 T MR-linac (MRIdian, ViewRay, USA) at the Department of Radiation Oncology of the LMU University Hospital. All patients had no artificial implants and went through prior anonymization to comply with data protection law. The ground truth MC dose was generated through Geant4, and RSP maps with respect to water were then created within Geant4 and exported. To perform dose calculations in the presence of a magnetic field, a 1.5 T homogeneous magnetic field was set to be aligned with the z-axis (parallel to the superior direction) and act within a cylinder of 30 cm radius. The dose was scored on the same voxel geometry as the CT input, and all the proton beams were simulated with 10^6 histories, which made the maximal relative standard error in all regions above 10% of the maximum dose always below 1.15%.
Pencil beams (PBs) with energies of 150 MeV, 175 MeV and 200 MeV were simulated, with an energy spread of 0.83 MeV and laterally the beam was Gaussian with a standard deviation of 4.2 mm. PBs were isotropically sampled over a nearly cylindrical surface surrounding the prostate region and confined within a predefined angular sector to ensure no PBs were placed posterior or anterior to the patient. The propagation of the PBs was chosen to take place in the transverse plane, always orthogonal to the B field. Defining the right lateral direction as the 0° reference line, the sampling was done within $\alpha \in [40°, 140°] \cup [220°, 320°]$ region in $\Delta\alpha = 16.\dot{6}°$ steps, yielding 12 different angles per patient. At each of the 12 angles, a 3×6 PB grid was generated in the plane orthogonal to the PB's direction. In total, 216 PBs were simulated per patient and 6480 PBs for each energy.
After applying the body mask to RSP and dose maps, utilizing the transformation relationship between the patient and BEV coordinate systems, the 3D RSP-dose cuboid pairs were cropped and resampled according to the initial position and orientation of PBs. Cuboid sizes of $170 \times 43 \times 23$, $188 \times 49 \times 25$, and $205 \times 55 \times 25$ were used for the PBs with energies of 150 MeV, 175 MeV and 200 MeV, respectively. For each energy, 4320 PBs from 20 patients were used to train the model, 1080 PBs from 5 patients for validation and the remaining 5 patients with 1080 PBs for testing. Then, a global normalization was performed for the training, validation, and testing cuboid datasets using the maximum RSP and dose cuboid values of the training dataset. Finally, a reflection transformation across the xy plane was used, which doubled the original training dataset from 4320 PBs to 8640 PBs for each energy.

2.3 Model training

The network architecture used in this work corresponds to the LSTM model used in [9] for proton dose calculation in the absence of a B field in lung cancer patients. The LSTM features one layer with 1000 neurons as internal layer, followed by two fully connected layers with 100 neurons and ReLu activation layers.
For model training, we used the Adam optimizer to minimize the mean squared error (MSE) loss between the output dose and ground truth dose sequences. The initial learning rate was set to 10^{-5} and batch size to 8. The model was implemented in Python 3.8 and Pytorch 2.0.1 and trained with an NVIDIA RTX A6000 GPU (48 GB memory) for around 15000 epochs, which took about a week. The model with the best overall MSE validation loss was identified and used for the prediction in the test dataset. Each energy was trained separately.

2.4 Evaluation metrics

After obtaining model predictions, all dose voxels below a threshold of 0.01% of the global maximum were set to 0, similarly to [10]. Then, 198 PBs that overshot the patient were filtered out in the test dataset with energy of 200 MeV and all the output doses were reverse-normalized for the final evaluation.
Comparison metrics used in our study were according to the metrics in [11]. The 3D global gamma pass rate γ_{pr} was calculated to compare the 3D dose distributions, which was implemented within an open-source project, PyMedphys [12]. The distance-to-agreement threshold was set to 2 mm, the dose difference threshold to 2% and with a dose cutoff to 10% of the maximum dose. The relative error ε_{rel} was used to quantify the relative disagreement between two laterally integrated dose profiles at a certain depth. The integrated dose difference ε_{int} was evaluated to allow a comparison between PBs of different energies with each other. To compare the depth range of PBs, $\Delta R_{D_{80}}$ was used to calculate the difference of the depth of the 80% dose distal to the Bragg peak between two dose distributions. Finally, to analyze magnetic deflection modeling and the agreement of two PBs' lateral profiles at a given depth, the difference in the center of mass F_{COM} and full width at half maximum value FW_{50} of the PBs were calculated.

3 Results

Figure 2 (a) and (b) show a simulated and predicted PB from a 175 MeV energy model on a test patient. The LSTM can accurately predict the entry point and angle of the PB

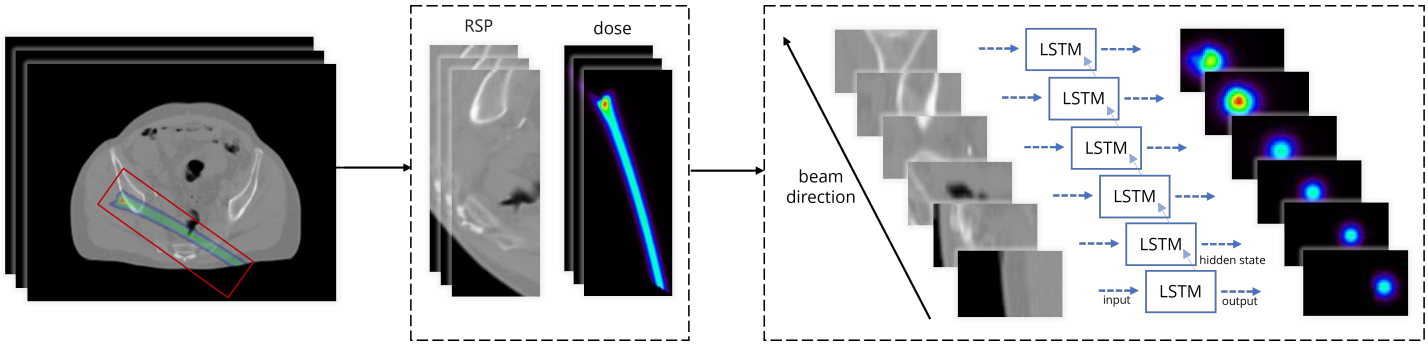

Figure 1: The framework of this study. (left) Dose distribution from a single pencil beam obtained from MC simulation with outline of 3D cuboid of interest. (middle) Resampling of input RSP and output dose for the cuboid of interest. (right) LSTM model converting sequence of RSP slices to a sequence of dose slices.

	$\gamma_{pr}(2\% \mid 2mm)$	$\Delta R_{D_{80}}$ [mm]	F_{COM} [mm]	FW_{50} [mm]	ϵ_{rel} [%]	ϵ_{int} [%]
Metric value	99.94	0.12	0.12	0.18	0.34	0.04

Figure 2: An example of a predicted 175 MeV PB in test patient. An *xy* slice of a) Geant4 simulated and b) LSTM predicted dose distribution is plotted over the RSP map input. The table shows the PB's performance regarding different metrics and percentile ranks with respect to all other PBs from the test set. A percentile rank of 0% corresponds to the best- and 100% to the worst-ranked PB. c) Integrated lateral dose profiles over depth and ε_{rel} of each slice. d) Γ (2%|2mm) index. e) F_{COM} and FW_{50} at each depth. f) Voxel-based relative dose difference of dose distribution integrated over z capped at ±5%. Black lines denote 80%, 10% and 1% isodose lines with respect to z integrated dose in the Bragg peak.

in the patient and the deflection of the PB caused by the magnetic field. In Figure 2 (c), laterally integrated profiles of the simulated and predicted PB are shown and agree well. The $\Delta R_{D_{80}}$ and mean ε_{rel} were less than 0.5 mm and 0.5%, respectively. The Γ index (2%|2 mm) map is shown in Figure 2 (d) and its corresponding γ_{pr} was 99.94%. To analyze the predicted PB trajectory and its lateral profiles, F_{COM} difference and FW_{50} difference are shown in Figure 2 (e), and were both less than 0.5 mm. In Figure 2 (f), the 2D distribution of relative dose differences integrated over z is displayed.

To further analyze the overall model prediction performance for the whole test dataset, Table 1 shows the worst and average values of each evaluation metric for the models at the three energies. The worst γ_{pr} (2%|2 mm, $D > 10\%D_{max}$) was above 95.9%, the maximum $R_{D_{80}}$, F_{COM} and FW_{50} differences were 2.07%, 1.99 mm and 3.28 mm, respectively. High accuracy was achieved with respect to almost every metric we evaluated. For calculation time, the cuboid extraction and interpolation (not optimized) took 45 to 60 ms, while LSTM inference time was 10 ms; our method can thus achieve proton dose calculation per spot within 70 ms.

Table 1: The performance of all evaluated metrics summarized by worst and mean values across all five test patients combined and for each energy model individually. Red cells indicate the worst value.

	$\gamma_{(2\%\,\vert\,2\,\mathrm{mm})}$[%]		$R_{D_{80}}$[%]		F_{COM}[mm]		FW_{50}[mm]		$\vert\varepsilon_{\mathrm{rel}}\vert$[%]		$\varepsilon_{\mathrm{int}}$[%]

4 Discussion

This study is an application of a previously developed architecture [9] to magnetic field dose calculation while using more extensive and rigorous criteria. To our knowledge, this work is the first one to utilize an AI architecture to speed up proton dose calculation in magnetic fields. Compared with recent transformer-based dose calculation methods [10], our study demonstrated that the LSTM architecture can also achieve state-of-the-art accuracy but has lighter trainable parameters; the GPU memory requirements of our model never increased above 1 GB and our network is easy to train and converged with a constant learning rate of 10^{-5}.

We can compare with recent analytical dose calculation methods for MRI-guided proton therapy [5], where maximum observed differences in water between their approach and MC ground truth were reported. For $\Delta R_{D_{80}}$, they reported 0.7 mm or 0.22% for the highest tested energy of 229 MeV. Furthermore, the maximum reported F_{COM} was 1.2 mm. In contrast, we reported for the highest energy model of 200 MeV a mean $\Delta R_{D_{80}}$ of only 0.17 mm and mean F_{COM} between 0.3 and 0.4 mm. This was in real test patients rather than in homogeneous water. Reference [6] presented a recent GPU-based MC algorithm for MRI-guided proton therapy called ARCHER. They report achieving a $\Delta R_{D_{80}} < 0.06$ mm and a mean $\varepsilon_{\mathrm{rel}}$ of 0.81% in water. For tissue and bone materials, which were also evaluated, they reported a mean $\varepsilon_{\mathrm{rel}}$ of 1.12% and $F_{\mathrm{COM}} < 0.05$ mm. Their 3D-gamma pass rate with a 2 mm/2% criterion in the region with dose greater than 10% of the maximum dose was over 99% for all tested cases. Although the computational time of ARCHER is found to range from 0.82 to 4.54 s for 10^7 proton histories, the potential advantage of the deep-learning method is that we can use more particles to simulate MC doses with lower statistical uncertainty as labels without increasing the prediction time. Finally, just like a MC engine has to be carefully adapted and commissioned for use in a specific treatment setting, a deep-learning model would have to be trained or at least fine-tuned. Unique settings and beam profiles of a specific machine necessitate a specific model per machine.

5 Conclusion

We successfully developed an LSTM network-based proton dose calculation method in a magnetic field and confirmed its accuracy for prostate patients. This sub-second dose engine has the potential to improve the efficiency of online plan optimization in the MR-guided proton therapy workflow.

Intraoperative radiation therapy requires fast and accurate treatment planning, as these procedures involve tumor removal surgeries preceding irradiation which may alter the original treatment plan. While Monte Carlo calculations are considered the gold standard, they require significant computational resources and time. The use of deep learning algorithms may provide a faster alternative. In this study, we trained and tested two deep learning models, U-Net and MultiResUnet, to predict 3D dose distributions for INTRABEAM spherical and needle applicators. A cohort of 800 paired CTs and dose distributions (720 training, 80 validation) of partial breast irradiations with a spherical applicator and 41 (36 training, 5 validation) of kyphoplasty using the needle applicator were used separately for training and validation. Doses were calculated using a fast MC algorithm, serving as the ground truth. Additional tissue material information was incorporated into the input channel as a segmentation mask, and an image augmentation technique was introduced to produce an image by taking different parts from other images in the dataset. Gamma analysis was performed to compare the predicted dose to the simulated dose. In general, dose predicted conformed well with the reference dose. Consequently, deep learning models show great potential in predicting dose distributions for IORT, especially the MultiResUnet model.

1 Introduction

The use of Intra-Operative Radiation Therapy (IORT) with low-energy X-rays has been experiencing a notable surge in the clinical field. The INTRABEAM system, developed by Carl Zeiss Surgical Gmbh in Oberkochen, Germany, stands out as a miniature low-kV X-ray generator specifically designed for IORT applications. Various applicators may be attached to the probe for different treatment scenarios. However, this technique is currently limited by the inherent difficulties associated with the planning process, as the treatment plan is usually done *in situ* just after the tumor resection inside the operating room. Therefore, it requires fast and accurate treatment planning.

Deep learning algorithms, with their capacity to analyze vast datasets and discern intricate patterns, offer a promising avenue for expediting and enhancing IORT treatment planning. Unlike traditional Monte Carlo (MC) calculations, which demand substantial computational resources and time, deep learning algorithms can swiftly process complex medical imaging data to generate treatment plans that accommodate the dynamic changes occurring during tumor removal surgeries.

In this study, we trained and tested two deep learning models to predict 3D dose distributions for INTRABEAM spherical and needle applicators.

2 Materials and Methods

Two deep learning models, U-Net [1] and MultiResUnet [2], were trained to predict dose distributions of the spherical and needle applicators of the INTRABEAM system. Neural networks (NN) were trained and tested from existing CT images from random patients and the corresponding dose distribution.

2.1. Datasets

Two different datasets were used separately for training and validation:

1) Partial breast irradiation with spherical INTRABEAM applicators. A cohort of 800 paired CTs and dose distributions were used (720 images for training, 80 for validation).

2) Kyphoplasty IORT with needle INTRABEAM applicator. A cohort of 41 paired CTs and dose distributions were used (36 images for training, 5 for validation).

2.2. CT image extraction

The dataset used in this work was extracted from thoracic DICOM images of anonymous patients. CT images were interpolated to have a (0.5,0.5,0.5) mm voxel size and regions of (128,128,64) voxels were extracted from the original CTs. This corresponds to a 6.4 cm x 6.4 cm x 3.2 cm CT image. The regions selected were the left and right breasts for the spherical applicator dataset and the thoracic spine for the needle applicator dataset. Specific cases such as bone structures, tissue-to-lung interfaces and tissue-to air interfaces were selected to provide variety in the dose distribution configuration. Figure 1 shows examples of the central slices of some regions.

2.3. Calculation of dose distributions

Reference doses were calculated using the XIORT-MC algorithm [3], an in-house developed algorithm for kilovoltage x-rays that delivers statistical noise-free distributions in a fraction of time of a MC simulation. A set of phase space files was used for each applicator size – 1.5 cm, 2.5 cm, and 3.5 cm for the spherical applicators and 4.4 mm for the needle applicator. The position of the applicator was defined at the center of the CT image. Each HMC simulation was done for $1x10^7$ histories.

2.4. Input of the neural network

The extracted CT images and reference doses were used as the input and output training set. Additional tissue material

information was incorporated into the input channel as a segmentation mask to help the neural network differentiate between the tissues of the CT image. The training set was normalized.

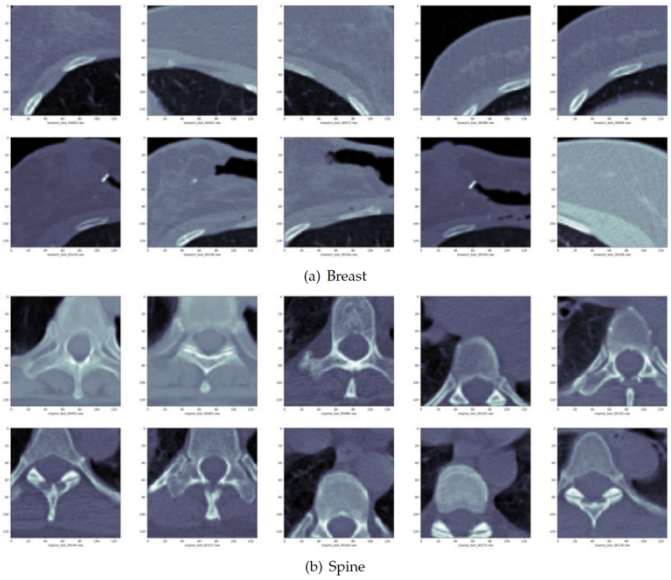

Figure 1. Sample CT central slice of the training set. (a) Breast (b) Spine

2.5. Image augmentation

We proposed an augmentation method based on the Culmix [4] data augmentation technique where a complete image made was built from different parts of other images. This method cannot be done for regular images in classification or segmentation tasks since the high-order features will be lost entirely, but our goal is to model the dose calculation, and this image will still represent the features of the dose calculation code. Moreover, this method will introduce structures that are generally not in the patient's anatomy, like air gaps between tissues, so the stability of the model will be increased. It will also allow us to produce a large and diverse dataset from few engineered images. An example of an artificial CT image generated with our augmentation method is shown in figure 2.

2.6. Model training

U-Net and MultiResUnet networks were used in this study. The models were optimized using the Adam optimizer [5] with a learning rate of 0.0001, beta1 was set at 0.9, beta2 at 0.999, and the epsilon value was equal to 1e-7. Each model was compiled using Keras, and the root mean squared error (RMSE) was the best performing loss function. A model checkpoint parameter was also implemented to save the model and weights of the best possible validation loss. The U-Net and MultiResUnet networks were trained using a subscription of Google Colab Pro running on a Tesla P100-16GB GPU for the model of the needle applicator and a V100-16GB GPU for the model of the spherical applicators. The training loss and validation loss values were saved for analysis. The training duration was also recorded for comparison.

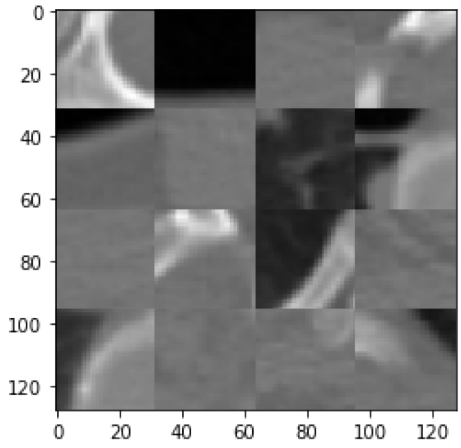

Figure 2. Artificial CT image generated from parts of different images.

2.7. Dose Analysis

The resulting predicted dose was compared to its corresponding ground truth (reference dose). The local dose profile, absolute and relative dose difference, and gamma index analysis were used to compare the ground truth to the predicted dose. The dose profiles located at the center, 5 mm and 15 mm from the center were extracted and compared for the spherical applicator doses. Similarly, the dose profiles at the center, 3 mm and 5 mm from the center were extracted and compared for the needle applicator doses. The absolute dose difference was calculated using pixel-by-pixel subtraction of the reference and predicted dose values. The absolute dose is divided by the reference dose for the relative dose difference calculation. Pixels resulting in a zero-value denominator were automatically set to zero to avoid run-time errors. The global gamma was calculated using 10%-0.5 mm criteria. The lower dose cut-off was set at 10%, and the maximum gamma was set to 2.

2.8. Model comparison

Both neural networks were trained with 2D CT images and doses of the partial breast irradiation dataset to compare between the U-Net and the MultiResUnet. A total of 1242 slices were extracted, 1118 were used for training and 124 for validation. The gamma index was calculated for all the validation images with dose difference criteria of 10%, 7%, 5% and 3%, with 0.5 mm distance-to-agreement (DTA).

3 Results

3.1. Model comparison

Figure 3 shows the box plots of the gamma passing rates obtained with the U-Net and with the MultiResUnet. The average of the gamma passing rate of the U-Net network was 97.9%, 97.14%, 96.51%, and 95.8% for a dose-difference criteria of 10%, 7%, 5%, and 3%, respectively, with 0.5 mm DTA, while for the MultiResUnet, the averages were 98.72 %, 98.12%, 97.59%, and 96.92%. From the averages and the box plot, we can see that the MultiResUnet outperformed the U-Net in all the criteria.

Therefore, the 3D models of the spherical and needle applicators were trained with the MultiResUnet network.

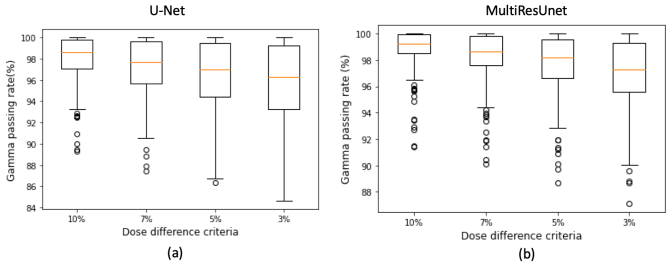

Figure 3. Box plot of the gamma index passing rate for the U-Net (a) and the MultiResUnet (b) with criteria of 0.5 mm and 10%, 7%, 5% and 3% dose difference.

3.2. Spherical applicator

The training of the neural network with the 3D images took 24 hours for 200 epochs on a V100-16GB GPU. An example of a predicted dose distribution for one of the cases is shown in figure 4. Looking at the dose profiles, one can see that the prediction conforms very well with the calculated dose. The network was able to predict the general shape and the gradient of the dose caused by the change in tissue.

3.3. Needle applicator

Training this model took 2 hours and 36 minutes on a P100-16GB GPU, with 500 epochs and a batch size of 2. An example of a predicted dose distribution obtained with the MultiResUnet for the needle applicator is shown in figure 5. In general, the prediction conforms well with the calculated dose, with a slight overestimation of the dose in the voxels next to the applicator.

4 Discussion

A deep learning application for predicting dose in intraoperative radiation therapy was presented in this study. Two convolutional neural network models were tested in this application – U-Net and MultiResUnet. As of the writing, there is no existing research on deep learning applications applied to dose prediction in intraoperative radiation therapy. A similar application developed by Mao et al. used a combination of deep learning algorithms to perform dose predictions for brachytherapy applications [6]. Other existing publications on the use of neural networks in radiation therapy are focused chiefly on external beam applications which several channel inputs such as dose-volume quantities for organs at risk and target dose for the primary target volume (PTV) [7-8]. The dataset used in these publications was based on actual treatment plans delivered to real patients. In this work, the dataset was arbitrarily generated from a set of CT images, and the ground truth for dose comparison was simulated using a Monte Carlo algorithm.

The use of the XIORT-MC algorithm [3] made the dose simulation faster, allowing for the generation of multiple applicator positions for both the spherical and needle applicators.

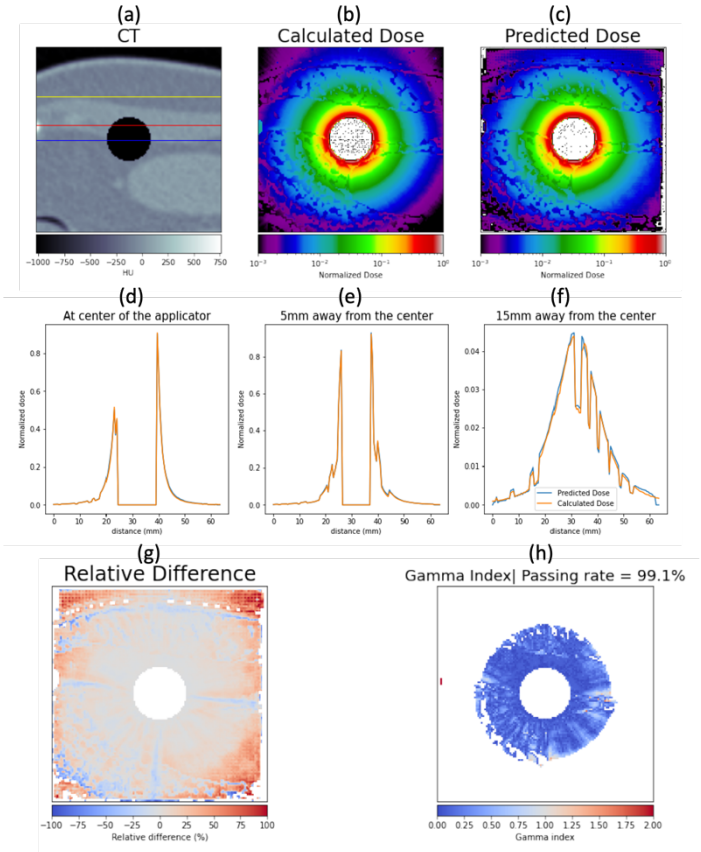

Figure 4: *An example of an equatorial CT slice (a) and the calculated (b) and predicted (c) dose distributions with the MultiResUnet for a spherical applicator. The horizontal lines that appear on the CT are the positions of line profiles (d-f). The relative difference (g) and gamma evaluation (h) are also shown.*

The U-Net architecture was developed initially for semantic segmentation of small dataset [1]. The small number of datasets forces the architecture to rely on data augmentation using deformation operations. The propagation of the filters for the U-Net model can generate a considerable number of trainable parameters, which might be computationally heavy, especially for datasets with multiple input channels. The number of the 3D U-Net structure parameters can reach up to 70 million parameters, requiring a huge video memory. The MultiResUnet is a more advanced structure and has a much lower number of parameters. For 2D, it has 7.2 million and 10.5 million for 3D. The MultiResUnet outperformed the U-Net by one point in average in the gamma passing rate, and it was more stable than the U-Net.

Normalization of the dataset transforms the data to a similar scale. A considerably extensive range in scales like that of the Hounsfield unit or the dose gradient can lead to the model not learning. Like most machine learning applications, data cleaning is essential to reduce extreme outliers.

In this study, the application of dose normalization and the use of a segmentation mask provides this option. Since the training set was directly generated using MC simulation, there is a higher chance of generating outliers due to the statistical nature of the algorithm. Treatment planning system (TPS) generated dose distribution may minimize this effect due to its existing built-in dose optimization algorithms. Nevertheless, the generated dose distribution using XIORT-MC is enough for the application in this study.

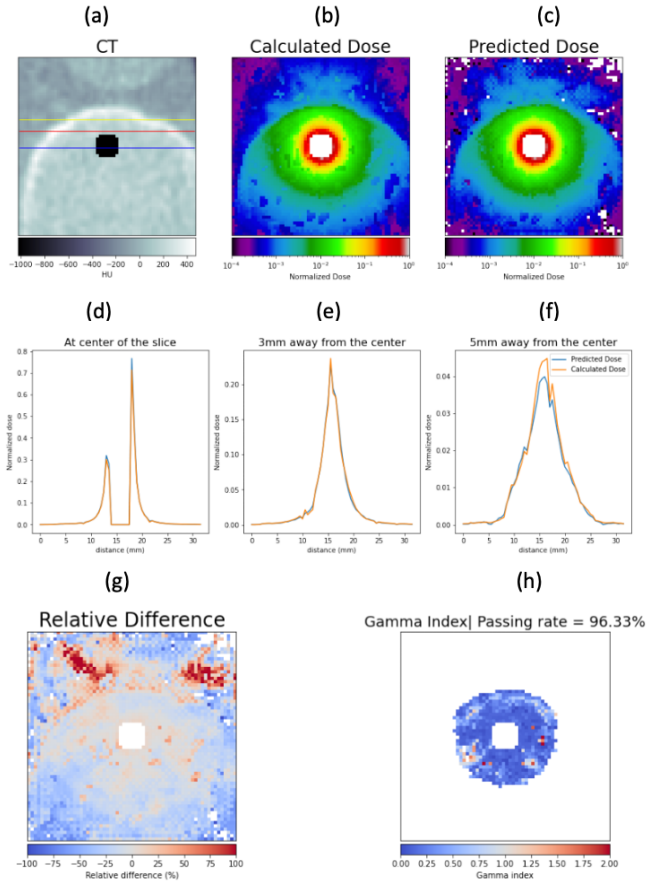

Figure 5: *An example of an equatorial CT slice (a) and the calculated (b) and predicted (c) dose distributions with the MultiResUnet for the needle applicator. The horizontal lines that appear on the CT are the positions of line profiles (d-f). The relative difference (g) and gamma evaluation (h) are also shown.*

We also proposed a new data augmentation technique where we produce an image by taking different parts from other images in the dataset. This technique will introduce a variety of structures around the applicator, consequently increasing the stability of the model and improving the ability to model the dose calculation code. It will also allow for the production of a large and diverse dataset from a small engineered data. The network was trained using the augmented dataset with the same spherical applicator to evaluate its effectiveness. The training took 24 hours. The average gamma passing rate increased by 2.54 points over the normal dataset; also, the prediction accuracy in lung tissue improved.

Our main objective was to produce a model that can calculate a treatment plan for IORT in real time. The XIORT-MC code takes 350 seconds to calculate the dose of a CT with a size of 128 ×128 × 64 voxels in a single-core CPU. Meanwhile, the inference time of the network is only 0.4 seconds, a factor of 875 faster.

5 Conclusion

Deep learning models show great potential in predicting dose distributions for INTRABEAM, especially the MultiResUnet model. This study has shown that 3D dose calculations can be accurately obtained with a trained neural network in less than a second, allowing for real-time treatment planning.

Abstract Calculation of robust electron beamlets for Mixed Beam Radiation Therapy (MBRT) is a computationally expensive process due to the need for Monte Carlo-based approaches. In this work, we use the GPU-based Pre-calculated Monte Carlo (PMC) algorithm to speed up electron dose calculation. PMC relies on pre-calculated electron tracks, generated ahead of time using the full Monte Carlo EGSnrc code. At run time, the tracks are used as look-ups to raytrace electrons. A photon transport method is added onto the PMC code to properly handle dose contributions due to bremsstrahlung and contamination photons. Excellent agreement in electron beamlets calculated with energies ranging from 6 to 20 MeV were found with an average latent uncertainty of 1.3%. Compared to single core EGSnrc calculations, a 12 MeV electron beamlet was calculated over 1800 times faster with PMC on the NVIDIA Titan RTX GPU.

1 Introduction

Mixed Beam Radiation Therapy (MBRT) is a novel technique that aims to combine the use of both external electron and photon beams in radiotherapy treatment plans [1–8]. For superficial tumours, it offers superior sparing of underlying normal tissue while providing equivalent target coverage to photon-only plans [1, 3–5, 8]. With MBRT, electron fields are collimated using the photon multileaf collimators (MLC), thus providing larger degrees of freedom in terms of deliverable aperture shapes and number. However, for treatment plan optimization purposes, beamlets for each beam angles must be pre-calculated. With robust optimization, the number of beamlets is then multiplied by the number of robust scenarios that are accounted for. To calculate robust electron beamlets for MBRT treatment planning, Renaud et al. [6] had used the Monte Carlo EGSnrc code, which required calculation times on the order of a week for all beamlets required in a typical plan. Although many analytical techniques have been developed for fast dose calculation of photon doses, this has not been the case for electron doses due to their erratic scattering. State-of-the-art treatment planning systems rely on fast implementations of the Monte Carlo method through usage of pre-calculated datas.

One such implementation of a fast Monte Carlo dose calculation algorithm was the Pre-calculated Monte Carlo (PMC) code first published by Jabbari et al. in 2009 [9]. The core idea of this technique was that the stochastic trajectory of an electron and of its secondary particles could be pre-sampled ahead of time and then used as look-ups at run time. Using the established EGSnrc Monte Carlo code, electrons would be generated in an identical initial direction and energy and transported through a homogeneous medium of interest. For each electron, in pre-determined step sizes, the position, direction and energy would be recorded until the electron reached a minimum threshold energy, called the cut-off energy. Any events along its path that would set in motion a new particle such as secondary electrons or bremsstrahlung photons would also be recorded. The compilation of these step information and events constitute an electron track. A sufficiently high number of these tracks would be generated for each medium and at differing energy intervals such as to cover the whole energy range of clinical electron beams. At run time, to transport an electron, a track is randomly selected at a suitable initial energy and used to transport the electron step by step through raytracing. Any secondary particles created along the track would be added to a stack to be transported subsequently. The dose deposited would be assumed to be uniform along an electron step. If an electron travels a pathlength r_v within a voxel v, then the dose deposited to the voxel e_{dep}, v can be calculated as:

$$e_{\text{dep},v} = e_{\text{dep}} \frac{r_v}{r}, \tag{1}$$

where r is the total length of the step of the electron track along which the electron travelled through v and e_{dep} is the total energy deposition along that step. As the electron is assumed to be going in a straight time along each step, a larger step size would induce a larger error in the location of the dose deposition. However, smaller step sizes would result in larger track sizes which must fit within the video random access memory (VRAM) at run time.

Although the generation of a track bank is done with EGSnrc, this time-consuming step is only performed once ahead of time and is independent of the treatment machine or the patient geometry. The time spent during this step can therefore be ignored for practical timing comparison. This method would provide a significant speed-up compared to conventional Monte Carlo methods as no costly interaction sampling

would then have to be performed during run time. The only significant computation time would be stemming from ray-tracing the electron voxel-by-voxel along the pre-calculated steps. Jabbari et al. observed speedups by a factor of 40 with PMC compared to EGSnrc calculations with dose discrepancies on the order of 2%. In 2015, Renaud et al. [10] published a graphics proccesing unit (GPU) implementation of the PMC technique which handled both electron and proton transport. They also quantified the uncertainty induced from the finite-size of the track bank as a latent uncertainty on PMC dose calculations. A second component of the PMC dose uncertainty is due to the statistical uncertainty arising from the finite number particles simulated at run time. While the latter can be reduced by increasing running more histories, the former is constant for a pre-generated track bank. If a PMC calculation is performed at high sufficiently histories N such that the statistical uncertainty can be ignored, then the latent uncertainty σ_L can be estimated as the root mean square deviation of local residuals between PMC doses D^{PMC} and benchmark doses D^b, calculated using a conventional Monte Carlo code such as EGsnrc:

$$\sigma_L = \lim_{N\to\infty} \sqrt{1/N \sum_V \left(\frac{D_V^{\text{PMC}} - D_V^b}{D_V^b} \right)^2}, \tag{2}$$

where the summation is performed over all voxels V.
Although the PMC code had been validated to provide accurate electron dose calculations when compared with EGSnrc by Renaud et al. [10], it was done without accounting for photon transports. However, in megavoltage external electron beam, bremsstrahlung photons and contamination photons generated in the gantry head account for a significant portion of the patient dose and must be corrected for. Therefore, to be adequate for beamlet calculations, in this work, a photon transport method was added to the PMC code.

2 Method

2.1 Photon transport

Bremsstrahlung photon creation events in electron tracks were recorded at pre-generation time in EGSnrc. During live calculations, each GPU thread loads up a particle from a phase space source file. If the particle is an electron, it is transported according to its track data until they either reach E<`ecut` or cross to a different medium. For all calculations presented in this paper, an electron total energy cutoff of `ecut`=0.7 MeV was used. If secondary electrons or bremsstrahlung photons are generated along the track, they are added to a stack of particles for the thread to transport subsequently. For photon transport, a method similar to the ones used in the EGS4 report [11] and by Fippel [12] is applied. The mass attenuation coefficient for photoeletric, Compton and pair production interactions in water are obtained from NIST [13] and are initialized on the GPU as texture objects. For each photon of energy E, its corresponding total mass attenuation coefficient $\mu(E)/\rho$ is fetched from the texture objects based on its energy E. Let $z(E)$ be the distance to be travelled by a photon. The probability that a photon interaction occurs within this distance $z(E)$ can be written as:

$$P(z(E)) = 1 - e^{-\mu(E)z(E)}. \tag{3}$$

Using the direct sampling method, we let $P(z(E))$ be represented by a uniformly distributed random number ξ between 0 and 1. By directly inverting Eq. 3, we obtain:

$$z(E) = -\frac{1}{\mu(E)} \ln(1-\xi). \tag{4}$$

As $1-\xi$ is also uniform between 0 and 1 for $\xi \in (0,1)$, the density-normalized distance $z(E)/\rho$ to be travelled by the photon before an interaction occurs can then be sampled as:

$$z(E)/\rho = -\frac{1}{\mu(E)/\rho} \ln(\xi'), \tag{5}$$

where ξ' is a uniformly distributed random number between 0 and 1. The photon is then ray-traced by accounting for each voxel's density ρ until the distance $z(E)$ has been fully travelled. Photons are transported as long as their energy is higher than `pcut`=0.01 MeV and while they remain within the phantom geometry. Photons below the cutoff energy `pcut` are forced to deposit all their energy in the voxel they are found in. Once the photon has travelled the full distance $z(E)$, one of the three interaction types is sampled from the interaction-specific mass attenuation coefficients. The methods described in EGSnrc [14] to sample energy and scattering angle of the secondary particles generated by each interaction type are applied. For pair production, secondary positrons are handled as if they were electrons.

Each thread is responsible for transporting one particle sampled from the initial source. Any ensuing secondary particle is appended to the thread's stack of particles and transported subsequently. For radiotherapy applications, all body tissue is treated as density scaled water. However, as the initial particle source must be transported from outside the patient body, the PMC code must also handle transporting particles in air. For electrons, the tracks are pre-generated in air with a larger maximum step size of 1 cm and lower history of 4000 tracks per energy. This is in contrast to tracks in water being generated with a maximum step size of 0.5 mm and with 40,000 tracks per energy [10]. This reduces the memory size of the air track bank such that it can be loaded onto the GPU simultaneously. If an electron is found to be outside the patient geometry (i.e. in air), the track segment is first verified to intersect the patient's bounding box [15] before performing more costly voxel-by-voxel raytracing. Any particle found to exit the phantom geometry is immediately discarded.

For beamlet generation, at each energy, a Varian-provided phase space file is transported through a TrueBeam model in BeamNRC to generate an intermediate phase space file at the MLC plane. The intermediate phase space is then further divided into 1080 sub-phase space files by binning particles into a regular square grid. Each sub-phase space file thus consists of particles found in a square area at the MLC plane that projects to 1×1 cm^2 at isocenter. Each beamlet is thus calculated by using its corresponding sub-phase space file as its particle source.

2.2 Validation and benchmark

For beamlet generation, at each energy, a Varian-provided phase space file is transported through a TrueBeam model in BeamNRC to generate an intermediate phase space file at the MLC plane. The intermediate phase space is then further divided into 1080 sub-phase space files by binning particles into a regular square grid. Each sub-phase space file thus consists of particles found in a square area at the MLC plane that projects to 1×1 cm^2 at isocenter. Each beamlet is thus calculated by using its corresponding sub-phase space file as its particle source.

To validate the accuracy of PMC dose calculations, percentage depth dose (PDD) curves were calculated for 5 electron energies (6, 9, 12, 16, and 20 MeV) in a homogeneous water slab of dimension $25.6\times25.6\times25.6$ cm^3. A profile curve is also traced at a depth of 1.5 cm. For each energy, one such aforementioned sub-phase space file was used as the particle source. The calculations are compared to Monte Carlo calculations using the same sub-phase space files as particle sources on EGSnrc. The latent uncertainty is estimated by using the formalism presented by Renaud et al. [10]. All simulations are configured such that the water phantom is located at 100 cm source-to-surface distance (SSD). The same phantom file (`.egsphant`) is used for both calculation methods with a voxel size of $0.2\times0.2\times0.2$ mm^3. For reference, a PMC calculation without photon transport is also included. The computation time for a beamlet calculation to a type-A uncertainty of 1% was recorded with PMC on 1 NVIDIA TitanRTX GPU and compared to the same calculation with EGSnrc on a single Intel(R) Xeon(R) Gold 6140 CPU core as well as compared to using all 160 CPU cores available on our computer cluster in Fig. 3.

3 Results and Discussion

Both the PDD (Fig. 1) and off-axis profile (Fig. 2) plots showed excellent agreement between PMC and EGSnrc. Sufficient histories were used with both calculation methods to reach a type-A uncertainty of less than 0.2% on voxels receiving at least 50% of the maximum dose. The latent uncertainty as averaged over the 5 electron beamlet energies

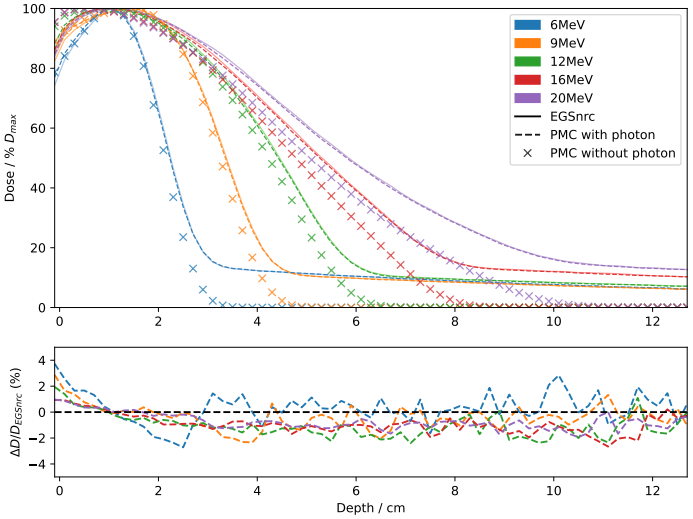

Figure 1: Validation of PMC PDD against EGSnrc in a homogeneous water slab. Both EGSnrc and PMC type-A uncertainties are below 0.2% in voxels receiving at least 50% of the maximum dose. The PMC dose as calculated without photon transport is included for comparison. Local residuals are plotted for the PMC dose with photon transport. Error bars were omitted for clarity as the type-A uncertainties are too small to be visually rendered.

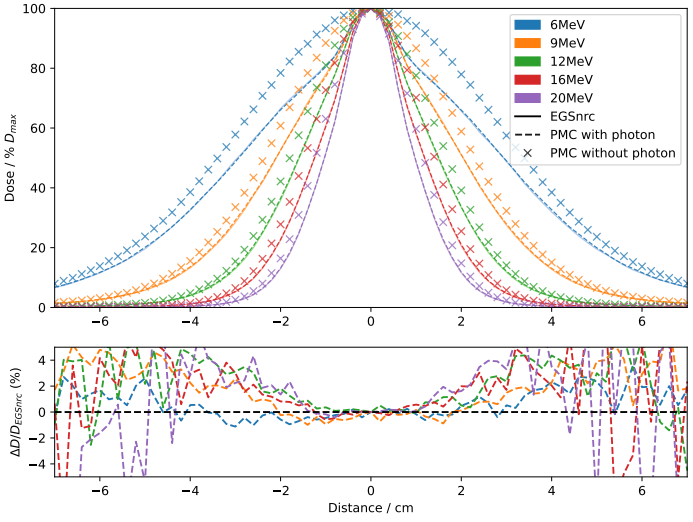

Figure 2: Validation of PMC profile against EGSnrc in a homogeneous water slab at 1.5 cm depth.

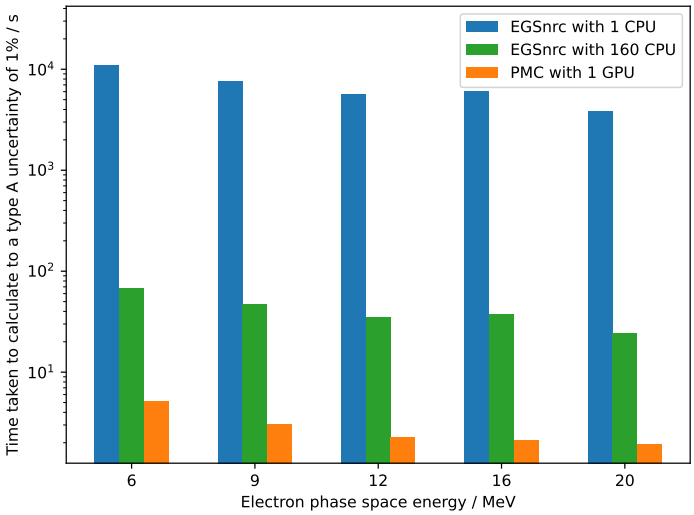

Figure 3: Comparison of time taken to calculate to 1% type-A uncertainty by EGSnrc and PMC. For a more practical comparison, the calculation time when using our entire computer cluster (160 CPUs) is also included.

was 1.3% as evaluated in voxels receiving at least 20% of the maximum dose [10]. The handling of photon transport in PMC was critical in the rapid dose falloff region and in the bremsstrahlung tail of electron beamlet PDDs. The total GPU memory usage was around 10 GB, mainly due to the track bank size.

To reach the same type-A uncertainty for a 12 MeV beamlet calculation, PMC is more than 1800 times faster than EGSnrc on a single CPU. Even when compared to our small computer cluster, PMC calculations on a single commercially available GPU outperforms EGSnrc by over a factor of 10. This speed-up in the electron beamlet computation time is crucial for the clinical translation of MBRT. Indeed, for robust optimizations, beamlets must be calculated in each robust scenarios, at each control points, and at each electron energy. For a typical MBRT plan, this can total to over 30 000 beamlets. With EGSnrc, this beamlet calculation step took on the order of 1 week to compute while PMC does it on the order of 1 day. Furthermore, as consumer GPUs are much more affordable to purchase than computer clusters with hundreds of CPU cores, PMC allows for a wider and more accessible implementation of MBRT in the clinic.

4 Conclusion

To speed up MBRT treatment planning times, a GPU-based Monte Carlo dose calculation method was improved to be used for MBRT electron beamlet calculations. A simplified photon transport method was added to PMC to handle bremsstrahlung photons and contamination photons. PMC allowed for faster Monte Carlo dose calculation of MBRT electron beamlets compared to EGSnrc by over 3 order of magnitude.

Abstract
In our proton facility, the Maastro Proton Therapy Center in Maastricht, we have entirely supplanted traditional measurements with machine logfile-based patient specific quality assurance (PSQA). This innovative approach is underpinned by the independent GPU-accelerated Monte Carlo code Fred. This study presents a comprehensive report on the clinical application of Monte Carlo based PSQA over a period exceeding three years at our proton therapy center.

1 Introduction

In the context of proton beam therapy, maintaining concordance between the planned and delivered doses is imperative. Ensuring the absence of disparities arising from factors such as planning intricacies, data transfer nuances, and delivery errors is paramount. Consequently, a rigorous validation process is adopted for each clinical plan in proton beam therapy. This validation, commonly conducted as part of patient-specific quality assurance (PSQA), involves the measurement of absolute dose distributions for each individual treatment field before the initiation of treatment, followed by a meticulous comparison with the predicted dose distributions. In an effort to streamline the beam-time required for PSQA measurements and enhance overall PSQA quality, the utilization of machine log files has been explored.

Machine log files can be procured either through a dedicated dry-run irradiation or inherently during the delivery of a treatment fraction. These log files encapsulate crucial information regarding spot position, dose, and energy, which can be restructured into a treatment plan and used to reconstruct the actual delivered dose. This reconstructed dose can then be compared against the originally prescribed planning dose.

For the generation of an independent dose distribution based on log files, the adoption of a Monte Carlo dose engine distinct from the clinical Treatment Planning System (TPS) is imperative.

At the Maastro Proton Therapy Center, we opted for the utilization of the GPU-accelerated Monte Carlo code Fred [1] owing to its efficient computational performance, precision, and capacity to accommodate the idiosyncrasies of our proton machine [2]. Fred can recompute a proton treatment plan using 1% of the total particles within a matter of minutes.
In the scope of this study, we present our endeavors to transition from a measurement-based approach to a simulation-based one for PSQA at the Maastro Proton Therapy Center. This paradigm shift involves the integration of Fred as an independent dose calculation engine, coupled with machine log files.

2 Materials and Methods

We devised a hybrid methodology for the integration of our proton machine system's beam model into Fred. The validation process of our beam model successfully met all clinical acceptance criteria.

The beam model and machine geometry of the therapeutic Mevion S250i proton accelerator were meticulously incorporated into the independent Monte Carlo code Fred, as extensively detailed in [3]. Given the Mevion S250i's unique delivery system, encompassing a range modulation system and an adaptive aperture in the beam path, special consideration was given during implementation.

A validation process, involving extensive comparisons with commissioning measurements [2] and alignment with the clinical TPS, was undertaken. The pristine proton beam is described by a phase space model situated in a plane at the scanning magnet position, while the dynamically extendable nozzle housing the beam monitor system, range modulation system, and adaptive aperture is explicitly simulated. Validation of Fred met all established clinical acceptance criteria [3].

For a comprehensive patient simulation, input data can be extracted either from the treatment plan or from the machine log files of the accelerator. An automated pipeline adeptly extracts CT images, RTstruct, and RTplan DICOM files from the clinical database system, linking them to the corresponding measured files of the proton machine. Subsequently, a new RTplan file is generated based on the log files and serves as input to Fred. The ensuing dosimetric validation report, inclusive of gamma index and dose volume histograms, is automatically generated. Each time a

new plan or log file in the clinical database, A comprehensive report, featuring visualizations and a quantitative dosimetric summary, is automatically produced.

A fully operational pipeline has been established, and the routine review of automatic verification reports has become part of our daily clinical practices. The recalculation of patient dose distributions takes mere minutes, enabling swift on-the-fly execution of the pipeline. During the initial months following the introduction of this pipeline in our clinical routine in the summer of 2020, full 3D Monte Carlo dose recalculations for QA plans complemented the conventional 2D patient-QA measurements. In the contemporary setting, Monte Carlo based QA has entirely supplanted patient-QA measurements. Nowadays, patient-QA measurements are only performed in the rare situation that a recalculation results in a failed verification.

3 Results

An exhaustive analysis of the generated data will be presented at the ICCR. To date, our pipeline has been used to recalculate over 4000 clinical plans, with 2812 of them originating from machine logfiles. The chronological record of the passing rate and its distribution per clinical indication are depicted in Figure 1. The Gamma index pass rate in percentage (%) was calculated using a gamma criterion of 3 mm and 3%. Notably, in December 2022 (indicated by the black vertical dotted line in the left panel), the scoring of dose to water in Fred was initiated. Subsequent to this implementation, the pass rate has consistently reached 99.7%

Sparring the measurements of more than 4000 clinical plans implies a reduction of approximately one working month (21 days) in routine QA annually, considering an average of 30 minutes for a PSQA measurement. Notably, this method enables the identification of cases that might have eluded detection through standard PSQA measurements in homogeneous media and that could potentially exert a non-negligible impact on clinical patient treatments, as elucidated in Figure 2.

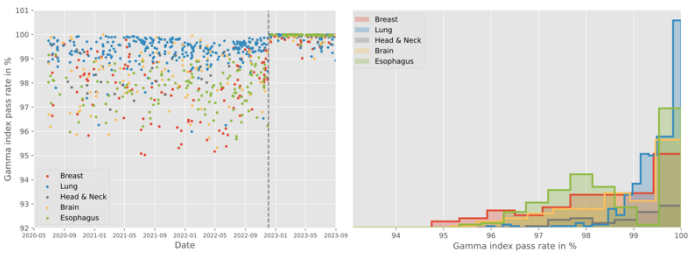

Figure 1: Gamma index pass rate in % (gamma criterion of 3 mm and 3%) for log file based PSQA as a function of time (left) and histogram per clinical indication (right). In December 2022 (black vertical dotted line), we started scoring dose to water in Fred. Since then, the pass rate is 99,7%.

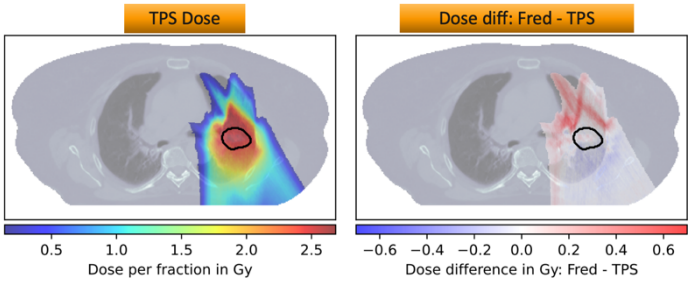

Figure 2: Example of a clinical case which would not have been detected with standard PSQA measurements in homogeneous media and which would have had a non-negligible impact in clinical patient treatments.

4 Discussion

This work delineates the establishment of a comprehensive pipeline for the automated recalculation of patient plans n proton beam therapy, leveraging both the clinical Treatment Planning System (TPS) plan and machine log files derived from the proton accelerator. The automated workflow adeptly extracts requisite patient information, including CT images and treatment plans, from the clinical database system. Recalculations performed on the clinical plan serve to automatically verify the integrity of the planning process and plan transfer to the proton accelerator. On the other hand, recalculations on the machine log files ascertain the accuracy of treatment delivery by the proton accelerator.
The dose recalculation pipeline followed by the creation of a dosimetric validation report alongside a quantitative dosimetric summary is triggered automatically by the upload of each new plan or log file in the clinical database. We are currently investigating a dedicated gamma index analysis tailored to and optimized for every clinical indication. The dose recalculation and verification pipeline could also be extended in the future to include considerations based on dose volume histograms.

5 Conclusion

The PSQA pipeline developed at Maastro significantly streamlines daily operations by furnishing invaluable and comprehensive 3D dosimetric information, eliminating the necessity for dedicated beam time.

Abstract Severe radiation-induced lymphopenia occurs in 40% of patients treated for primary brain tumors and is an independent risk factor of poor survival outcomes. We developed an in-silico model that estimates the radiation doses received by lymphocytes during brain irradiation. The simulation consists of two interconnected compartmental models describing the slow recirculation of lymphocytes between lymphoid organs ($\mathcal{M}_1$) and the bloodstream ($\mathcal{M}_2$). We used dosimetry data from 33 patients treated for glioblastoma to compare three scenarios: H1) lymphocytes circulation only in the bloodstream; H2) lymphocytes recirculation between lymphoid organs H3) lymphocytes recirculation between lymphoid organs and deep-leaning computed out-of-field dose to head-and-neck lymphoid structures. According to H3 case, almost all lymphocytes were irradiated after treatment, at a mean dose of 265.6 ± 48.5mGy. Our study is the first to take into account out-of-field doses and recirculation in lymphocyte dose assessment during brain irradiation. Our results demonstrate the need to clarify the indirect effects of irradiation on lymphopenia, in order to potentiate the combination of radio-immunotherapy or the abscopal effect.

1 Introduction

Severe radiation-induced lymphopenia (sRIL) occurs in 40% of patients treated for primary brain tumors with radiochemotherapy and is an independent risk factor for inferior overall survival outcomes [1]. One hypothesis put forward to explain the occurrence of sRIL after brain irradiation is the cytotoxic doses received by the blood lymphocyte pool. Therefore, several research groups have been interested in developing models to evaluate the doses received by the peripheral blood [2]. However, none has yet considered the out-of-field (OOF) dose to the head and neck (H&N) region rich in lymphoid structures, or the slow recirculation and homing of lymphocytes between lymphoid organs such as the spleen or lymph nodes and blood (which only contains about 5% of the total lymphocyte pool at any given time [3]). To tackle these shortcomings, this work proposes a new model to assess more accurately the doses received by recirculating lymphocytes during brain irradiation.

2 Materials and Methods

To assess the doses received by the lymphocyte pool during irradiation, we modeled their dynamics within the organs. We distinguished two distinct but interdependent processes: (i) the slow recirculation of lymphocytes between lymphoid organs, mediated by specific biological process [4], and (ii) the rapid circulation of lymphocytes through all organs via the bloodstream. These 2 phenomena were modelled in this work by implementing 2 interconnected compartmental models, named $\mathcal{M}_1$ and $\mathcal{M}_2$ respectively and shown in Figure 1. Both models are associated with a stochastic continuous-time semi-Markov chain process to simulate lymphocyte paths between compartments during the whole treatment. In practice, the implementation was based on a Kinetic Monte Carlo algorithm. Each compartment of the $\mathcal{M}_1$ and $\mathcal{M}_2$ models were associated with 2 parameters: 1) a continuous distribution of lymphocyte residence times, which enables a residence time to be stochastically determined for each lymphocyte passage through that compartment via inverse transform sampling, and 2) a vector of transition probabilities to the connected compartments, in order to stochastically determine which compartment the lymphocyte will migrate to.

Model $\mathcal{M}_1$ (Figure 1) is a modified model based on the work of Ganusov et al. [5], which describes lymphocyte recirculation via *circulating blood* between *spleen*, *subcutaneous lymph nodes (SCLNs*), *mesenteric lymph nodes (MLNs)* and *Peyer's Patches (PPs)*, using rats experimental data. In accordance with [5], residence times were distributed according to an exponential law with a parameter $\lambda_{M1} = \frac{1}{Mean\,residence\,time}$ for the *Spleen*, *PPs* and *Blood Circulation* compartments, and according to a gamma distribution with a shape $k'_{M1} = 2$ and a scale $\theta_{M1} = \frac{Mean\,residence\,time}{k'_{M1}}$ for the *NCLNs* and *MLNs* compartments.

Model $\mathcal{M}_2$ (Figure 1) was based on the ICRP Publication 89 [6], which describes a transition matrix for blood flow between 28 organs in the male and female human body. Mean residence time values were calculated considering a total blood volume of 5.3 L and 3.9 L and a cardiac output of 6.5 L.min^{-1} and 5.9 L.min^{-1} for male and female patients respectively. In accordance with the data given in [7], residence times were distributed according to a Weibull distribution with a shape $k_{M2} = 2$ and a scale $\lambda_{M2} = \frac{Mean\,residence\,time}{\Gamma(1+\frac{1}{k_{M2}})}$, with Γ the gamma function.

A cohort of 33 patients with glioblastoma treated after 2018 with conventional VMAT (Volumetric Modulated Arc Therapy) irradiation was created. To simulate a treatment, each patient was characterized by 1) his gender, which defined which variant of the $\mathcal{M}_2$ model (male or female) to apply, and 2) his irradiation parameters. For a given patient, a conventional VMAT treatment was defined

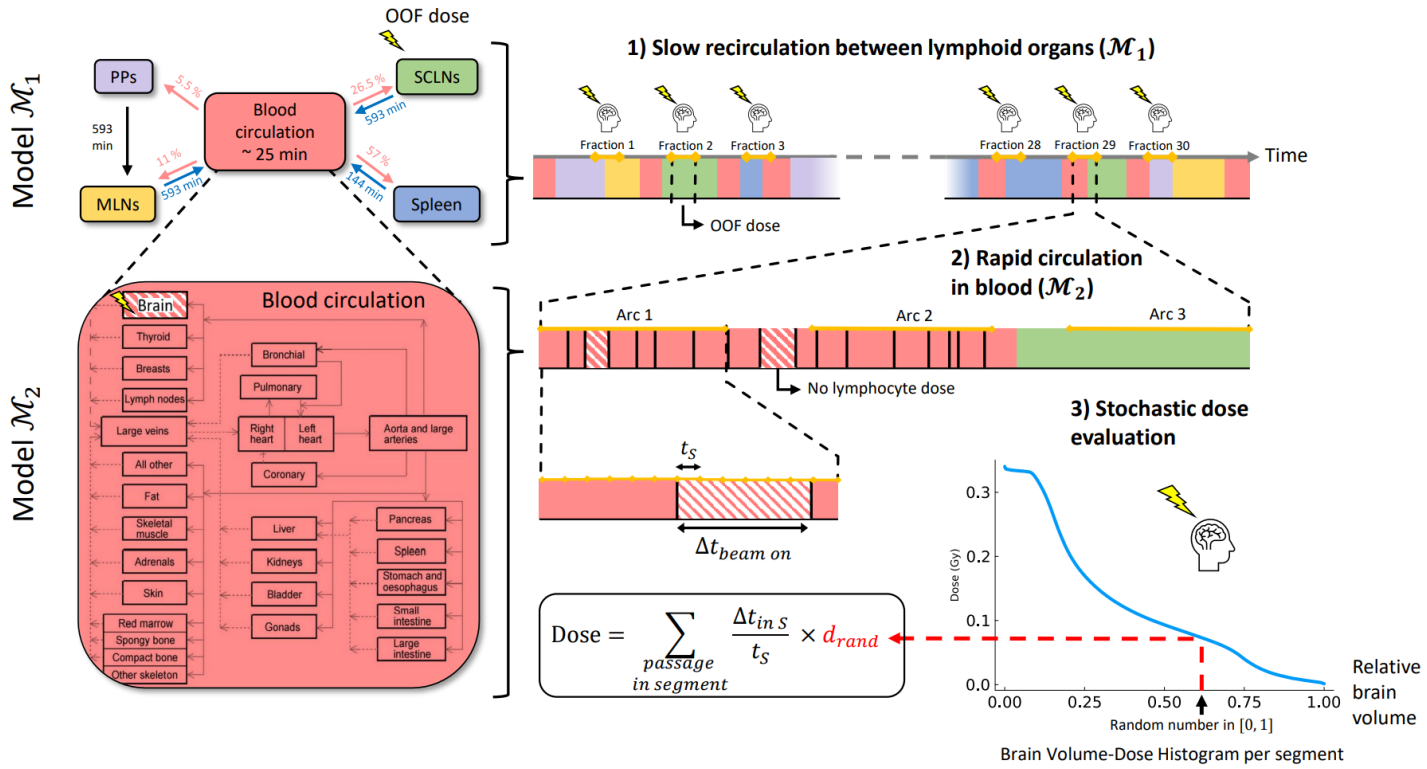

Figure 1 *On the left, compartment models $\mathcal{M}_1$ and $\mathcal{M}_2$ describing lymphocyte recirculation between lymphoid organs and blood flow, respectively. On the right, a schematic representation of a recirculating lymphocyte path and the dose it receives in the continuous time semi-Markov chain simulation SCLNs: subcutaneous lymph nodes, MLNs: mesenteric lymph nodes, PPS: Peyer's Patches (PPs), OOF: Out-of-field*

by a succession of N_F fractions F_i ($i \in [1, N_F]$) spaced 24 hours apart. Each fraction F_i was composed of a succession of N_A arcs $A_{i,j}$ ($j \in [1, N_A]$), each lasting $t_{A_{i,j}}$ seconds and spaced 5 seconds apart. Each arc $A_{i,j}$ was itself subdivided into N_S successive segments $S_{i,j,k}$ ($k \in [1, N_S]$), with the assumption that its duration was $t_{S_{i,j,k}} = \frac{t_{A_{i,j}}}{N_S}$. For each segments $S_{i,j,k}$, a whole brain dose-volume histogram $DVH_{i,j,k}$ were recalculated using a Collapsed-Cone Convolution dose engine provided by TheraPanacea company (Paris, France).

In order to evaluate the doses received by lymphocytes using the models described above, the logic is as follows (Figure 1): since the brain contains few lymphoid organs, a given lymphocyte circulating in $\mathcal{M}_1$ is likely to be irradiated in the field if it is in the $\mathcal{M}_1$ *Blood circulation* compartment during a segments $S_{i,j,k}$. In this case, the lymphocyte enters $\mathcal{M}_2$ via the *Large Veins*. The latter is then effectively irradiated in the field if it is in the *Brain* during the beam-on time, and the received dose is stochastically evaluated using an inverse transform sampling on the whole brain $DVH_{i,j,k}$.

Because of the high radiosensitivity of lymphocytes [8], the contribution of low doses outside the brain irradiation field and delivered to the H&N region, rich in lymphoid structures, was also considered. To do this, the right and left lymph nodes areas, including Ia, Ib, II, III, IVa, V, VIIa et VIIb regions [9], were automatically contoured using ART-Plan software v1.11.5 (Therapanacea, Paris, France), and an in-house deep learning neural network [10] was used to generate "whole body" dose map from the patient's external contour and the in-field dose map from the TPS. Together, lymphoid structures contour and H&N OOF dose map allow calculation of the average $\overline{OOF}$ dose to lymphoid structures in the H&N region for each patient: $\overline{OOF} = \frac{\sum_i d_i \times v_i}{\sum_i v_i}$, with v_i and d_i the volume and the mean dose received by the lymphoid structure i, respectively. Finally, based on the analysis of 1,200 lymph nodes performed on the Visible Human Data Set [11], having shown that 31.5 ± 0.7% of subcutaneous lymph nodes (simply defined as non-mesenteric as in [5]) are located in the H&N region, we considered that a lymphocyte had a probability of 0.315 of receiving an $\overline{OOF}$ dose if it is in the SCLNs during an irradiation fraction.

To compare different physical and biological assumptions, assumptions, the dose to lymphocytes has been computed with three cases of the model: H1) circulation only in the bloodstream i.e., lymphocytes circulate in $\mathcal{M}_2$ only; H2) with recirculation between lymphoid organs i.e. $\mathcal{M}_1$ and $\mathcal{M}_2$ interconnected; H3) with recirculation between lymphoid organs and with OOF dose to H&N lymphoid structures.

The code was developed in Julia language version 1.9.3 and simulations were performed considering 10^5 particles.

3 Results

Case H1 resulted in the irradiation of almost all the circulating blood ($V_{>0Gy}$ = 99.8 ± 0.7%) at the end of VMAT treatment, at a mean dose of 309.9 ± 74.7 mGy (Figure 2). Taking into account lymphocytes recirculation in H2 case, the fraction of lymphocytes receiving a non-zero dose dropped to 40.4 ± 10.2%, with a lower mean dose estimated at 52.6 ± 21.1 mGy, especially because irradiated lymphocytes passed through the irradiation field only 1.58 ± 0.91 times on average due to slow recirculation between lymphoid organs in the $\mathcal{M}_1$ model. The most realistic scenario, including the OOF dose component (case H3), showed that almost all the lymphocytes (97.6 ± 2.5%) were irradiated at the end of the treatment, mostly due to the OOF dose (mean dose equal to 265.6 ± 48.5 mGy).

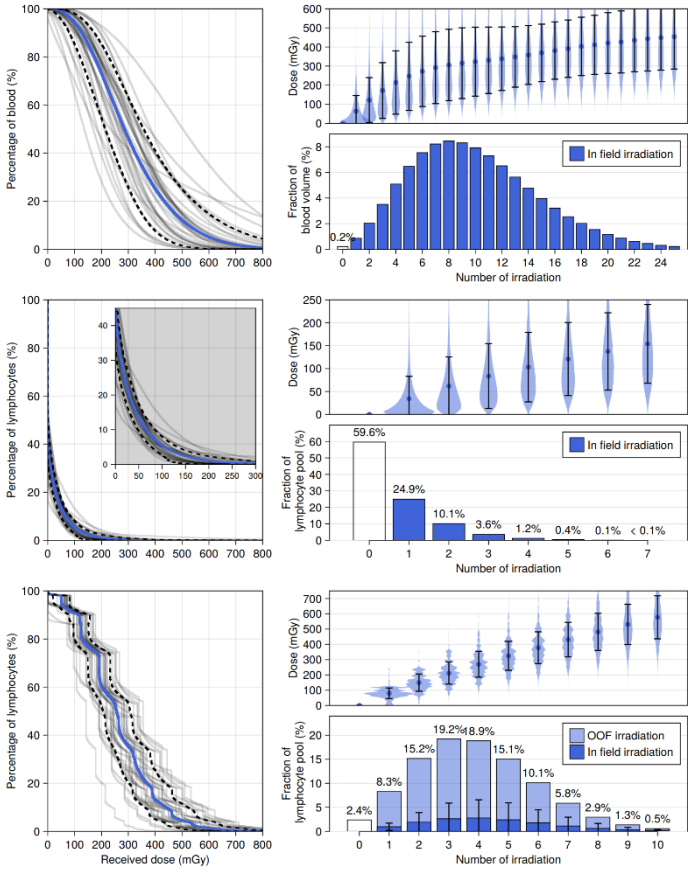

Figure 2 The left column represents Dose Volume Histograms (DVH) of blood (H1) and of the recirculating lymphocyte pool without (H2) and with (H3) consideration of the low out-of-field (OOF) dose in the lymph nodes of the head and neck region at the end of treatment. In each figure, the mean DVH over the whole cohort is shown in solid blue, the associated standard deviation in dotted line and the DVHs for each patient in the cohort in solid light grey. On the right column, the average number of lymphocyte irradiations (bottom), and the associated dose (top), averaged over the whole cohort are described

4 Discussion

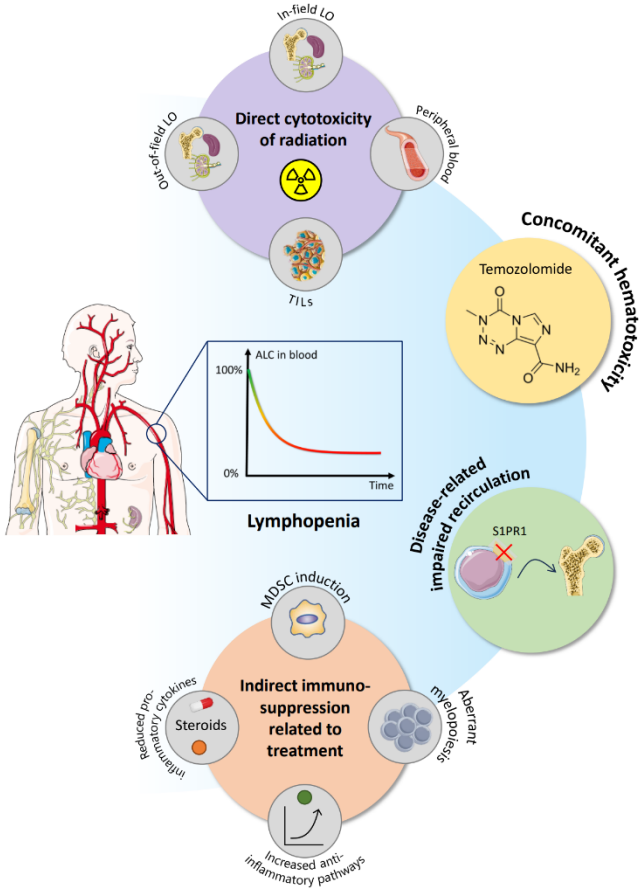

Figure 3 Several immunomodulatory factors can alter both quantitatively and qualitatively the patient blood lymphocyte composition and contribute to lymphopenia. Thus, a decrease in blood ALC, used to characterize lymphopenia, can have several different causes. The cytotoxic effect of irradiation on lymphocytes is one of these factors, but our results suggest that its relative contribution to the development of lymphopenia might be limited, especially in the context of brain irradiation. LO: Lymphoid organs, TILs: Tumor infiltrating lymphocytes, ALC: Absolute Lymphocyte Count, S1PR1: Sphingosine-1-phosphate receptor 1.

In this work, a new in-silico model, efficient in terms of calculation time and closer to biological reality, was proposed. Compared to previously published studies [2], out model highlighted the major role of OOF doses and recirculation for the correct calculation of the dose received by lymphocytes during brain irradiation. Despite the high level of radiosensitivity of lymphocytes [8], our results (regardless of the H1, H2 or H3 cases used) hardly explain the 40% sRIL rates observed clinically in patients with brain tumours treated with radiochemotherapy. These results call into question the relative contribution of the direct cytotoxic effect of irradiation on lymphocytes to the induction of RIL, and several other immunosuppressive effects will certainly have to be taken into account in order to potentiate treatments (Figure 3). First, lymphopenia can be influenced

by the concomitant exposure to systemic medications, including temozolomide and corticosteroids [12]. Then, it has been shown that intracranial tumors are intrinsically characterized by a S1P1-mediated sequestration of T cells in the bone marrow [13]. In addition, radiation can trigger an aberrant myelopoiesis in the bone marrow leading to an increase of lymphotoxic myeloid-derived suppressive cells (MDSC) in the peripheral blood [14]. All these direct and indirect mechanism could contribute to the worsening of lymphopenia upon radiotherapy treatment.

Several perspectives are open for future research. Firstly, clinical and pre-clinical data are essential to experimentally validate our results and to complete the modelling. Secondly, the recirculation model ($\mathcal{M}_1$) used is based on rats data. Data in humans would be valuable, as the immune systems of the 2 species are patiently different [15]. Moreover, several different lymphocyte subpopulations with different recirculation patterns coexist in the blood [16], and therefore models different from the $\mathcal{M}_1$ model are required. Thirdly, average residence times used in the $\mathcal{M}_2$ model, for the *Brain* compartment in particular, are those of circulating blood. However, it could be significantly higher for the lymphocytes it contains, in particular because of their ability to adhere to endothelial cells, or simply because their diameter (~7µm) is of the same order of magnitude as diameters of some cerebral capillaries [17]. Finally, Neural Network used to evaluate OOF dose was trained on pediatric data. It therefore probably overestimates OOF doses, and experimental measurements are required to validate these results

5 Conclusion

We have developed an in-silico model based on continuous time semi-Markov chain process to evaluate the dose to peripheral blood and to circulating lymphocytes after brain radiotherapy treatment. The model consider the rapid circulation of lymphocytes in blood, the recirculation of lymphocytes between lymphoid organs and the OOF dose to lymphoid structure of the H&N region. It is an important preliminary step towards a better understanding of the radiobiological mechanisms underlying RIL, and the model could be applied to other irradiation locations in the future. From a clinical point of view, reducing the incidence of RIL could not only improve the response to radiotherapy and chemoradiation, but also enhance the potential of radioimmunotherapy combinations or abscopal effect.

This work has benefited from the grant ANR-21-RHU5-0005 within the FRANCE2030 investment plan.

Abstract The aim of our work is to develop a Deep Learning (DL) algorithm capable of efficiently generating dose distributions for particle beams within heterogeneous mediums, such as the human body. This model computes dose as a function of the beam parameters, as entry point, energy, and fluence with an accuracy comparable to Monte Carlo algorithms but at an exceptionally rapid pace (0.01 seconds per beam on a single GPU). The resulting dose maps hold great potential for integration into the cost function of forthcoming Radiotherapy (RT) auto - planning algorithms, particularly those based on differentiable optimization. The core of our DL architecture is a U-Net based on Graph Neural Networks, with a purpose-developed pooling technique. Trained on Geant4 Monte Carlo simulations using a patient CT scan and beam characteristics as inputs, our model achieve satisfactory performances through rigorous training and testing on diverse beam orientations and energies.

1 Introduction

External beam RT is a widely recognized and effective cancer treatment [1]. In order to deliver the correct amount of dose which satisfies the medical prescription, a "treatment plan optimization" which considers beams orientation, energy and fluence is needed. At the basis of a reliable treatment plan optimization there should be a robust method to estimate the dose delivered by the therapeutic beams. Nonetheless, while MC simulations provide precise dose estimation, their time-consuming nature often leads to reliance on faster deterministic algorithms, which may sacrifice accuracy, especially near organ boundaries.

Recent interest in high-dose-rate therapies, particularly electron FLASH therapy, offers ultra-fast radiation delivery with many potential benefits. FLASH-RT, characterized by ultra-high dose rates (>40 Gy/s) and approximately 400 times faster than traditional radiotherapy, exploits the "FLASH effect", sparing healthy tissues while effectively targeting tumors [2, 3]. Very High Energy Electrons (VHEE) are currently considered one of the best candidates to exploit the FLASH effect on deep seated tumors, also benefiting from the greater simplicity in changing beam's orientation and energy [4, 5].

At present, building a treatment plan optimization strategy for FLASH electrons which simultaneously considers beams orientation, energy and fluence is still a challenge, also because of the lack of quick algorithms for dose estimation.

In this context, DL can emerge as a promising tool to overcome present limitations. DL models can learn to emulate MC simulations, facilitating the fast generation of precise dose distribution maps. Their versatility, makes DL models applicable to various RT treatments, possibly leading to a broad impact on the RT treatment field.

In the existing literature which explores DL applications in dose deposition estimation and treatment planning, there is a focus on replicating entire treatment plans for clinically established treatments [6, 7]. Only a limited number of studies focuses on the bare prediction of dose maps [8, 9]. We propose a DL model which aims to replicate MC-simulated dose distributions for VHEE beams, utilizing a voxelated cylindrical volume strategy for efficient and accurate predictions. Employing Graph Neural Networks, specifically a U-Net-like model based on Graph Convolutional Networks, our model provides an ultra-fast (~ 0.01 s) estimate of the deposited energy distribution within a cylindrical volume around the beam.

2 Materials and Methods

We trained a DL model to emulate the energy deposition distribution of an electron beam on a human head. The DL model takes the beam's energy and organ densities in a cylindrical volume around the beam as input, providing the deposited dose distribution in the same cylindrical volume as output.

We utilized a Geant4 simulation with a CT scan of a patient's head coming from the HaN-Seg dataset [10]. The CT scan, comprising 116 slices with a thickness of 2 mm and 512×512 pixels per slice, served as the detector geometry. Materials were assigned based on Hounsfield Unit (HU) values, and nominal densities were assigned using the standard calibration curve from [11].

VHEE beams were simulated as Gaussian pencil beams with a full width at half maximum (FWHM) of 0.5 cm. A cylindrical scorer was used to collect dose deposition data, and a dataset of 10,000 low statistics examples (10,000 primaries) was generated for DL model training, varying beam energies between 70 and 130 MeV. A small set of 10 examples with

high statistics (1 million primaries) was also generated for the final evaluation of the DL model. The cylindrical scorers are 40 *cm* long, with a radius of 8 *cm*. Each cylindrical voxel is 4 *mm* long along the z and r axis. Inner voxels have an angular length of ~ 1 *mm*, while the outer ones have an angular length of ~ 2 *cm*. In this way we can provide a higher resolution near the beamline, where most of the dose is deposited, keeping the number of voxels, and thus the computational requirements, relatively low.

Density values in cylindrical voxels were computed through interpolation using $N = 100$ random 3D points inside each voxel. This process ensured reliable density estimates for input to the DL model. The cylindrical voxels were considered as nodes of cylindrical graphs and each node was connected to its two nearest neighbours in each dimension: z, θ, r.

The DL model, to which we will refer as ReNN GU-Net, is based on Graph Neural Networks with a U-Net structure and comprises three modules: encoder, embedder, and decoder. The encoder processes cylindrical graphs containing density information through a series of GraphConv layers and regular pooling operations [12], while the embedder handles the beam energy. The outputs of the encoder and the embedder are summed and pased to the decoder. The decoder reconstructs the dose distribution using GraphConv layers and un-pooling operations with skip connections from the encoder. The model is based on the one already presented in [13], with some improvements.

The main improvement regards increasing the connectivity in the graphs basing on a simple prior related to the physics of the dose deposition: the dose deposited in the "deeper" voxels in the cylinder depends on the dose deposited at smaller depth. Thus we wired additional direct links between each node and its 4 neighbours in the positive z direction of the cylinder. In order to inject other nodes' spatial information in the model, we also concatenated to the input graphs a 3D positional encoding on the cylindrical coordinates. Overall, this modifications led to a $\sim 10\%$ improvement in the model performance on the dose prediction task.

The model was trained with Binary Cross-Entropy loss function.

3 Results and discussion

We divided our 10,000 examples into train, validation, and test sets. The test set, comprising 275 examples, met specific conditions for beam energy, angle θ, and angle ϕ. The remaining data was split into a training set (8,752 examples) and a validation set (973 examples), maintaining a 1:10 ratio. This test set configuration aimed to rigorously assess the ReNN GU-Net model's ability to interpolate between samples and generalize to unseen configurations, considering both patient anatomy and beam energy.

The 10 high-statistics examples for the final evaluation and plots were generated in the parameter range of the test set.

MAE $[\mu Gy]$	(0.26 ± 0.05)
$\delta < 3$	$(99.8 \pm 0.2)\%$
MRE z	$(0.6 \pm 0.3)\%$
MRE r	$(0.4 \pm 0.2)\%$
MRE E	$(0.2 \pm 0.2)\%$

Table 1: We report the results for all the metrics used to compare the prediction of our DL model with the MC simulation. Reported values of mean and standard deviation are computed on the high-statistics evaluation set.

The model was trained with a learning rate of 0.005, a batch dimension of 16, and a learning rate scheduler (ReduceOnPlateau) with a patience of 20 epochs. Training stopped at the convergence of the validation loss after 104 epochs. Training was performed on a Tesla V100 GPU and lasted approximately 4 hours.

3.1 Evaluation Metrics

We employed four metrics to evaluate model performance:

1. Mean Absolute Error (MAE): Voxel-wise mean absolute error between MC and DL dose deposition.
2. δ-index: Introduced by Mentzel [14], it quantifies voxel-wise absolute error differences between MC and DL dose depositions normalized by the maximum deposited dose. We considered the δ-index 3% passing rate, which measures the percentage of voxels with δ-index less than 3%.
3. Mean Relative Error (MRE) on Dose Profiles: Mean Relative Error for integrated dose deposition profiles along the cylindrical axes z and r.
4. Mean Relative Error (MRE) on Total Dose: Mean Relative Error on the full integral of the dose deposition, representing the total deposited dose.

Results for all metrics, on the evaluation high-statistics set, are presented in Table 1. They show a high level of agreement between the MC simulated and DL emulated dose with a δ-index 3% passing rate of 99.8% and a MRE on dose profile around 0.5%.

In Figure 1 we illustrate the comparison between the integrated dose deposition profiles along the z and r axis of the cylinder. In the top plots, we report in blue, the dose profile computed with MC simulation, in orange, the one computed with our DL model and with dashed grey line, the average density in g/cm^3. In the bottom plots, the relative error between the two profiles is reported. As it can be seen, the relative error is always bounded between -2% and 2%.

The similar level of agreement is also found locally. In Figure 2 we show the same plot computed considering only one voxel in the r dimension. the dose profiles are thus computed considering only the inner cylinder with radius

equal to 4 *mm*, where most of the dose is deposited. In this case, the relative error is bounded between -4% and 2%. However, it is possible to note that the relative error increase in the tail of the distribution, where also the MC simulations typically present greater variance, due to the decreased statistics.

Overall, while maintaining a satisfactory precision level, our DL model allows to generate dose distributions in an ultra-fast way. While the high-statistics MC simulations takes around 18 *min* in multi-threaded mode on a 16 cores CPU (HP Z2 Tower G5 Workstation), our DL model can generate the same dose map in around 0.02 *s* on the same device -i.e. on a CPU- leading to a speed up factor of approximately 5×10^4 times. Moreover, making the model run on GPU devices shorten even more -up to 6 orders of magnitude in batch mode- the execution time.

Finally, the greater advantage of a DL dose map generation resides in the fact the dose maps predicted by DL models are, by construction, differentiable with respect to the beam parameters, which are model inputs. This characteristic will allow us to build a treatment planning optimization strategy completely based on exact gradient-based optimization.

4 Conclusion

In conclusion, this study addresses the critical challenge of developing a treatment plan optimization strategy for VHEE beams, specifically in the context of FLASH therapy. The reliance on MC simulations for dose estimation poses time constraints, necessitating the exploration of alternative methods. Leveraging the potential of DL, we introduced the ReNN GU-Net model based on Graph Neural Networks, aiming to efficiently and accurately predict MC-simulated dose distributions for VHEE beams.

Through extensive training and evaluation using a Geant4 simulation with a CT scan of a patient's head, our model demonstrated remarkable performance. The evaluation metrics, including Mean Absolute Error (MAE), δ-index passing rate, and Mean Relative Error (MRE) on dose profiles, revealed a high level of agreement between MC-simulated and DL-emulated dose distributions. The model's ability to generalize to unseen configurations, considering both patient anatomy and beam energy, was rigorously assessed.

Furthermore, our improvements to the model, involving increased connectivity in the graphs and the incorporation of spatial information, resulted in a notable enhancement in performance. The ReNN GU-Net achieved an ultra-fast estimate of the deposited energy distribution within a cylindrical volume around the beam, with an execution time approximately 0.02 seconds on a CPU.

The significance of this DL model extends beyond its speed and accuracy. The differentiability of the predicted dose maps with respect to beam parameters opens up avenues for exact gradient-based optimization in treatment planning.

In essence, the successful development and validation of the ReNN GU-Net model present a promising leap forward in the integration of AI, specifically DL, in the optimization of treatment plans for advanced radiation therapies, showcasing potential transformative impacts on the field of radiotherapy.

Abstract Skin dose in radiation therapy is a key issue for reducing patient side effects, but dose calculations in this high-gradient region is still a challenge today. To support radiation therapists and medical physicists in their decisions, a computational tool has been developed to systematically recalculate the skin dose for each treatment session, taking into account changes in breast geometry. This tool is based on Monte Carlo skin dose calculations from deformed vector fields (DVF)-driven CT images, using non-ionizing 3D-scanner data. The application of deformation fields to the initial patient CT, as well as the validation of Monte Carlo skin dose calculations and comparison with TPS algorithm, are presented. The tool is currently being evaluated using a dataset of 60 patients from the MorphoBreast3D clinical study.

1 Introduction

Breast cancer is the most common cancer among women in France, with around 60,000 new cases and over 10,000 deaths per year. Some 85% of patients are currently treated with radiotherapy [1]. Despite continuous improvements in techniques to optimize dose distribution, i.e. increase the precision of radiation targeting while minimizing exposure to normal tissues, a significant number of patients still suffer from acute toxicity (burns) to the skin and subcutaneous tissues. In order to reduce these side effects, one needs to better estimate the exact dose delivered to the skin during irradiations. However, calculating the dose distribution in this very high-gradient region is complicated by the combination of the lack of precision of treatment planning systems (TPS) at the air-tissue interface [2], the compromise to be made on the calculation grid size in order to remain within acceptable calculation times, and the inevitable changes in breast geometry during and throughout treatment (breathing, breast swelling between fractions) [3].

Radiotherapy centers have developed protocols to limit the possible side-effects of inaccurate surface dose estimation, such as modifying the patient's target or body volume margins [4], or using a bolus during the optimization process to spare dose build-up to the skin. But the main difficulty encountered by medical physicists is the lack of tools available for determining the optimal solution for each patient, especially when considering intensity modulated techniques with regard to changes in breast geometry during treatment.

In this context, the Strasbourg Europe Cancer Institute (ICANS), the ICube laboratory, and the Hubert Curien Interdisciplinary Institute (IPHC) are collaborating on the development of a computational framework dedicated to skin dose calculation in breast radiation therapy. This framework combines a Monte Carlo dose calculation tool and a breast deformation algorithm by using 3D surface data recorded during treatment sessions.

This framework allows:
1) to evaluate the necessity for recalculating the treatment plan, based on the production of deformed CT images that reproduce the inter-fraction evolution of breast geometry;
2) to exploit the precision of the Monte Carlo calculation to estimate the dose delivered in the 1st millimeter of skin. This complements and evaluates the calculations of the TPS algorithms, thereby improving the understanding of the induction of side effects introduced by the breast deformation.

After introducing the general framework architecture, we present experimental measurements and Monte Carlo calculations of skin dose, the method to compute CT images of deformed breast by using 3D surface measurements, as well as the results we obtained on the first patients as part of a clinical study.

2 Materials and Methods

The skin is a complex organ, characterized by a layered structure with different cell types. The thickness of the epidermis varies between 0.05 and 1.5 mm depending on the anatomical region. The International Commission on Radiological Protection (ICRP) and the International Commission on Radiological Units and Measurements (ICRU) recommend a thickness of 0.07 mm for the practical study of the dose to the skin.

70 μm remains a precision that is difficult to access with current clinical dose calculation algorithms, thus motivating the use of Monte Carlo calculation to address the problem of skin dose in breast radiotherapy. Our dose calculation tool is based on the GATE Monte Carlo software [5], and has been previously validated on a 6 MV TrueBeam STX accelerator [6]. This tool uses the phase spaces provided by the manufacturer and the information available in the DICOM-RT files (image, plan, structure, dose) to calculate the dose delivered to the patient. A digital phantom of the patient is created from the scanner images and the HU-materials conversion method proposed by Schneider et al. [7].

The dose to the skin is due to low energy photons scattered from the accelerator head, photons backscattered into the medium, and contamination electrons produced in the accelerator head and the head-patient interface (air, accessories). Significant validation work was therefore carried out to ensure the good accuracy of the Monte Carlo dose calculation in the first millimeters of tissue. Contamination electrons, which can contribute up to nearly 50% of the dose delivered to the skin depending on the configurations, have been particularly studied from Varian phase spaces.

A clinical study carried out at ICANS in 2019-2020 enabled the acquisition of 60 patient datasets (*MorphoBreast3D*). These data contain CT images of the patients used for planning (with contouring of the organs including the skin), to dose maps calculated by the TPS, and a set of 3D surfaces meshes of the patient bust acquired at different treatment sessions using Artec Eva 3D hand-held scanner (Figure 1).

Figure 1. Artec Eva 3D scanner

The objective is to use the 3D surfaces recorded during a session in order to deform the initial CT image of the patient and to obtain a new CT image representing the exact breast geometry during the session. A per-vertex correspondence has been found between a 3D surface pair, one acquired from the CT scan (M_{init}), and another during a session (M_s). Then a deformation vector field is calculated by aligning the two surfaces and connecting the vertices in correspondence. The displacement vector field is then transferred to the CT image by rigidly aligning the surface M_{init} and the CT image. We finally obtain the deformed CT image via the use of radial basis functions (RBF), whose point specifications are defined by the displacement vector. The latter step uses voxelization and interpolation techniques to ensure the overall consistency of the distorted CT image which will serve as input for dose calculations.

CT images containing deformed breast geometry serve as input to both TPS global dose calculations and GATE Monte Carlo skin dose calculations. The use of TPS to recalculate the dose map on the exact geometry of the breast during the session should enable medical physicists to estimate whether a replanning of the treatment is necessary, by examining deviations from the initial dose plan. The calculation of dose to the skin via our Monte Carlo tool is used to provide additional information to the TPS calculations in the first millimeter of tissue, and to precisely study the impact of deformations on the distribution of dose to the skin, such as under and over-estimation or hot spots.

3 Results

Figure 2 shows an example of a deformation vector field calculated on a patient's 3D surface mesh M_{init}.

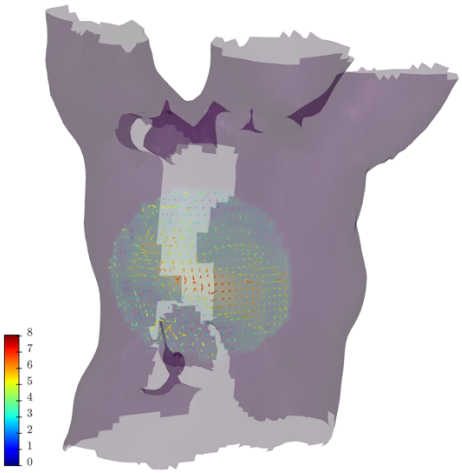

Figure 2. Deformation vector field

From this deformation field, our algorithm produces a CT image representing the new geometry of the deformed breast for a given treatment session (Figure 3).

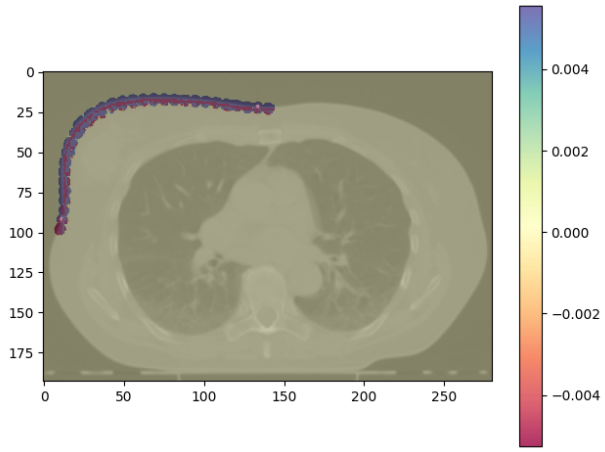

Figure 3. Breast deformation (colored voxels (a.u.)) from pre-treatment patient CT

Before applying Monte Carlo calculations to initial and deformed CT images, experimental validations of skin dose have been carried out on PMMA phantoms for various treatment plans. Monte Carlo dose calculations in the first millimeter have been compared to EBT3 (Ashland, Bridgewater, NJ, USA) Gafchromic films [8], demonstrating the good calculation performance of GATE Monte Carlo algorithm at this millimeter scale (Figure 4).

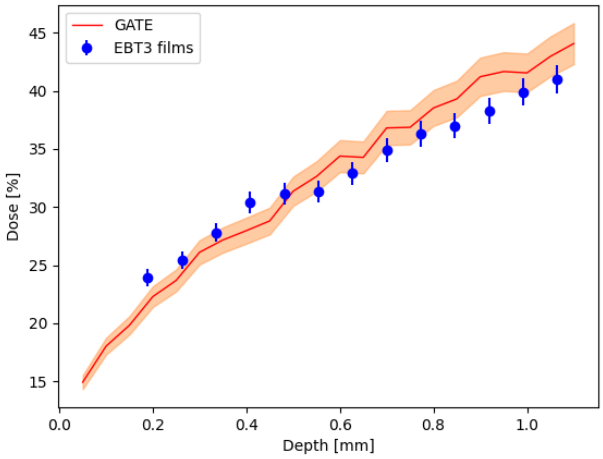

Figure 4. Depth dose comparison between GATE (Monte Carlo) and EBT3 film measurements (PMMA phantom)

We have currently tested our method on two patients of the clinical trial. For these patients, a mean breast deformation field length of about 5 mm has been obtained. For each patient, dose maps were calculated by using the Acuros TPS and GATE MC tool for five deformed CT images (D+5, D+10, D+15, D+20, and D+25), and subsequently compared to the dose map from the original treatment plan.

4 Discussion

These first tests of a skin dose calculation framework, carried out as part of this work, are very encouraging. The study will continue its systematic application to all 60 patients who participated in the clinical study. The ultimate goal is then to exploit the developed framework in several complementary applications:
a) verification of the dose calculation after each session, taking into account the exact geometry of the breast, offering both to the radiation therapists and medical physicists a decision support tool to determine the necessity of treatment replanning;
b) set up research work on the precision of surface dose calculations from TPS algorithms (contour, thresholding) by a systematic comparison with MC calculations
c) provide data for a new clinical study on understanding the side effects of breast radiotherapy depending on the type of in-therapy deformation (shrink, inflation, folds)

Other tools exist today that allow recalculation of the treatment plan based on breast deformations at each session. These tools are mainly based on the use of CBCT images taken at the beginning of the session for the repositioning of the patient. One of the specificities of the proposed framework compared to these tools consists of using 3D surfaces obtained from an optical scanner. Its application does not require an additional X-ray image, relying solely on the initial CT, thus avoiding extra imaging doses for the patient and adhering to the ALARA principle for patient radiation protection. Another advantage of the algorithm developed in this work is its applicability to exploit images provided by the SGRT (Surface Guided Radiation Therapy) systems, which are increasingly present in treatment centers.

5 Conclusion

Skin dose calculation in breast radiation therapy is a key issue for reducing patient side effects. A framework has been developed to enable systematic recalculation of the skin dose at each session, taking into account breast deformations from 3D-scanner images. This framework enables Monte Carlo skin dose calculations based on deformed vector fields (DVF)-driven CT images. The first encouraging results on patients, as well as the increasing availability of SGRT images, point to the future clinical use of this non-ionizing method. This tool will support radiation therapists and medical physicists in their replanning decisions during treatment, and provide useful data for improving treatment precision and better understanding the induction of skin toxicity.

Abstract Radiotherapy (RT) has long been designed using a set of population-wide dose prescriptions that do not fully reflect the individual patients' biological makeup. Although powerful machine learning (ML) models are available for predicting patient-specific outcomes of RT, these models remain disconnected from the realm of dose personalization. Here, we propose a novel strategy for bridging the gap between ML-based outcome modeling and dose-based RT treatment planning. The novelty of our approach lies in directly addressing data uncertainty (from predictive biomarkers) during the outcome modeling and optimization. On the modeling side, we train *adversarially robust* neural networks that are immune to reasonable perturbation of the underlying data. On the computational side, we propose efficient algorithms for embedding the resulting robust NNs directly within conventional treatment planning for personalized dose adjustment. We test our methodology on a cohort of non-small cell lung cancer patients, with the endpoint of minimizing radiation-induced cardiac toxicity.

1 Introduction

Radiotherapy (RT) treatment plan optimization (TPO) has long adhered to population-wide guidelines for setting tumor dose prescriptions and "safe" tolerances for normal tissues. In ignoring considerable individual differences in tumor and normal tissue radiosensitivity, the resulting treatment plans can lead to insufficient tumor dose or excessive normal tissue damage in patients who are farther from the average population. Variability in patient response highlights the need for outcome-centric approaches that reflect patients' unique characteristics and therapeutic responses. In recent years, power machine learning (ML) models have been proposed for predicting patient-specific RT outcomes. These models are capable of synthesizing conventional dosimetric factors with more patient-specific biological information derived from patients' medical history, imaging, and genetic or molecular assays and predict individualized outcomes [1]. Despite this promise, current ML-based outcome models remain largely disconnected from clinical RT planning. Outside of simple patient stratification strategies, there is no clear path toward translating the predictions of these models into "clinically actionable decisions", i.e., to truly personalize the dose for patients at higher risk of toxicity and/or disease progression. We have recently introduced a novel methodology for the direct embedding of ML-based outcome models within conventional (dose-based) RT TPO, enabling ML-driven RT planning [2]. Guided by powerful ML outcome models such as Random Forests, Gradient Boosting Machines, and Neural Networks (NN), the methodology is capable of automatically steering the RT plan of high-risk patients towards desired (predicted) clinical outcome, thereby bridging the gap between ML-based outcome modeling and RT plan optimization.

An important issue in outcome-driven TPO is the *uncertainties* associated with the outcome models' predictions, specifically those stemming from data and the model uncertainties. The former (hereafter called *biomarker uncertainty*) is especially relevant in RT outcome modeling, as the underlying data, particularly those derived from imaging, genetic, or other biological assays, are subject to measurement uncertainties and thus have the potential to severely hamper the performance of outcome-driven RT planning.

The goal of this study is to address biomarker uncertainties in ML-driven RT planning. Extending our previous work, here we will (i) build on the emerging field of Adversarial Robustness [3, 4] to train RT outcome models whose predictions are robust against (reasonable) perturbations in the underlying biomarker data, and (ii) offer mathematical strategies for embedding these models and deriving "robust" (with respect to biomarker uncertainties) ML-driven plans. We will test our approach on a retrospective cohort of non-small cell lung cancer (NSCLC) patients who had undergone chemoradiation, focusing on minimizing the risk of radiation-induced cardiotoxicity (RICT) for high-risk NSCLC patients.

2 Methods

Our methodology consists of three interconnected steps: first, we will introduce the concept of adversarial robustness (AR) to design NN outcome models that are less sensitive to reasonable perturbations in the underlying training data (biomarkers); we then introduce an efficient methodology for embedding the resulting NN models as *patient-specific* planning constraints within the conventional TPOs; finally, we will derive fully outcome-driven plans that are robust *w.r.t.* biomarker uncertainties.

2.1 Defining biomarker uncertainty

Throughout this work, we will define "biomarker uncertainty" as *how accurately the biomarker reflects the 'true' (unknown) state of the variable being measured.* This is tied to the inherent accuracy of the measuring instrument. In the case of

imaging uncertainty, this could be interpreted as the difference between the imaging signals and the true underlying anatomy (e.g., tumorous vs. normal cells in pathology slices), whereas for liquid biopsies, it could be the difference between the biomarker expression (e.g., circulating tumor DNA [5]) in the sample vs. in the body.

2.2 ML-driven treatment plan optimization under biomarker uncertainty

The general ML-based outcome-driven TPO under biomarker uncertainty can be expressed as:

$$\max_{\mathbf{d},\mathbf{x}\geq 0} \Gamma(\mathbf{d},\tilde{\phi}) \tag{1}$$

$$\text{subject to: } A\mathbf{x} = \mathbf{d}, , \tag{2}$$

$$\sup \Psi(\mathbf{d},\tilde{\phi}) \in \mathscr{H},\ \tilde{\phi} \in \Phi_P. \tag{3}$$

where $\Gamma(.)$ and $\Psi(.)$ are the (ML-based) outcome models predicting, respectively, the tumor control and normal tissue toxicity probability. The vectors $\mathbf{d}$ and $\tilde{\phi}$ denote the vectors of physical dose and patient-specific (biological) characteristics (biomarkers), and $\sup(.)$ denotes the supremum of a set. Constraint (3) ensures that the predicted toxicity profile of the patient belongs to a set $\mathscr{H}$ of 'safe' states (e.g., no severe toxicity), as long as the biomarker measurement $\tilde{\phi}$ belongs to a known confidence interval Φ_P.

The above formulation can incorporate instances where the mathematical expressions of $\Gamma(.)$ and $\Psi(.)$ are unknown, such as in the case of complex ML models, in which case their functional forms have to be directly learned from data. Without loss of generality, we will assume that only the normal tissue outcome model $\Psi(.)$ has to be learned from data and replace $\Gamma(.)$ with a known surrogate such as the conventional dose fidelity term, i.e., $\max \Gamma(\mathbf{d},\phi) \approx \min \|\mathbf{d}-\mathbf{d}_{\text{ref}}\|$, where $\|.\|$ is an arbitrary norm that penalizes the deviation from a set of given dose prescription $\mathbf{d}_{\text{ref}}$.

In the following sections, we will first provide a way for obtaining outcome models $\Psi(.)$ which are less sensitive to the perturbation in $\tilde{\Phi}$, focusing on the case of neural networks, and follow that with the method for embedding the learned model within RT TPO.

2.3 Designing robust neural networks using Adversarial Robustness

For a given set of input-label pairs $\mathbf{x} \in \mathbb{R}^d$ and $y \in \mathbb{R}$ and a NN classifier $f(\mathbf{x},\theta)$, the conventional training algorithms seek to find a set of parameters $\theta \in \mathbb{R}^p$ that minimize a given loss function $\mathscr{L}(f(\mathbf{x},\theta),y)$. Traditionally, such loss functions do not account for the cases where the input $\mathbf{x}$ could be contaminated or noisy, therefore, oftentimes, the trained networks are not robust against even slight perturbations of x. This can pose significant challenges in the noisy context of medical data, where various sources of measurement uncertainty (arising due to image registration, equipment inaccuracy, for instance) exist. Therefore, it is desirable to *immunize* the model against *adversarial* perturbations of the input x.

We define such perturbations as $\text{Adv}(x) = \{x' : \|x'-x\|_\infty \leq \delta\}$, where $\|.\|_\infty$ is the l_∞ norm. An *adversarially robust* (AR) model can then be trained by solving the following optimization problem:

$$\min_\theta \left\{ \max_\delta \mathscr{L}(f(\mathbf{x},\theta),y) : x \in \text{Adv}(x) \right\}. \tag{4}$$

While the inner maximization aims to find an adversarial version of a given data point x to incur a high loss, the outer minimization seeks to minimize the resulting "adversarial loss" by adjusting the model parameter θ [3, 4]. Note that this is an instance of the *min-max* robust optimization (RO) [6]. Unfortunately, due to the complexity (nonconvexity) of the resulting loss function, conventional RO algorithms either do not apply or are prohibitively expensive to run. We therefore attempt to solve the inner maximization problem (the "adversarial attack" problem) by the Fast Gradient Sign Method (FGSM) heuristic [3]. At each iteration t of the outer minimization problem, FGSM produces the most adversarial example by linearizing the loss function around the current value of θ^t, that is, a linear perturbation of x is given by $x' = x + \delta \mathbf{sgn}(\nabla_x \mathscr{L}(\mathbf{x},y,\theta^t))$, where $\mathbf{sgn}$ is the sign function. This approach essentially expands the set of training data points by the adversarial examples and "prepares" the model for encountering such perturbation.

2.4 Embedding NN models within RT treatment plan optimization

Once the network parameters θ are learned using the AR training algorithm, the resulting model could be embedded within the ML-TPO problem. Embedding a trained NN with the weight and bias parameters $\theta^* = (\mathbf{W}^*, \mathbf{b}^*)$ and a rectified linear unit (ReLu) activation function ($\text{ReLu}(\mathbf{x}) = \max\{\mathbf{0},\mathbf{x}\}$) can be achieved by the following set of linear mixed-integer constraints per neurons [2]:

$$v \geq x, \tag{5}$$

$$v \leq x - M_L(1-z), \tag{6}$$

$$v \leq M_U z, \tag{7}$$

$$v \geq 0. \tag{8}$$

where $v \in \mathbb{R}$ and $z \in \{0,1\}$ are the auxiliary variables used for linearizing the ReLu output and M_L and M_U are the lower and upper bound on all possible values of the decision vector $\mathbf{x} = (\mathbf{d},\phi)$. The constraints for embedding NNs can be recursively generated, starting from the innermost input layer, thus allowing the embedding of trained networks with an arbitrary number of hidden layers. The use of mixed-integer constraints imposes significant algorithmic and computational challenges due to the imposed nonconvexity. We use a simple column generation approach [7] for handling the size of the integer variables.

2.5 NSCLC dataset

To test the performance of our approach, we test it, retrospectively, on an NSCLC cohort [8] with the endpoint of limiting cardiotoxicity. The dataset contains 154 patients (photon and proton) NSCLC patients and includes the RT dose distribution, clinicopathological information (e.g., age, sex, pre-existing heart disease), as well as pre- and mid-treatment measurements of high-sensitivity cardiac troponin T (hs-cTnT), an important cardiac-specific biomarker secreted by the cardiac muscle upon injury. Prior works [9] have associated baseline hs-cTnT level with a higher risk of RICT (hazard ratio = 4.06, p = 0.005). We, therefore, treat *baseline* measurement of hs-cTnT as our *uncertainty-prone* biomarker ϕ. We use this dataset both to train our NN model for predicting the risk of RICT grade ≥ 2 (the endpoint) and to test the result of ML-TPO dose adjustment after embedding the predictive model.

3 Results

All experiments were coded in MATLAB v2022a and run on a PC with 3.70GHz CPU and 32GB of RAM. We used Gurobi for solving the optimization problem and matRad [10] for dose calculation/ visualization.

3.1 Characterizing hs-cTnT measurement uncertainty

In the absence of ground truth (the true state of the hs-cTnT expression in the body), to characterize the amount of expected uncertainty in the hs-cTnT measurement, one needs repeated measurements taken at the same time point. Unfortunately, such data did not exist in our dataset. Therefore, we used a surrogate by taking the variation across different time-points during the RT for patients who (i) had received limited heart doses (MHD<=5Gy) and (ii) did not have prior heart disease. The assumption is that the hs-cTnT expressions for these patients are less (negligibly) affected by the treatment, and any changes in its repeated measurements are likely due to other (non-treatment) factors (which we use as a surrogate for the measurement uncertainty).
Our analyses revealed that the average hs-cTnT variation across the eligible patients (measurement uncertainty) was $30.7\% \pm 37\%$ (standard deviation).

3.2 Robust NN training

We used a compact (shallow) neural network with one fully connected layer with 50 neurons and ReLu activation function as our benchmark NN model. Input variables to the model included mean heart dose, mean lung dose, baseline hs-cTnT, pre-existing heart disease (Yes/No), along with standard clinicopathological factors (e.g., age, sex, performance status, tumor size, etc.).
We then ran the AR NN training with three different levels of uncertainty: $\delta = 10\%, 20\%$, and 30%. Table 1 shows the results. The reported accuracy (in %) is normalized to the highest accuracy achieved under the conventional NN training, corresponding to the 5-fold cross-validation area under the curve of 62.5%. The column 'Adversarial attack' reports the misclassification rates caused by perturbing the biomarker measurement by the amount of δ. All results were averaged after five training runs. Despite the increase in the training time and the lower accuracy under the perfect condition compared to the conventional training, as expected, the AR-trained models show significantly higher stability under slight (and expected) perturbation in the biomarker measurement.

	Time	Accuracy	Adversarial attack (δ)		
			0.1	0.2	0.3
Conventional NN	23 s	100%	61%	53%	45%
AR NN - $\delta = 10\%$	587 s	95%	89%	78%	67%
AR NN - $\delta = 20\%$	605 s	91%	87%	85%	68%
AR NN - $\delta = 30\%$	497 s	87%	81%	83%	76%

Table 1: The results of the Adversarial Training for constructing the NN model. The column 'Time' refers to the training time (in seconds) under each training strategy. AR=adversarially robust, NN=neural networks.

3.3 Embedding NN models within conventional TPO

We ran the NN-embedded TPO algorithm on 5 NSCLC patients who were classified as high-risk according to the NN model (based on the clinical dose distribution). The algorithm automatically adjusted the dose distribution for these patients to ensure a favorable risk profile (i.e., no predicted RICT). To ensure clinical deliverability, in addition to the NN-learned constraint, we enforced conventional planning criteria [11]. We chose the AR-trained model with 10% uncertainty consideration, as it delivered the best combination of accuracy (under normal conditions) and stability (under perturbation). Overall, there was a 1.78Gy reduction (range=0.54-3.42Gy) in MHD as the result of the NN-guided dose adjustment. For two patients, the algorithm failed to reclassify the patient into the low-risk group, as the other (non-controllable) risk factors for these patients had an outsize effect on the predicted risk (both had pre-existing heart disease with high baseline hs-cTnT level). Figure 1 shows the result for one of the patients.

4 Discussions

In this work, we have built upon our recent effort to bridge the gap between ML-based outcome modeling and dose-driven radiotherapy planning. Specifically, we have attempted to address an important bottleneck in many outcome-driven strategies, namely, the impact of (biomarker) data uncertainty on the resulting outcome predictions. We have employed an emerging technique in the field of machine learning for

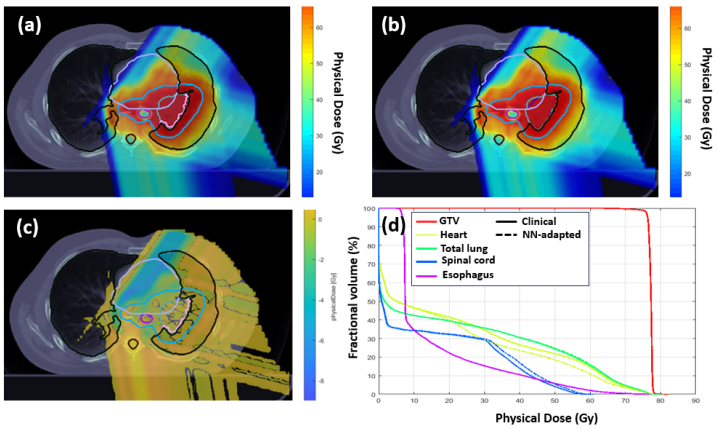

Figure 1: The results of ML-guided adaptation for an exemplary NSCLC case, to minimize the risk of cardiac toxicity. (a)-(c) Original, NN-guided, and difference dose distribution; (d) DVH plots for the original (solid) and NN-guided (dashed) plans.

designing outcome models (neural networks) that are reasonably robust against normal perturbations (adversarial attacks, as they are known in the ML community) in the underlying data. By directly accounting for these perturbations in the loss function during the training phase, the resulting models show superior (up to 30%) stability (i.e., lower misclassification rates) compared to the normally trained model.

We further embedded these robust models within the conventional dose-based treatment planning for a fully outcome-driven RT planning. The results show that in 3/5 cases, it was possible to safely *de-escalate* the heart dose to avoid excessive cardiac damage, without a significant compromise in tumor coverage (Figure 1). Although this improvement naturally comes at the expense of extra dose to other organs (higher mean dose to the spinal cord, SC, in Figure 1), these did not constitute a constraint violation (max-dose to the SC stays below 54Gy).

A limitation of our approach was the relatively small sample size used in the model training. With the sample size of ~ 150, the performance of the AR training algorithm (Table 1) should be taken with a grain of salt (the relatively low AUC of 0.63 is likely the result of the insufficient data points). Moreover, the introduction of integer variables for embedding large NN models causes computational issues during the optimization, an issue that we had previously reported [2]. Although we tried to counter the added complexity using column generation, more work has to be done before the resulting ML-embedded models can be safely deployed in clinics and used to solve large, complex clinical cases.

Nevertheless, the works presented here should be interpreted as a proof-of-concept and not a full-on clinical demonstration. By harnessing the power of ML and mathematical optimization, the algorithms and methodologies developed here will lay the foundation for facilitating the transition towards a fully outcome-driven RT treatment planning and provide the necessary tools for a future clinical trial to test these concepts.

5 Conclusions

A novel approach is proposed for personalized radiotherapy by (i) combining machine learning (ML)-based outcome modeling and dose-based treatment plan optimization, and (ii) addressing an important bottleneck in outcome-driven RT, namely, the data-driven uncertainties caused by biomarker measurement errors. The new uncertainty-aware ML models exhibit superior stability in the face of biomarker uncertainty, and the resulting ML-driven treatment plans carry the potential for improving the therapeutic outcome of patients through selective dose personalization.

Abstract Machine learning (ML) models on tumor control probability (TCP) or normal tissue complication probability (NTCP) are on the verge of replacing classical radiotherapy treatment outcome models. In spite of this, solving the inverse problem in intensity-modulated radiotherapy (IMRT) treatment planning still relies on mathematically simple, non-model-based surrogate functions with empirical dose prescription and tolerance parameters, rather than directly optimizing (N)TCP based on such outcome models. In this paper, we present the open-source Python package *pyanno4rt*, a toolkit which implements a technical framework for ML outcome model-based IMRT optimization. *pyanno4rt* leverages transformations of the probability prediction functions as (N)TCP objectives and backward propagation of the gradients from these objectives to the fluence vector, both of which could then be embedded in any gradient-based solver. To demonstrate *pyanno4rt*, we first fitted ML outcome models (logistic regression, neural network, support vector machine) internally, using two outcome data sets from a head-and-neck patient cohort. Second, we optimized photon treatment plans on a head-and-neck patient by adding the corresponding (N)TCP objectives to the conventional plan. Our results show that *pyanno4rt* is able to generate ML model-based treatment plans with appealing dose distributions, while allowing for improved outcome predictions.

1 Introduction

Machine learning models are increasingly applied in radiotherapy treatment outcome prediction, and have already been shown to outperform classical outcome models [1]. One of the main advantages is the ability to handle high-dimensional and mixed inputs, which allows them to exploit large amounts of treatment and patient data and therefore provide a highly personalized treatment outcome prediction. This makes machine learning outcome models interesting for application in intensity-modulated radiotherapy (IMRT), where the inverse problem is commonly solved by using surrogate functions with empirical dose prescription and tolerance parameters, e.g. squared deviation from a reference dose, rather than directly generating outcome-oriented treatment plans.
One possible approach for the integration of inverse treatment plan optimization and machine learning outcome models is at the level of the optimization components (objectives and constraints). However, this poses some challenges, e.g. in terms of model stability with changing input over the optimization iterations or the dependence on the efficiency of the forward objective and backward gradient calculations.
In this paper, we present *pyanno4rt* [2], a toolkit which implements a technical framework for addressing these issues. We first introduce the software framework and the underlying mathematical concepts to derive feasible (N)TCP objectives and gradients from the machine learning model prediction functions, then outline the datasets used for model fitting and provide details on treatment planning. To showcase *pyanno4rt*, we integrate the best-fit models into photon treatment plan optimization on some independent head-and-neck patient. An analysis of the results concludes this paper.

2 Materials and Methods

In this chapter, we present the software framework and the underlying mathematical concepts, as well as the datasets used for model fitting and some treatment planning details.

2.1 Software Framework

pyanno4rt is an open-source Python package for conventional and outcome prediction model-based inverse photon and proton treatment plan optimization. It encompasses an extensive and scalable number of optimization components, feature definitions, different solution methods and algorithms, plan evaluation and visualization tools, as well as a graphical user interface in addition to the code-based interface (see Figure 1). The package is under continuous development and currently being actively maintained. All results in this paper were generated from *pyanno4rt*.

2.2 Inverse Treatment Plan Optimization with Machine Learning Model-based Components

We now explain how *pyanno4rt* combines inverse planning and machine learning outcome prediction models.
First, we define the weighted-sum optimization problem for the conventional intensity-modulated treatment plan as

$$\begin{aligned} \min_{\mathbf{w}} \; & f(\mathbf{w}) = \sum_r \omega_r f_r(\mathbf{D}_r \mathbf{w}) \\ \text{s.t.} \; & c_m^l \leq c_m(\mathbf{w}) \leq c_m^u \,. \end{aligned} \tag{1}$$

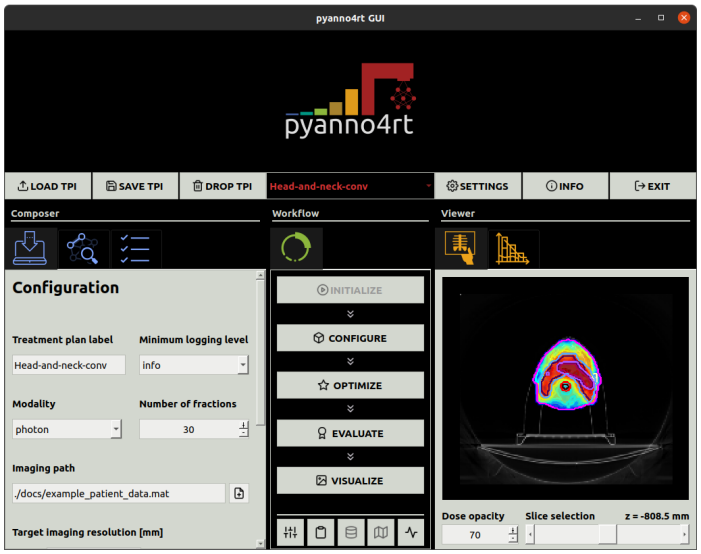

Figure 1: pyanno4rt GUI interface

with the fluence vector $\mathbf{w} \in \mathbb{R}^J_+$, the dose-influence matrix $\mathbf{D}_r \in \mathbb{R}^{I_r \times J}_+$, the objective function f_r and the weight ω_r for the segment r, as well as the (optional) constraints c_m.
The novelty of our approach lies in the interpretation of the machine learning outcome prediction functions as objectives or constraints (where we only show the objective case below). Throughout, we denote by $\mathbf{x} \in \mathbb{R}^p$ the p-dimensional feature vector, and by y the corresponding (binary) class label. Additionally, let n with index $i = 1,\dots,n$ be the number of samples. Under the assumption that $\mathbf{x}$ can be grouped into dosiomic ($\mathbf{x}^{dose}$), radiomic ($\mathbf{x}^{rad}$) and demographic features ($\mathbf{x}^{dem}$), all possibly with a transformation t, the generalized outcome prediction function becomes

$$(N)TCP_{ML} = p_\theta\left(t(\mathbf{x}^{dose})|t(\mathbf{x}^{rad}),t(\mathbf{x}^{dem})\right). \tag{2}$$

In principle, $(N)TCP_{ML}$ could be used directly for optimization. However, it may show unfavorable mathematical properties, e.g. non-convexity or vanishing gradients. We therefore propose an equivalent formulation $f_{ML}(p_\theta)$ as objective and the backward gradient of f_{ML} with respect to $\mathbf{w}$ as

$$\nabla_{\mathbf{w}} f_{ML}(p_\theta) = \nabla_{\mathbf{w}}\mathbf{d}^\top \nabla_{\mathbf{d}}\mathbf{x}^{dose}\nabla_{\mathbf{x}^{dose}} t(\mathbf{x}^{dose})\nabla_{t(\mathbf{x}^{dose})} f_{ML}(p_\theta). \tag{3}$$

pyanno4rt handles both reformulation of $(N)TCP_{ML}$ and differentiation of $f_{ML}(p_\theta)$ as well as the iterative recalculation of $\mathbf{x}^{dose}$ efficiently through JIT compilation and automatic differentiation using *JAX* [3], with the following machine learning model-based objective and gradient functions:

Logistic regression (LR)

Fitting the logistic regression model yields the coefficient vector $\beta \in \mathbb{R}^p$ and the outcome prediction function reads

$$(N)TCP_{LR} = p_\beta(y=1|t(\mathbf{x})) = \sigma\left(\beta^\top t(\mathbf{x})\right). \tag{4}$$

Inversion of the enclosing sigmoid function $\sigma(z) = (1-\exp(-z))^{-1} \in (0,1)$ yields the objective

$$f_{LR}(p_\beta) = \beta^\top t(\mathbf{x}). \tag{5}$$

This function is convex in $t(\mathbf{x})$ with the constant gradient

$$\nabla_{t(\mathbf{x})} f_{LR}(p_\beta) = \beta. \tag{6}$$

Neural networks (NN)

Let $\mathbf{W}_l$ be the weight matrix, b_l the bias, and g_l the activation function in layer $l = 1,\dots,L$, the outcome prediction function can be described by the recursive rule

$$(N)TCP_{NN} = p_{(\mathbf{W},\mathbf{b})}(y=1|t(\mathbf{x})) = \mathbf{h}_L, \tag{7}$$

with the input $\mathbf{h}_0 = t(\mathbf{x})$ in the first layer and

$$\mathbf{h}_l = g_l\left(\mathbf{W}_l\mathbf{h}_{l-1} + b_l\cdot\mathbf{1}\right), \quad l = 1,\dots,L. \tag{8}$$

In the output layer L, we use the sigmoid activation function $g_L(z) = \sigma(z)$ for projecting onto the $(0,1)$ interval.
By the same reasoning as before, the objective after inverting the sigmoid activation function in the output layer reads

$$f_{NN}(p_{(\mathbf{W},\mathbf{b})}) = \mathbf{W}_L\mathbf{h}_{L-1} + b_L\cdot\mathbf{1}. \tag{9}$$

The gradient function can therefore be expressed as

$$\nabla_{t(\mathbf{x})} f_{NN}(p_{(\mathbf{W},\mathbf{b})}) = \nabla_{t(\mathbf{x})}\mathbf{h}_0 \prod_{l=1}^{L-1} \nabla_{\mathbf{h}_{l-1}}\mathbf{h}_l \nabla_{\mathbf{h}_{L-1}} f_{NN}(p_{(\mathbf{W},\mathbf{b})}). \tag{10}$$

Tensorflow's GradientTape API provides the gradient function via automatic input differentiation. We implemented both standard feedforward and input-convex neural networks [4, 5] in *pyanno4rt* to enable the comparison between the less restrictive but non-convex feedforward architecture and the more restrictive but input-convex architecture.

Support vector machines (SVM)

With the learnable dual parameters $\alpha \in \mathbb{R}^n$ and $b \in \mathbb{R}$, the outcome prediction function can be formulated as

$$(N)TCP_{SVM} = p_\alpha(y=1|t(\mathbf{x})) = \sigma_P\left(\sum \alpha_i K(t(\mathbf{x}_i),t(\mathbf{x})) + b\right), \tag{11}$$

where $\sigma_P(z) = (1-\exp(-Az-B))^{-1}$ denotes the Platt scaling function with extra parameters $A,B \in \mathbb{R}$ [6] and K is a kernel. Table 1 shows the kernels implemented in *pyanno4rt*. By inverting the Platt scaling function, we end up with

$$f_{SVM}(p_\alpha) = \sum \alpha_i K(t(\mathbf{x}_i),t(\mathbf{x})) + b \tag{12}$$

as the objective, so that the gradient function is simply obtained by differentiation of the kernel, i.e.,

$$\nabla_{t(\mathbf{x})} f_{SVM}(p_\alpha) = \sum \alpha_i \nabla_{t(\mathbf{x})} K(t(\mathbf{x}_i),t(\mathbf{x})). \tag{13}$$

Kernel	Definition
linear	$K_{lin}(\mathbf{x}_i,\mathbf{x}) = \mathbf{x}^\top \mathbf{x}_i$
rbf	$K_{rbf}(\mathbf{x}_i,\mathbf{x}) = \exp(-\gamma\|\mathbf{x}-\mathbf{x}_i\|^2)$
poly	$K_{poly}(\mathbf{x}_i,\mathbf{x}) = (\gamma\mathbf{x}^\top \mathbf{x}_i + c_0)^p$
sigmoid	$K_{sig}(\mathbf{x}_i,\mathbf{x}) = \tanh(\gamma\mathbf{x}^\top \mathbf{x}_i + c_0)$

Table 1: Kernel functions for the SVM [7].

Kernel	Definition
linear	$\nabla_\mathbf{x} K_{lin}(\mathbf{x}_i,\mathbf{x}) = \mathbf{x}_i$
rbf	$\nabla_\mathbf{x} K_{rbf}(\mathbf{x}_i,\mathbf{x}) = -2\gamma(\mathbf{x}-\mathbf{x}_i)K_{rbf}(\mathbf{x}_i,\mathbf{x})$
poly	$\nabla_\mathbf{x} K_{poly}(\mathbf{x}_i,\mathbf{x}) = \gamma p\mathbf{x}_i(\gamma\mathbf{x}^\top \mathbf{x}_i + c_0)^{p-1}$
sigmoid	$\nabla_\mathbf{x} K_{sig}(\mathbf{x}_i,\mathbf{x}) = \gamma\mathbf{x}_i \cosh(\gamma\mathbf{x}^\top \mathbf{x}_i + c_0)^{-2}$

Table 2: Kernel gradients for the SVM [7].

Table 2 lists the kernel gradients implemented in *pyanno4rt*.

Putting everything together, we can expand the weighted-sum objective function from Equation 1 to yield

$$f(\mathbf{w}, p_\theta) = f(\mathbf{w}) + \sum_s \omega_s f_s(p_{\theta_s}), \tag{14}$$

where we add the machine learning model-based objectives f_s. Note that this approach also allows to (partially) substitute $f(\mathbf{w})$, or integrate outcome model-based constraints c_{ML}.

2.3 Datasets, Modeling and Treatment Planning

Machine learning modeling in this paper is based on two outcome data sets from a retrospective cohort of 153 head-and-neck patients treated with IMRT at Heidelberg University Hospital between the years 2010 and 2015.
The first data set includes features of the parotids to predict the probability of long-term grade 2+ xerostomia, and we refer to [1] for details on data structure and handling. To prevent multicollinearity, we focus on 6 dosiomic (mean, standard deviation, skewness, gradients) and 3 radiomic features (volume, sphericity, eccentricity) for each parotid.
The second data set has 14 dosiomic and radiomic features of the PTV to predict the probability of progression-free survival. From these, we removed 3 dosiomic features (maximum, minimum, quantile at 10% volume), which we found to cause over- or underdosing of the PTV after optimization.
Internal to *pyanno4rt*, the outcome models from Section 2.2 are fitted with *scikit-learn* [8] and *tensorflow* [9], and equipped with individual preprocessing, hyperparameter tuning, evaluation and inspection units, where we currently restrict the preprocessing to feature standardization and the hyperparameter tuning to sequential model-based global optimization using tree-structured Parzen estimators from *hyperopt* [10], modified by a robust "worst-case" variant of stratified k-fold cross-validation to prevent overfitting.

Segment	$\mathbf{d_{mean}}$			$\mathbf{d_{std}}$		
	S1	S2	S3	S1	S2	S3
Par. (L)	0.72	0.66	0.55	0.28	0.23	0.31
Par. (R)	0.70	0.61	0.22	0.28	0.22	0.21
PTV63	2.09	2.09	1.56	0.20	0.25	0.75
PTV70	2.30	2.31	2.30	0.10	0.12	0.10

Table 3: Dose mean and deviation for the scenarios S1–S3.

Segment	$\mathbf{d_{max}}$			$\mathbf{d_{min}}$		
	S1	S2	S3	S1	S2	S3
Par. (L)	1.66	1.52	1.87	0.24	0.33	0.16
Par. (R)	1.73	1.36	1.35	0.15	0.14	0.01
PTV63	2.48	2.78	3.07	0.25	0.24	0.11
PTV70	2.48	2.66	2.51	0.46	0.46	0.47

Table 4: Dose maximum and minimum for the scenarios S1–S3.

Treatment planning relies on an independent head-and-neck patient from the CORT dataset [11]. The segments of interest are left/right parotid, skin, PTV63 and PTV70. To evaluate the impact of machine learning outcome models for optimization, we investigate three optimization scenarios:

(**S1**) Dose objectives only (squared overdosing on left/right parotid and skin, squared deviation on PTV63/PTV70)

(**S2**) S1 with additional machine learning model-based objectives on left/right parotid and PTV63

(**S3**) S2 with only machine learning model-based objectives on left/right parotid and PTV63

Moreover, we opt for photon irradiation with 30 fractions and the L-BFGS-B algorithm from *scipy* [12] for optimization.

3 Results

In this chapter, we report the most important findings on the resulting dose distributions and outcome predictions.

3.1 Dose Distributions

The optimal 2D dose distributions are shown in Figure 2, with the corresponding dosimetrics in Table 3 and 4. S1 achieves good coverage of the PTV63/PTV70 and sparing on the left/right parotid. Adding the best-fit models, the LR models, in S2 (center) implies a minor shift of dose away from the parotids and more pronounced hotspots in the PTVs. The impact of the LR models is most evident for S3, where the heterogeneity of the dose distribution in the PTV63 increases, while the dose distribution in the PTV70 compares well with S1. Due to the overall lower dose in the PTV63, there is also a larger dose reduction in the parotids. We attribute the changes in dose to the most contributing features, i.e., the mean dose in the parotids or the median dose in the PTV63.

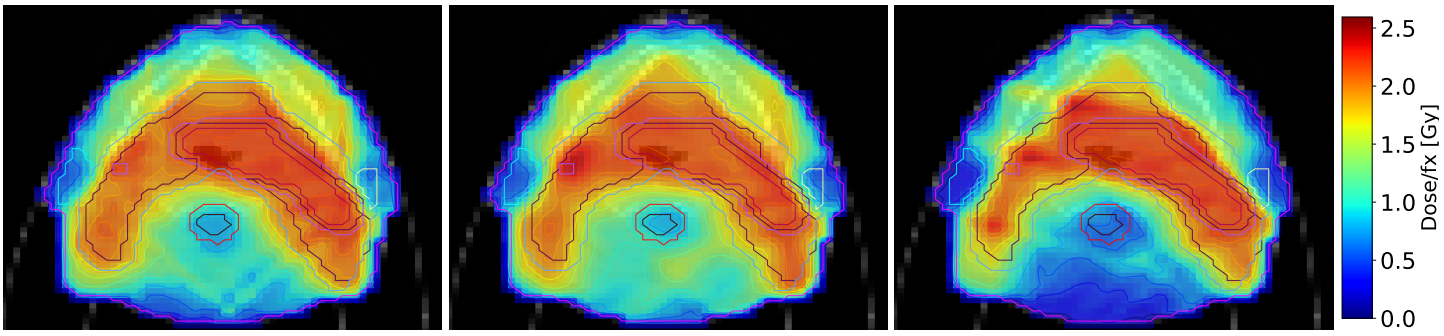

Figure 2: Optimal 2D dose distributions for the scenarios S1–S3 (from left to right).

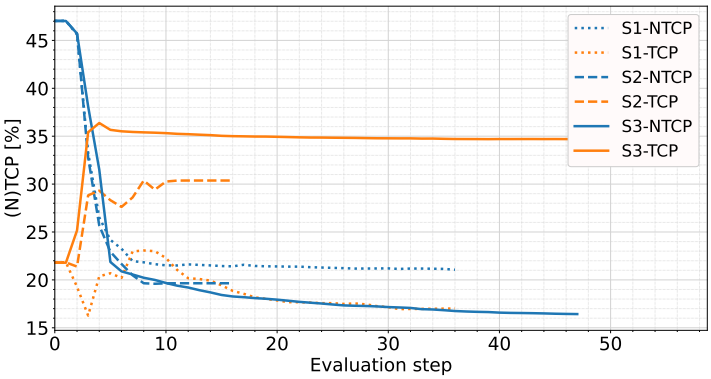

Figure 3: (N)TCP curves for the scenarios S1–S3. Our optimization approach allows for improved outcome predictions, even though the range of the outcome values seems fallacious.

3.2 Outcome Predictions

Figure 3 displays the (N)TCP curves for the three planning scenarios S1–S3. We observe both an increase in TCP (S1: 17%, S2: 30.4%, S3: 34.7%) and a decrease in NTCP (S1: 21%, S2: 19.7%, S3: 16.3%) as the LR models become more influential. This meets our expectation that, on the one hand, the mere inclusion of the (N)TCP objectives in S2 should already improve the outcome predictions, and on the other hand, that the removal of the parallel dose objectives in S3 resolves some trade-offs, allowing the LR outcome models to shape the dose distribution in a less restricted way.

4 Discussion

pyanno4rt shows the ability to optimize machine learning outcome model-based treatment plans with low additional overhead and generate appealing dose distributions with improved outcome predictions. We are also able to (partially) interpret some effects of the fitted outcome models on the optimal dose distribution. However, there is still a lack of sufficient data and high-quality prediction models, which can be observed from the fact that the (N)TCP values from Figure 3 are in a clinically unacceptable range. In addition to that, convexity of the derived (N)TCP objectives only holds under conditions, with no absolute guarantees for a gradient-based algorithm to find a reasonably good optimal point.

5 Conclusion

pyanno4rt is an open-source toolkit for conventional and outcome prediction model-based inverse planning, written purely in Python. It efficiently implements machine learning model-based treatment plan optimization by utilizing the outcome prediction functions. This has a great potential to support the future use of machine learning models in IMRT.

Intelligent Automatic Treatment Planning for Radiation Therapy

Yin Gao[2], YangKyun Park[2], Daniel Yang[2], and Xun Jia[1]

[1]Department of Radiation Oncology and Molecular Radiation Sciences, Johns Hopkins University, Baltimore, MD 21287, USA
[2]Department of Radiation Oncology, University of Texas Southwestern Medical Center, Dallas, TX 75390, USA

Abstract The current workflow of treatment planning in radiation therapy (RT) heavily relies on human planners, leading to variable plan quality and low efficiency due to complex interactions among physicians, planners, and the treatment planning system (TPS). We propose an Intelligent Automatic Treatment Planning (IATP) framework including two artificial intelligence agents to emulate the roles of human physicians and planners. Based on a Virtual Physician Network, constructed with the deep neural network to model physicians' preferences for plan approval for prostate cancer Stereotactic Body Radiation Therapy (SBRT), we developed a Physician Preference-guided Virtual Treatment Planner Network (PgVTPN) via an end-to-end deep reinforcement learning approach. PgVTPN was able to operate the Eclipse TPS autonomously, like a human planner under physician's guidance, to generate prostate SBRT plans that meet dosimetric requirements and closely align with physicians' clinical desires. We connected PgVTPN to Eclipse TPS via ESAPI. Statistical analysis revealed that PgVTPN-generated plans exhibited a significantly higher total score of 252.99 ± 15.57 compared to clinical plans with a score of 237.29 ± 18.72. PgVTPN demonstrated superiority over human planners in key metrics, including target conformality, $V_{Rectum}[36Gy]$, $D_{Rectum}[40\%]$, $D_{Urethra}[20\%]$, $D_{Bowel}[1cc]$, and $D_{RFemoralHead}[max]$, with statistical significance. The plans were deliverable and successfully passed quality assurance with a gamma passing rate (3%/3mm) of 96.3%. Blind evaluation by experienced physician and physicists favored PgVTPN-generated plans on average 90% over corresponding clinical plans.

1 Introduction

Radiation therapy (RT) uses high-energy radiation beams generated by a medical linear accelerator (LINAC) to deliver a potent amount of radiation dose to the cancerous target and kill cancer cells. Patient-specific treatment planning, the process of determining LINAC control parameters to generate a desired 3D dose distribution based on the patient's anatomy, is crucial for RT's success, as it ensures optimal coverage of the tumor target with a prescription dose while minimizing exposure to nearby healthy organs. Advanced delivery techniques such as Intensity-modulated RT (IMRT) and Volumetric-modulated RT (VMAT) are planned by human operators using a commercial treatment planning system (TPS). This process requires the planner to optimize a multi-criterion problem to achieve the desired dose distribution under physician guidance. The trial-and-error parameter tuning process in TPS and the iterative planner-physician evaluations contribute to a complex planning workflow. Heavy reliance on human intervention results in variable plan quality and low workflow efficiency, emphasizing the need for a more streamlined approach. The fundamental issue is that TPS can only solve an optimization problem defined by the human planner, but lacks the human intelligence to decide on plan acceptability and steer a plan toward that.

To overcome this problem, we proposed an Intelligent Automatic Treatment Planning (IATP) framework (Fig. 1) that generally follows the current human-centered planning workflow but with two artificial intelligence (AI) agents to emulate the roles of human physicians and planners in this process, hence achieving automatic treatment planning. Specifically, a Virtual Physician Network (VPN) was trained to assess the likelihood of clinical plan approval based on patient anatomy and identify areas for improvement in achieving the desired dose. A Virtual Treatment Planner Network (VTPN), developed via deep reinforcement learning (DRL), autonomously operates the TPS to refine treatment planning parameters to generate high-quality RT plans, similar to a skilled human planner.

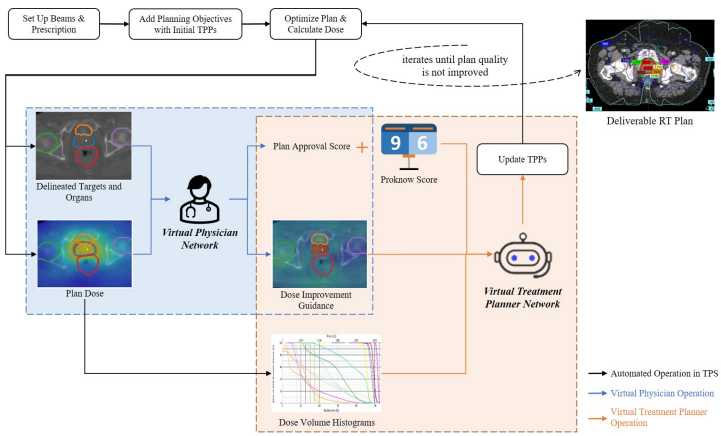

Figure 1: Proposed IATP framework, consisting of two AI agents, to emulate the roles of human physicians and planners in the treatment planning process using a commercial TPS.

In a previous study for prostate cancer Stereotactic Body Radiation Therapy (SBRT), we successfully developed a VPN[1]. This study reports the incorporation of VPN into the development of a Physician Preference-guided VTPN (PgVTPN) that can operate a clinical TPS as a virtual agent to produce treatment plans aligning with the physician's clinical desire. In addition to employing the VPN's output of the likelihood of clinical plan approval as the reward function in the DRL training process, our study also used the VPN's output of identified areas for improvement to guide the PgVTPN model training, effectively overcoming the low-efficiency burden of DRL training.

2 Materials and Methods

2.1 Virtual Physician Network

In a previous work[1], we have developed a VPN with decision-making capabilities on plan approval of prostate SBRT. The input to VPN included binary masks of PTV and eight OARs and a dose distribution to be evaluated (shown in blue in Fig. 1). The VPN consists of two sub-networks. One employs a hierarchically densely connected U-Net (HD U-Net) to generate a dose distribution highlighting desired changes from the input. The second sub-network has the structure of HD U-Net's encoder, followed by fully connected layers and a sigmoid activation function, to output the probability of approval for the given plan based on the anatomy. Since the clinical routine only stores approved plans in the TPS database whereas the unapproved plans were discarded, we trained VPN using the approved plan data via an adversarial training scheme.

VPN was trained on 60 patients with a four-fold cross-validation scheme, and subsequently evaluated on 8 independent test cases. It was able to differentiate approved and unapproved plans with Area under the curve 0.97 for testing data. For unapproved plans, after applying VPN's suggested dose improvement, the improved dose agreed with ground truth with relative differences $2.03 \pm 2.17\%$ for $D_{PTV}[98\%]$, $0.49 \pm 0.29\%$ for $V_{PTV}[95\%]$, $3.08 \pm 2.24\%$ for $D_{PenileBulb}[mean]$, $3.73 \pm 2.20\%$ for $V_{Rectum}[50\%]$, and $2.06 \pm 1.73\%$ for $V_{Bladder}[50\%]$. For more detailed information, readers can refer to the full paper [1].

2.2 Virtual Treatment Planner Network

For VTPN, we constructed it with three sub-networks in a hierarchical form [2], Structure-Net, Parameter-Net, and Action-Net, to mimic the decision-making process of a human planner operating a clinical TPS, Eclipse (Varian Medical System Palo Alto, CA), in terms adjusting treatment planning parameters (TPPs, e.g. priority, dose limit, or volume constraint) in the inverse optimization interface to steer plan towards high quality. Specifically, the VTPN took Dose-Volume Histograms (DHVs) of planning structures as input. By observing the DVHs, the three networks sequentially determine the structure for which TPP should be adjusted, which parameter to adjust for the selected structure, and how to adjust the TPP (increase or decrease.)

Training VTPN was achieved via an end-to-end DRL scheme with a hierarchical Q-learning framework. Let us denote the state of observed DVHs d and the action of TPP adjustment C. The goal of training VTPN is to determine the action-value function $Q^*(d,C)$ represented by the hierarchical networks.

For this purpose, we trained the VTPN to operate an in-house developed GPU-based Eclipse-like TPS with the same inverse planning optimization algorithm implemented and realistic dose engine. The purpose of using this in-house TPS rather than Eclipse was to overcome the low efficiency challenge when using Eclipse repeatedly in the long DRL training process. VPTN repeatedly interacts with the plan optimization process with certain actions and observes plan changes. Each interaction step l generates a data (d^l, C^l, d^{l+1}, r^l), where d^{l+1} is the DVHs for the plan after applying the action C^l to the TPS's optimization engine to generate a new plan, and r^l is the reward by going from d^l to d^{l+1}, which will be presented in the next subsection.

Through the data generated in this process, the network training was achieved by the update:

$$Q^*(d^l,C^l) \leftarrow Q^*(d^l,C^l) + \alpha \cdot [r^l + \gamma \cdot \max_C Q^*(d^{l+1},C^{l+1}) - Q^*(d^l,C^l)], \tag{1}$$

where α is the learning rate to control the weight given to the new information obtained. $\gamma \in [0,1]$ is a discount factor that determines the importance of future rewards in the learning process.

2.3 Physician Preference-guided VTPN

In clinical practice, physicians determine the treatment plan's acceptability based on quantitative metrics on plan quality and other considerations such as patient conditions. To realize PgVTPN, we incorporated the previously developed VPN in the VTPN training process from two angles.

First, PgVTPN employs a reward function combining the ProKnow system and the probability of plan approval from the VPN to represent the requirements both from quantitative plan evaluation and the physician's preference. The ProKnow system comprises 15 metrics specific to prostate SBRT, resulting in a full plan score denoted as $P(d)$ with a maximum of 150. We further denote the plan approval probability of the trained VPN as $VPN(A,d)$, where A is the patient anatomy represented by structure masks. We define the reward when changing a plan with DVHs d to d' as $r(d',d,A) = [P(d') + \kappa VPN(A,d')] - [P(d) + \kappa VPN(A,d)]$, where $\kappa = 150$ is a scaling factor to equally weight the ProKnow score with the plan acceptance probability. The reward r measured the difference in plan quality considering both quantitative metrics and the likelihood of physician approval. A positive reward represented the plan quality was improved, and a negative value otherwise.

Second, PgVTPN incorporates in the training process suggested dose improvements by the VPN. An important aspect in training the VTPN is to have it interact with the TPS, and observe the consequences represented by the reward for making certain actions, namely changes in TPPs. Two aspects have to be balanced in this training process. First, this process has to allow exploration of various actions to allow the VTPN to discover effective strategies in TPP adjustment. We achieved this via a ε-greedy scheme. At each step, PgVTPN

randomly selects an action of TPP adjustment with probability ε to the solution space. Second, meanwhile, it is equally important to have the process to adequately observe effective TPP adjustments to learn the strategy to generate them. Yet it is conceivable that effective TPP adjustments are much more scarce than ineffective ones. It is hence imperative that the training process can effectively generate effective TPP adjustment actions to improve overall training efficiency. As such, we used the dose improvement suggested by the VPN to identify which planning structure should be prioritized to optimize and which direction of TPP adjustment should be implemented in the next planning iteration.

2.4 Evaluation

We retrospectively identified 25 prostate cancer patients who were treated with 45 Gy in 5 fractions SBRT using VMAT between 2017 and 2020 at our institution [3]. We conducted a thorough assessment to evaluate the performance of the IATP framework. For testing, we coupled the trained PgVPTN with the real clinical Eclipse TPS, as opposed to the in-house one in the development, using ESAPI to allow PgVTPN to directly control the plan optimization process. Like a human planner, the trained PgVPTN was able to autonomously operate Eclipse TPS to generate a plan for each patient. Standard clinical metrics, emphasizing target coverage and critical organ sparing in line with clinical guidelines, were employed to assess all RT plans. Additionally, a blinded assessment was carried out by three clinical reviewers (a radiation oncologist and two experienced physicists), who compared the plan generated by PgVPTN with the clinical plan used in treatment for each patient case. To assess the clinical deliverability of the IATP system, we randomly selected three plans and performed patient-specific quality assurance (QA).

3 Results

3.1 Planning Process of a Representative Case

Fig.2 shows improvements in plan quality for a representative case during the planning process. The ProKnow score $P(d)$, VPN plan approval score $\kappa VPN(A,d)$, and total plan scores $P(d)+\kappa VPN(A,d)$ exhibited an overall increasing trend, rising from 138.98 to 142.10, 43.33 to 122.37, and 182.31 to 264.47, respectively. The clinical plan used in treatment for this case scored 140.06, 109.15, and 249.21. Fig.2 (b) display cross-sectional dose distributions at planning steps 0, 4, and 10 for PgVPTN to operate Eclipse TPS, and (c) compare DVHs at these steps, demonstrating the autonomous behavior of PgVPTN in making decisions to perform treatment planning like a human.

3.2 Comprehensive Assessments on 25 Patients

Fig. 3 (a) displays the distribution of plan scores in terms of likelihood of plan approval $\kappa VPN(A,d)$ and quantitative ProKnow scores $P(d)$. The IATP plans generated by PgVPTN are slightly more clustered in the upper right corner, indicating the higher plan quality in both two aspects. Fig. 3 (b-d) plots the plan scores $P(d)+\kappa VPN(A,d)$, ProKnow scores $P(d)$, and the likelihood of plan approval $\kappa VPN(A,d)$ for each patient, with the two axes being the clinical plan and IATP plan scores. The distribution below the diagonal line revealed that IATP plans exhibit superior quality with higher scores.

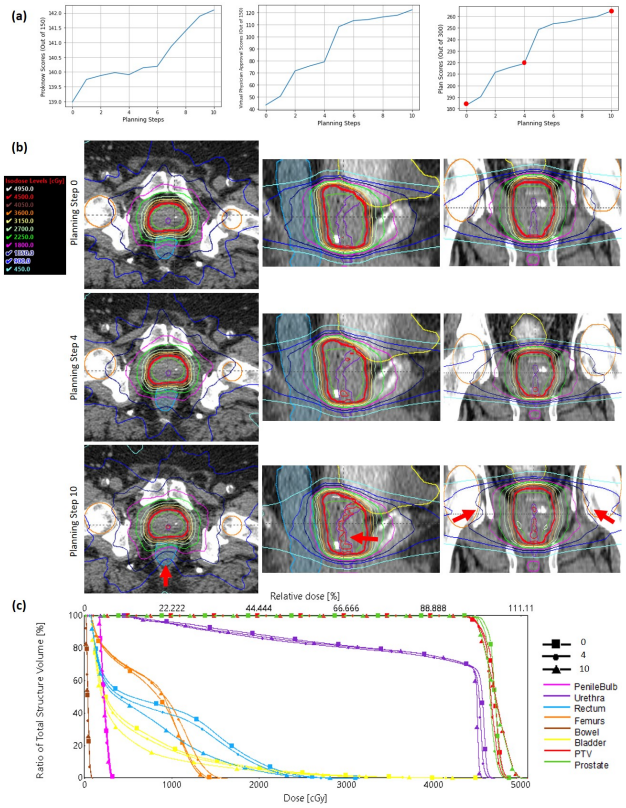

Figure 2: (a) Evoluation of plan scores during the planning process. (b) and (c) are cross-sectional dose distributions and DVHs at steps 0, 4, and 10 of PgVPTN operating Eclipse.

Fig. 4 provides a detailed comparison of clinically relevant plan quality metrics, monitor units (MUs), VPN plan approval scores, and total plan scores between clinical plans and their IATP counterparts. The IATP-generated plans achieved an average total score of 252.99 ± 15.57 and an average VPN plan approval score of 121.63 ± 13.44 compared to the clinical plans scored at 237.29 ± 18.72 ($p = 0.003$) and 110.41 ± 17.63 ($p = 0.017$), respectively. Overall, the IATP-generated plans outperformed the clinical plans, achieving higher scores in both total plan score and VPN plan approval score, with statistically significant differences. Furthermore, IATP-generated plans also demonstrated statistically significant improvements over human-planned ones in several specific metrics such as the Conformality Index of PTV ($p = 0.0$), $V_{Rectum}[36Gy]$ ($p = 0.013$), $D_{Rectum}[40\%]$ ($p = 0.0$), $D_{Urethra}[20\%]$ ($p = 0.0$), $D_{Bowel}[1cc]$ ($p = 0.049$), and $D_{RFemoralHead}[max]$ ($p = 0.018$). While the average monitor units for IATP-generated plans were slightly higher

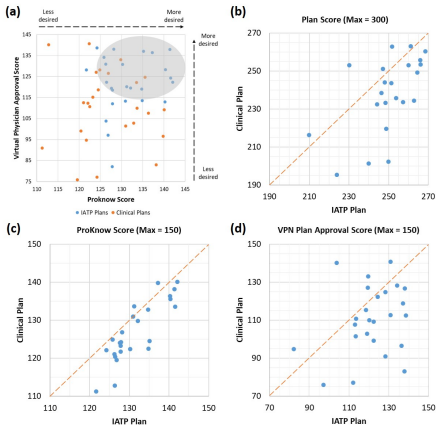

Figure 3: (a) Distribution of plan scores for the clinical plan and the PgVTPN generated plans. The shaded area indicates a cluster of high-quality plans. (b-d) Comparison of total plan scores, ProKnow score, and VPN plan approval score between clinical plans developed by human planners and those generated by IATP.

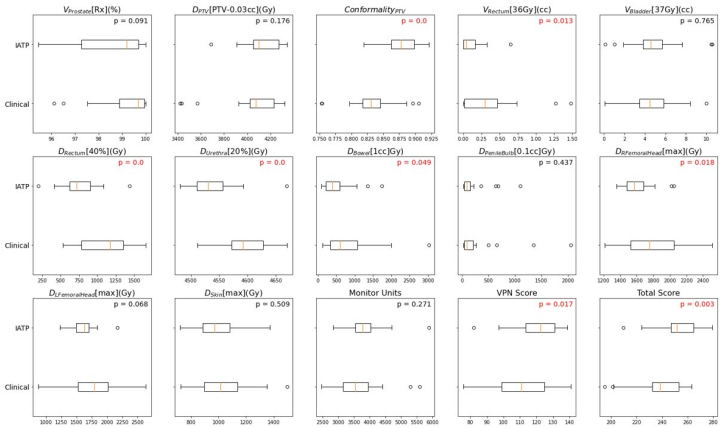

Figure 4: Boxplots of clinically relevant plan quality metrics, MUs, VPN plan approval score, and the total plan score, comparing clinical plans and their corresponding plans generated by IATP. The left and right quartiles define the edges of the boxes, and any point exceeding 1.5 times the interquartile range is considered an outlier. Vertical lines inside the boxes represent median values. The p-values below 0.05 are highlighted to indicate statistical significance.

(3836.62 ± 552.75) than clinical plans (3627.56 ± 733.54), the difference was not statistically significant $p = 0.271$. The IATP workflow spent an average of 42.05±10.71 minutes to generate a high-quality prostate SBRT plan, with the majority of time spent on plan optimization and dose calculation in Eclipse. The decision made by PgVPTN to adjust TPP was almost instantaneous, highlighting the efficiency. All three randomly selected PgVPTN-generated plans for QA successfully passed the gamma index analysis (3%/3 mm), with a passing rate of an average of 96.3%, confirming its clinical deliverability.

3.3 Blinded Evaluation by Three Reviewers

Figure 5 displays the results of a blinded assessment conducted by three reviewers including one physician and two

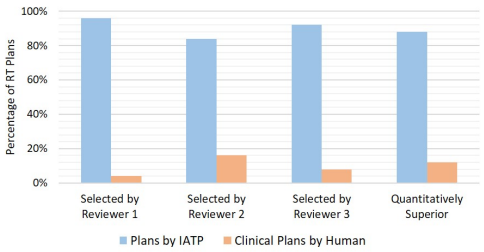

Figure 5: Three clinical reviewers evaluated 25 patients, each having one plan generated by IATP and one clinical plan, in a blinded assessment.

medical physicists. Reviewers favored IATP-generated plans over clinical plans in 96% of patient cases (24/25), 84% of cases (21/25), and 92% of cases (23/25), respectively. The one IATP-generated plan not chosen by all reviewers involved a patient with a left femoral head hip replacement, where the human planner utilized beam angle avoidance, which the IATP system failed to consider.

4 Conclusion

This study presented the IATP framework for prostate cancer SBRT treatment planning. Through end-to-end DRL training, a PgVTPN was developed to autonomously operate a clinical TPS, like a human planner, to generate plans meeting dosimetric requirements and aligned with physicians' clinical preferences. The integration of IATP into the clinical workflow was achieved seamlessly with a commercial TPS. The IATP-generated plans exhibited a statistically superior total score of 252.99 ± 15.57 compared to 237.29 ± 18.72 of the clinical plans. IATP outperformed in dosimetric metrics such as PTV conformality, $V_{Rectum}[36Gy]$, $D_{Rectum}[40\%]$, $D_{Urethra}[20\%]$, $D_{Bowel}[1cc]$, and $D_{RFemoralHead}[max]$ with statistical significance. In a blind evaluation conducted by three experienced reviewers, PgVPTN-generated plans were preferred over the corresponding clinical plans in 90% of cases on average, demonstrating the effectiveness of our development.

An exploration of the complexities of CTV mapping

Marcel van Herk, Matt Craddock, Mairead Daly, Eliana Vasquez Osorio

Division of Cancer Sciences, University of Manchester, UK
The Christie NHS Foundation Trust, Manchester, UK

Abstract. A naïve CTV description could be a population-averaged cell density of microscopic disease. We show, by simulation, that there is a huge impact of the *mode* of cell density variation on margin requirements. Our model consists of a spherical GTV, surrounded by small nodules at given distance. Geometrical errors were simulated and TCP calculated for many scenarios with varying margin. The three modes of CTV nodules variation were: 1: varying cell density; 2: varying nodule probability, with all nodules present/absent at once, 3: varying nodule probability with each nodule independent. We report the CTV+PTV margin at 2% TCP loss from large margins. Per 0.1 times density reduction (mode 1) CTV margin reduces 1mm. For mode 2, CTV margin reduced by 4mm at p=0.1. For mode 3, the margin is in-between. Since all these modes share the same population averaged tumour cell density, we demonstrated that this representation is insufficient.

1 Introduction

There is currently a renewed interest in providing a more detailed description of the CTV, rather than using fixed or anatomical margins based on historical data. According to ICRU, "*The Clinical Target Volume (CTV) is a volume of tissue that contains a demonstrable GTV and/or subclinical malignant disease at a certain probability considered relevant for therapy".* In the lung setting, there have been clinical studies omitting a CTV margin in higher stage patients with apparently no loss of local/marginal control [1]. Also, the latest pathology findings show that current 5 mm CTV margins may be generous in small lung tumours [2]. However, to qualify such results a more quantitative definition of the CTV would be required.

A naïve assumption would be to describe the CTV by a population averaged tumour cell density [3]. In clinical practice quantitative information about the CTV is very hard to collect, and significant efforts are required [4]. Better TCP modeling and statistical methods are required to make a more scientific definition of the CTV possible. But even if such information would be available, is it enough? Here we simulate a very simple model of GTV and CTV to demonstrate the large impact of the details of *how* the tumour density varies on the required safety margins, given that the actual CTV would be unknown. We hope that these results contribute to a better understanding of the requirements of CTV 'maps' that form a core element of the current discussions and upcoming ICRU recommendations.

2 Materials and Methods

Our (very simple) tumour model consists of a spherical GTV with radius of 2.5 cm, surrounded by 26 small nodules with 1/1000 of the GTV volume at 8 mm distance (**Figure 1**). This distance is the median nodule distance observed previously in lung cancer [5]. We chose 26 nodules to easily cover all directions around the sphere. Random and systematic geometrical errors were simulated (Σ=3.9mm, σ=2.6mm), requiring about 11 mm PTV margin according to the van Herk recipe [6]. We assumed a dose prescription of 66Gy (in 2Gy fractions). Density variation of the nodules was simulated in three modes (**Figure 2**): 1: by only varying cell density, all nodules at the same time, 2: by varying the probability of nodule presence, with all nodules present our absent at the same time, 3: by varying the probability of nodule presence with each nodule independently absent or present. Using an existing simulation framework [7] (**Figure 3**), TCPs were calculated for a range of isotropic margins. Our parameters where chosen to give a more or less realistic TCP of 62% for stage 3 lung cancer, $\alpha = 0.35\text{Gy}^{-1}$, $\sigma_\alpha = 0.08\text{Gy}^{-1}$ and tumour cell density of $1.8*10^7/\text{cm}^3$. We arbitrarily define the optimal CTV margin as that margin where the population-based TCP loss is 2% compared to very large margins. Such a choice represents a reasonable balance of the risk of geometrical miss versus organ at risk damage at larger margins.

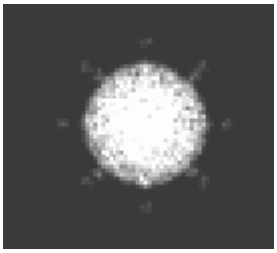

Figure 1: Visualisation of the very simple simulated GTV and CTV. The GTV is surrounded by 26 nodules at 8 mm distance and equally distributed in all directions in 3D. Depending on the simulation, nodules may be turned off such that the average number of present nodules can be much smaller.

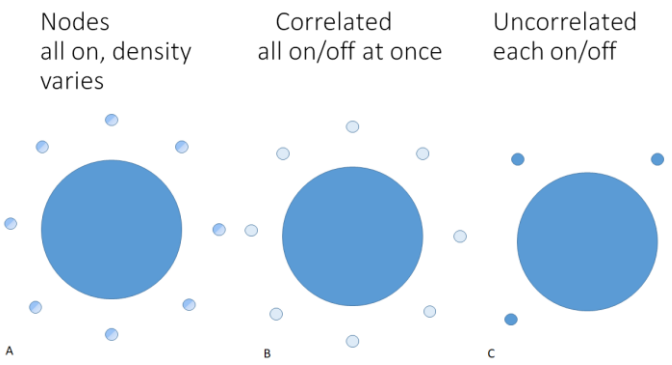

Figure 2: Visualisation of the difference of CTV simulation. The 26 nodules are A) all varied in cell density, B) all switched on or off at the same time at given probability, or C) independently switched on or off at a given probability. Note that these three simulations are fully identical in terms of population-averaged cell density.

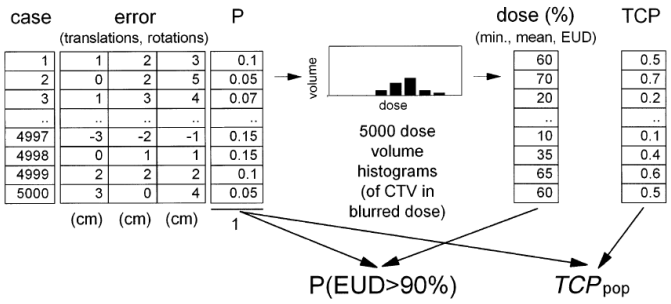

Figure 3: Simulation framework (taken from [7]).The simulation applies 5000 error scenarios and for each scenario a random CTV is drawn according to the modes shown in **figure 2**. An idealised dose distribution with varying margins is used as input. The population TCP is reported here.

To summarise our simulations, we plot contour lines of TCP as function of (PTV+CTV) margin and density/ probability, the latter simulated over a logarithmic range from 1 to 0.0001 in half decade steps.

3 Results

Figure 4 shows the summary plots for our experiments, where we observed the highest TCP to be 0.62.

The required margin to achieve 60% TCP as function of density or probability is quite different for the three types of simulations. Cell density reduction allowed a linear reduction of margin at about 1% per decade lower density (**Figure 4a**).

Nodule probability reduction behaves quite different, because at low probability the population TCP is no longer affected, since e.g. at p=0.001 only one in thousand patients will fail. There is a large difference between correlated (**Figure 4b**) and uncorrelated probability (**Figure 4c**). With uncorrelated probability, the required margin increases by 2mm for at a 0.1 probability level.

4 Discussion

This work simulates three possible modes of variation for tumour density and nodule presence probability in the same geometry that have identical cell density distributions on a population level. However, the margin required at 2% TCP loss depends strongly on the mode of variation. As expected, we find that all margins are the same at p=1, about 16mm. This is about 3 mm less than calculated by the van Herk recipe (11 mm) plus the distance from the GTV to the simulated nodes (8 mm). A somewhat lower margin based on TCP considerations is expected because TCP based margins are more resilient to

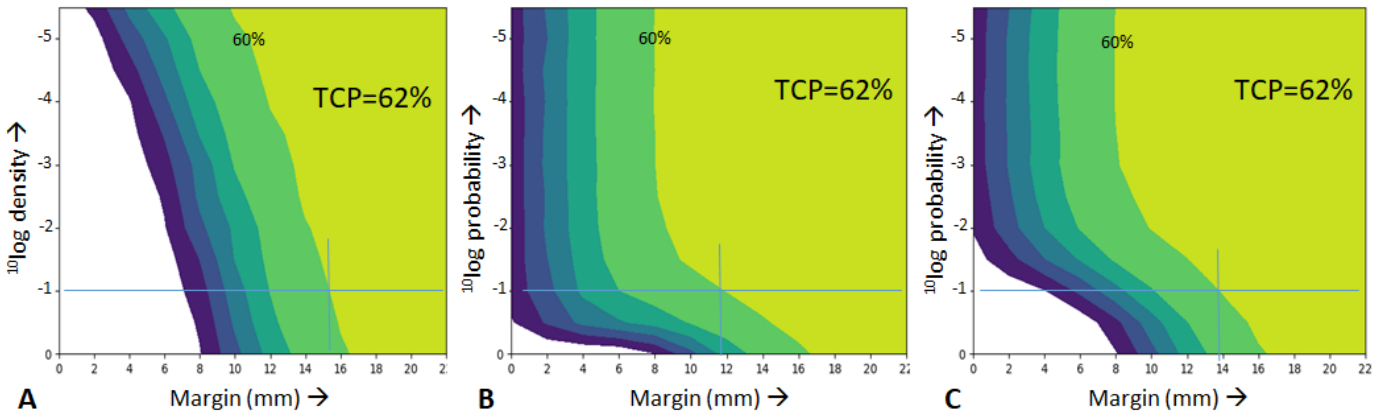

Figure 4. Dependence of TCP (colour) on margin (horizontal axis) and average tumour density/probability (vertical axis) for different modes of tumour density variations. In all three graphs, the population-based cell density distribution is the same. Colour steps are per 5% TCP. The green-yellow transition is at a TCP of 60%, while the highest TCP is 62%. A) Cell density reduction, the same for all patients and nodules. B) Nodule probability reduction, where all nodules are either present or absent at the same time for each individual patient. C) Nodule probability reduction where each nodule is treated independently. The lines indicate the required PTV+CTV margin at a probability or density of 0.1 to achieve a TCP of 60%.

edge under-dose than dose-probability based margins [7].

Most surprising is the difference between correlated and uncorrelated probability of node presence. We believe this finding demonstrates a combination of two effects. First, there is an effect of CTV distribution on margins for *geometrical* uncertainties. If nodules are present all around the GTV, geometrical errors in any direction will cause a nodule miss, i.e. the CTV is at risk in 3 dimensions. At lower probability, there will be fewer nodules. This means that only errors exactly in the direction of a nodule will lead to miss. In other words, the CTV will be at risk in less than 3 dimensions and therefore a reduced margin can be accepted [6]. However, here we find an increased margin requirement. This is related to the degrees of freedom in the variation. In mode 2 there is one degree of freedom, if all nodes are on at once they be missed everywhere at once. In mode 3 there are up to 26 degrees of freedom, and the likelihood of missing one or more of them is bigger for $p>0.04$. The combined effect is a margin increase of 2mm at $p=0.1$.

We chose to use 26 nodules and of course mode 3 will be enormously affected by this number as they translate to degrees of freedom. In modes 1 and 2, the total nodule volume is nodules is more likely to determine the behaviour. However, it is very likely that the results for mode 3 will scale, e.g. taking 10 times more nodules at 10 times lower probability would give the same results, The degrees of freedom for geometrical miss relates to a spatial correlation in nodule presence that *must* be taken into account for proper margin calculation. This is a similar situation as described for contouring, where Mckenzie et al [8] described ‘dimples and pimples’, and Vasquez Osorio et al used spatial filtering on a level set to create realistic contours [9]. Biologically, such a behaviour may be plausible due to development of different clonal regions in a tumour where only those with certain mutations start disseminating. Correlation descriptions are required to correctly add CTV and PTV margins and for robust treatment planning for the CTV.

By necessity our simulation is very simplistic and it would be of interest to add more variation. However, our results do clearly show the insufficiency of a population-averaged cell density model.

5 Conclusion

This is a first simulation of the mode of CTV density variation and its effect on margin requirements. The average density does not and cannot reflect the mode of cell density variation and is insufficient for defining a CTV margin, It would not give the expected average TCP in a real patient population with unknown mode of density variations, and should not be used for CTV mapping. Correlation must be considered to correctly add CTV and PTV margins. Given the many unknowns it is important to perform clinical trials to determine the optimal CTV margin for each clinical site.

Abstract

Purpose: Functional imaging of heterogeneous organ function offers the opportunity to explore and evaluate novel treatments that maximize preserved organ functionality while satisfying other constraints. Designing such treatments with clinical planning systems is a challenge since these systems cannot drive an optimization according to an image-based functionality surrogate. The purpose of our work is to demonstrate an optimization approach that overcomes this challenge entirely with tools available in a commercial treatment planning system (TPS).

Methods: We implemented the optimization approach with multicriteria optimization (MCO) and scripting tools in Eclipse TPS v15.6 (Varian, Palo Alto). We start with a standard plan for which an organ with heterogeneous imaging appearance meets clinical dose-volume constraints. We segment this organ in non-overlapping sub-regions of equal volumes and increasing functional image intensity. For these sub-volumes and planning targets, starting with the clinical plan, we generate a database of plans with (MCO). We then optimize functionality sparing with simulated annealing exploration of the plan database. In this exploration we select a plan by setting sub-volume objectives to track closely their randomly assigned maximum limits. We gauge the utility of a selected plan by a user-defined cost function that calculates a surrogate metric of preserved functionality from image and dose values at voxels within the organ.

Results: We used this approach with interactive exploration to support a Phase I/II study," Bone Marrow Sparing Image-Guided Radiation Therapy Incorporating Novel Use of GCSF and FDG-PET Imaging", NCT04514692. The surrogate metric of preserved functionality was the cumulative FDG activity receiving doses below 20 Gy in pelvic bone. For 70% of the enrolled patients treatment proceeded with an MCO plan as functional sparing was deemed significant.

Conclusion: We have demonstrated a clinically deployable planning approach to support single- and multi-institutional clinical trials of novel biologically-guided function-preserving radiotherapy treatments.

1 Introduction

Functional and molecular imaging of heterogeneous organ function offers the opportunity to design and conduct clinical trials that evaluate the benefit of novel treatments that incorporate such imaging in plan optimization to maximize preserved organ functionality while still satisfying other treatment planning constraints. While designing such treatments with clinical treatment planning systems (TPSs) is highly desirable to assure all treatment workflow and quality aspects are met, it poses several challenges. First, once structures (organs) are segmented from anatomical, molecular, or functional images clinical TPSs treat these structures as homogeneous in function, completely ignoring the functional imaging context. Second, clinical TPSs optimize treatment plans with hard-coded pre-defined (typically) dose-volume histogram (DVH) metrics of plan quality (cost functions) which cannot drive an optimization according to user-defined image-based functionality metrics that will vary depending on which organ and function are considered for preservations and which imaging modality is used to capture the heterogeneity of this function.

One potential approach to overcome these challenges is to segment a structure with heterogeneous function in non-overlapping sub-regions (sub-structures) with equal volumes and increasing functional intensity and then include these structures with the hard-coded TPS objective (cost) functions (also termed objectives) and user-assigned objective weights in the standard TPS optimization to generate a plan. Using TPS scripting tools, the image-based functionality metric can be then calculated and in principle used to guide a new selection of the objective weights automatically or interactively.

A conceptual "viscous circle" type of problem with this approach is that in selecting an optimal plan a clinician will have to gauge the relative merit of gains and losses of standard DVH metrics against gains and losses of a newly investigated functionality metric, when the goal of the clinical study itself is to establish the validity and the merit of using such functionality metric. Hence, in what follows we propose and demonstrate a novel "First do no harm" optimization approach to functionally-guided radiotherapy that is entirely implemented with tools available in a commercial TPS, thus making it immediately deployable clinically.

2 Materials and Methods

Description of Optimization Strategy

Our optimization approach is based on the use of multicriteria optimization (MCO) available in commercial TPSs and is described below with reference to a simple scenario shown in Figure 1. We start with a clinical plan that is optimized as per physician and institutional guidelines and accepted for treatment. For this plan the structure with heterogeneous function attains a clinical DVH objective such as V_D (absolute or relative volume below dose D) equal to $V_{attained}$ (see Figure 1). We segment this organ in N (N = 2 in Figure 1) non-overlapping sub-structures of equal volumes and increasing functional image intensity (substructure **R**educed **I**mage **I**ntensity or ***RII***, and **E**levated **I**mage **I**ntensity or ***EII*** in Figure 1). Starting with the clinical plan, for these sub-structures and for planning targets (the TPS requires targets to be included), we generate a database of plans with multicriteria optimization (MCO) after removing the initial structure from the optimization. The initial target value of the DVH objectives for the substructures ($^{RII}V_D$ and $^{EII}V_D$ in Figure 1) are set to match the values attained

by the clinical plan. To enforce the "First do no harm" principle other objectives are excluded from the MCO and thus effectively locked at their previously achieved and clinically acceptable values with the clinical plan.

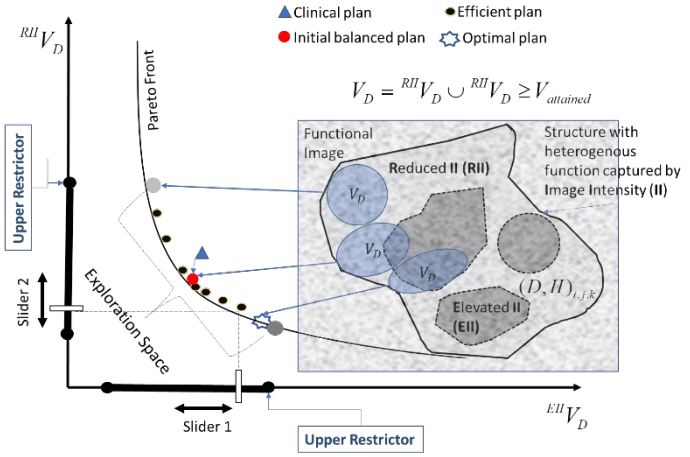

Figure 1 A simple example to illustrate the MCO strategy for maximizing spared functionality. The initial balanced plan (red marker) generated from a clinical plan (blue triangle) spares a given region V_D (in blue) from the structure with heterogeneous function as reflected by substructures with elevated (EII) and reduced image intensity (RII). MCO optimization with trade-off objectives ${}^{RII}V_D$ and ${}^{EII}V_D$ creates exploration space of Pareto efficient plans (black dots) with dose distributions that trade between target objectives, ${}^{RII}V_D$, and ${}^{EII}V_D$ resulting in different dose distributions, illustrated by different V_D regions. In exploration the optimal plan is selected as the one that maximizes a user-defined cost function that calculates a surrogate metric of preserved functionality from paired dose and image intensity values $(D,II)_{i,j,k}$ while still maintaining the initial V_D.

Given a set of competing (trade-off) objectives and starting with an initial balanced plan generated from the clinical plan, the MCO tool in the commercial TPS generates a database of Pareto efficient plans which belong to a certain exploration space of the Pareto Front [1, 2]. Any plan that belongs to the Pareto front balances the trade-off objectives in efficient manner that is a trade-off objective cannot be further improved without worsening at least one or more other trade-off objective. This database of efficient plans is then made available for exploration in a "Trade-Off Exploration Context". In interactive mode a user manipulates sliders linked to each trade-off objective to express preferences towards different trade-off objectives and evaluates the generated treatment plan that corresponds to these preferences.

When the goal of such exploration is to maximize preserved organ functionality while conforming to other plan constraints, the user's preference should additionally be guided by an update of a cost function that calculates a surrogate metric of preserved functionality from paired dose and image intensity values for the currently selected plan.

While interactive exploration may be intuitive and feasible for small number of substructures, it becomes non-intuitive and impractical when an increased number of substructures is used to capture significant imaging heterogeneity within a structure. For this reason, we maximize functionality sparing with simulated annealing [3] exploration of the plan database ("Trade-Off Exploration Context"). In this exploration, at each step, we select a new plan candidate by setting new upper restrictors (Figure 1) for the substructures with random step from the upper restrictors current values. We then set the trade-off objective (Sliders in Figure 1) to track the upper restrictors as closely as possible while satisfying all other constraints. The utility of a plan candidate selected by the values of the trade-off objective is then gauged by a cost function of preserved functionality and acceptance or rejection of the candidate is performed according to the simulated annealing algorithm. Further detail on the simulated annealing exploration are given in the pseudocode in Figure 2.

ENDWHILE
```

Figure 2 Pseudocode for the simulated annealing exploration of the MCO database.

Implementation

We have implemented the optimization strategy discussed above to enable functionality optimized planning for a pilot Phase I/II study," Bone Marrow Sparing Image-Guided Radiation Therapy Incorporating Novel Use of GCSF and FDG-PET Imaging", NCT04514692. We have developed the simulated annealing exploration using the Eclipse Scripting Application Programing Interface, Varian Medical Systems, Palo Alto, CA (ESAPI) v15.5. The surrogate

metric of preserved functionality is the cumulative FDG-PET activity $CA_{20\ \mathrm{Gy}}^{ABM}$ that receives doses lower that 20 Gy in an **A**ctive **B**one **M**arrow structure (ABM) segmented from the FDG-PET image. The corresponding functionality cost function is the relative Functional Loss

$$Functional\ Loss = 100 \times \left(1 - \frac{CA_{20\ \mathrm{Gy}}^{ABM}}{CA_{0\ \mathrm{Gy}}^{ABM}}\right)$$

whereby $CA_{0\ \mathrm{Gy}}^{ABM}$ is the total ABM activity (that would be spared if zero dose is delivered). To set the initial temperature we sample extreme (but unlikely to be clinically acceptable because of other planning constraints) plans from the plan database with maximum functionality sparing, calculate the differences in cost between these extremes and the balanced plan, and set the initial temperature T_0 high enough to allow high initial acceptance (0.8) of uphill moves for such differences. We use a standard acceptance probability function with Boltzmann distribution, and annealing schedule that reduces the initial temperature as $T_0 \times (0.95)^k$ where k is the iteration number of the annealing schedule. The initial step size for the upper restrictors is set to 0.5 (a half of the 0 to 1 exploration range) and at each iteration the step size is reduced by a factor of 0.98. Since setting a trade-off upper Restrictor and Objective automatically impacts all other tradeoff-objectives and available ranges for exploration, at each step we set the order of manipulating the different upper restrictors and objective randomly and we update the "Trade-Off Exploration Context" after manipulating a pair of an upper Restrictor and corresponding Objective. Furthermore, the currently manipulated Objective is scaled back if necessary by automatically evaluating clinical constraint and measures for the current plan candidate and subsequently updating the "Trade-Off Exploration Context". Thus, the optimal objectives for the final functionally sparing plan are not set solely by the values of the upper restrictors but also by the enforcement of clinical DVH constraints at each iteration step and the competition between all MCO objectives.

3 Results

Figure 3 shows an example of simulated annealing exploration of an MCO generated database for a clinical case. For this patient an active bone marrow structure was segmented at the mean FDG uptake in the pelvis bone and further sub-segmented in 2 structures HA (High Activity) and LA (Low Activity). Figure 3 shows that our approach led to ~ 8% reduction in functionality loss (from 89% to 81%). Figure 4 compares the optimized plan with the initial balanced plan to demonstrate the changes in dose distributions at 20 Gy that spare uptake activity in the pelvic bone. Figure 4 also illustrates that with regard to other clinical objectives and constraints the plans are equivalent.

We have also used our approach with interactive exploration to generate clinical plans for the pilot Phase I/II study," Bone Marrow Sparing Image-Guided Radiation Therapy Incorporating Novel Use of GCSF and FDG-PET Imaging", NCT04514692. In 70% (5/7) of the enrolled patients activity sparing with MCO was deemed significant to proceed with the MCO plan.

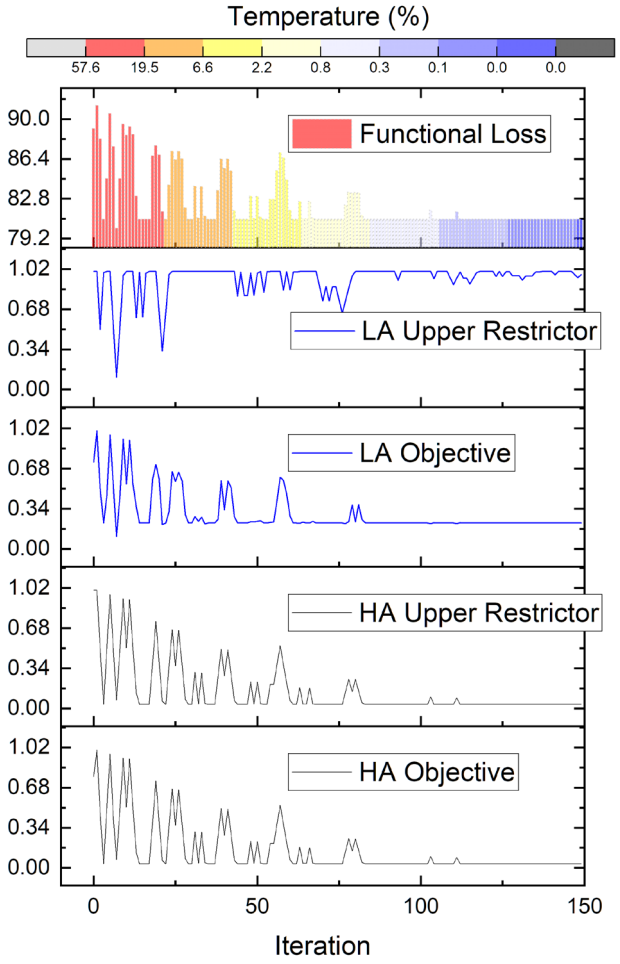

Figure 3 Example of simulated annealing exploration of an MCO generated database for a clinical case. HA and LA correspond to a High Activity Substructure and Low Activity Substructure. The accepted values of the Functional Loss are shown as a function of the iteration number colored with the temperature. Also shown are accepted values of restrictors and objectives during the optimization. Note that while the values for the HA Objective track closely these of the set values for the corresponding HA Upper Restrictor, at the solution the accepted LA Objective values are not limited by the corresponding LA Upper Restrictor but other clinical constraints.

4 Discussion

Our optimization approach offers several benefits.
First, it allows functional and molecular imaging information to guide the optimization of clinically deliverable plans to spare heterogeneous function for a

given organ while maintaining clinical DVH constraints for other structures by excluding these structures from the MCO.

Figure 4 ***Top:*** *Color wash dose display for a plan optimized with our approach.* ***Middle:*** *Color wash dose display for an initial balanced plan. At the same time other constraints are met by both plans, as indicated by the green indicators below the images.* ***Bottom:*** *DVHs showing equivalent target coverage (in red) but decreased dose at 20 Gy for the Low Activity and High Activity substructures. MCO plan: solid lines, balanced plan: dashed lines.*

Second, our approach offers a way to navigate the MCO ("Trade-Off Exploration Context") in case where large heterogeneity in functional images requires many sub-structures to be segmented and interactive navigation is no longer intuitive. Third, it generalizes immediately to any functionally defined cost function, as no specific knowledge about the structure of the cost function is necessary. Furthermore, by normalizing the functionality loss from 0 to 100% and automatically selecting the initial temperature as discussed, it is likely that the hyper-parameters of the algorithm are applicable to other functionallity cost functions.

5 Conclusion

We have presented and implemented an optimization framework based on simulated annealing and multi-criteria optimization to support planning for clinical studies of functionality sparing radiotherapy based on heterogeneous functional imaging.

Abstract In radiation therapy (RT), choosing an appropriate treatment modality is a crucial yet complex task due to the unique features of each modality that impact dose distribution. This complexity is compounded by the lack of a quantitative, patient-specific method for modality selection. To address this gap, we developed an efficient multi-task convolutional neural network. This model utilizes patient-specific data, such as computed tomography image and dosimetric goals, to predict dose distributions for various modalities simultaneously. To evaluate our model's performance, we used a dataset consisting of 92 plans from 28 patients undergoing accelerated partial breast irradiation and divided it into training, validation, and test subsets. Across the test subset, the multi-task model dose predictions achieved Mean Absolute Percent Error of 1.1033 ± 0.3627%. Our approach shows promise as an efficient, quantitative tool for guiding clinicians in RT modality selection. In the future, we aim to expand upon this work with a site-agnostic model to improve its applicability and generalizability in RT.

1 Introduction

Selection of the most suitable treatment modality in radiation therapy (RT) is a critical and nuanced task. The landscape of External Beam Radiation Therapy (EBRT) presents a variety of modality designs, including Cobalt-60-based systems and linear accelerators (LINACs) with C-arm, O-ring, or robotic arm design. Aside from design, modalities may differ in other aspects such as beam energy, beam collimation, mechanical degrees of freedom, and shielding. A modality's unique attributes, advantages and limitations crucially influence a patient's corresponding RT treatment plan and dose distribution.

Adding to the complexity, dose distributions may be further impacted by the choice of treatment technique, treatment planning system (TPS), and dose calculation algorithm. Advanced treatment techniques like intensity-modulated radiation therapy (IMRT), volumetric modulated arc therapy (VMAT), and helical tomotherapy (HT) can offer precise shaping of dose distributions but may increase treatment plan complexity. Additionally, the accessibility of these techniques varies across machines. This complexity emphasizes the need for a comprehensive, quantitative, and patient-centric assessment to aid in modality selection.

Addressing this need is challenging given the myriad of planning options and the time-intensive nature of plan generation. In current clinical practice, it is impractical to create multiple treatment plans for each patient as guidance for final modality selection. For example, Cilla *et al.* [1] utilized auto-planning to reduce time spent on creation of a single treatment plan but it still required 60-80 minutes. This limitation in clinical efficiency and flexibility poses a significant hurdle in providing quantitative, patient-specific data for modality selection.

In consideration of this hurdle, we believe a deep-learning based approach is desirable for its ability to rapidly predict quantitative, patient-specific data. By utilizing patient-specific data, a trained model could predict dose distributions to provide clinicians with essential quantitative information to aid in the decision-making process. Furthermore, we desired an efficient approach that could predict multiple unique dose distributions simultaneously while leveraging the shared knowledge across the broader domain.

In response to this need, we developed a deep learning-based multi-task convolutional neural network (CNN) that is capable of predicting dose distributions for various RT modalities simultaneously. Our network, inspired by the U-Net architecture, consists of a shared encoder, shared decoder, and task-specific convolutional layers to output predicted modality-specific dose distributions. We hypothesize that this model will exhibit statistically significant differences in dose prediction performance as compared to traditionally trained single-task dose prediction networks

2 Materials and Methods

Figure 1 shows a high-level schematic of our deep learning-based multi-task CNN that was developed using the PyTorch framework. The network processes input data as a 4-D NumPy array to represent a channel dimension and the three spatial dimensions. The input data has four distinct channels: computed tomography (CT) image, planning target volume (PTV) contour, a PTV distance array, and a goal array. For model training, the input data is formatted into patches of size 112x112x64 and grouped into batches of 4. Detailed pre-processing steps will be explained later in this section.

The input data is sent to the network's encoder, which is composed of four encoding layers. Each encoding layer includes two convolutional layers (kernel size 3, stride 1) and a downsampling layer. The downsampling layer concatenates the outputs from 3D max and 3D average pooling operations (both with kernel size 2) before passing them through a convolutional layer (kernel size 1, stride 2).

The convolutional layers in this network generally sequence through convolution, activation (using Convolved Concatenated ReLU or CCReLU), normalization (group normalization across five groups), and dropout (3D DropBlock with a rate of 0.05 and a maximum block size of 5x5x5). Our CCReLU activation function concatenates outputs from a positive ReLU function and a negative ReLU function, followed by convolution (kernel size 1, stride 2).

Following the final encoding layer, the network integrates two additional convolutional layers. Subsequently, the decoder contains four decoding layers. Each decoder layer consists of an upsampling layer and a

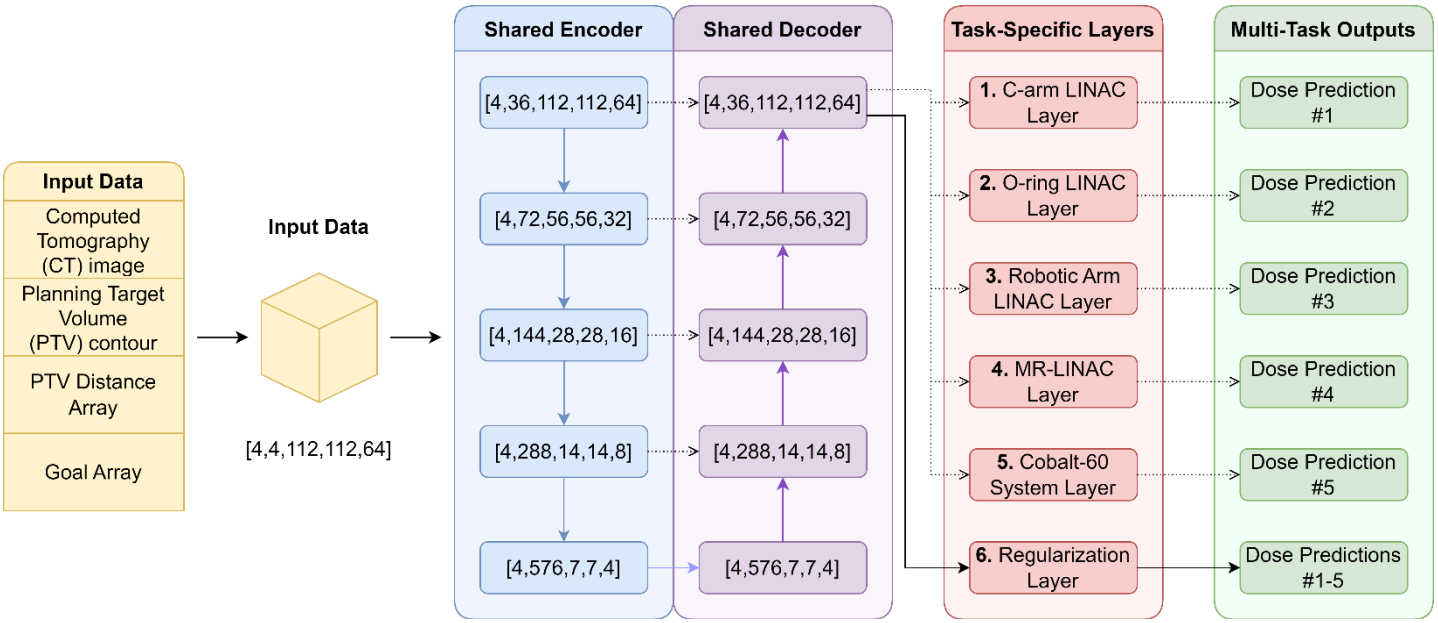

Figure 1: Our convolutional neural network architecture. Dotted lines represent the path that used skip connections.

two simultaneously utilized paths. In the upsampling layer: First, the input data undergoes nearest-neighbor interpolation, trilinear interpolation, and transposed convolution. Then, the operations' outputs are concatenated and finally passed through a convolutional layer (kernel size 1, stride 1). The output of each upsampling layer is sent to two unique paths: The first path utilizes skip connections, concatenating the upsampling layer's output with the corresponding encoder layer output, whereas the second path directly proceeds with the upsampling layer's output. The output from both of these paths is passed through two convolutional layers (kernel size 3, and stride 1).

The bifurcation of feature maps in the decoder, which results in two separate outputs, is a distinctive feature of our CNN. The output derived from the skip connection path is shared with each modality-specific convolutional layer, whereas the output that bypasses skip connections is fed into a regularization task convolutional layer. The modality-specific and regularization task convolutional layers have independent weights and all perform a single convolution and a linear activation to produce the final network outputs. The modality-specific convolutional layers, which receive input from the skip connection path, can utilize high-resolution features for dose prediction. In contrast, the regularization convolutional task layer only employs the decoder's upsampled, high-level data representation to predict doses for all trained modalities.

In overall consideration of our network, we sought to leverage shared knowledge within the broader domain by sharing feature maps across the modality-specific convolutional layers. Additionally, our regularization task aims to encourage a robust, generalized representation of the input data, and to prevent the model from overfitting to modality-specific tasks. To briefly summarize the flow of data in this network, the encoder receives an input tensor of shape [4, 4, 112, 112, 64], based on the batch size, number of channels, and extent of each spatial dimension. The output from the first encoding layer is [4, 36, 112, 112, 64], with 36 representing the initial number of feature maps. Immediately prior to the decoder, the tensor shape is [4, 576, 7, 7, 4]. The final outputs include the modality-specific task predictions, shaped as [4, 1, 112, 112, 64], and the regularization task predictions, shaped as [4, m, 112, 112, 64] where 'm' represents the number of modality-specific tasks.

To test the performance of our model, we selected a group of 28 patients that underwent Accelerated Partial Breast Irradiation (APBI). This patient cohort comprised two groups of 16 supine patients and 12 prone patients, based on their CT position. Each of the 16 supine patients had adaptive treatment plans for 4 distinct modalities: C-arm LINAC, O-ring LINAC, robotic arm LINAC, and Magnetic Resonance LINAC (MR-LINAC). Additionally, each of these supine patients had a conventional treatment plan for the C-arm LINAC. Lastly, each of the 12 prone patients had an adaptive treatment plan for a Cobalt-60-based system. In total, there were 92 treatment plans across the 28 patients. All patients were prescribed 30 Gy over 5 fractions to the PTV.

Gross Tumor Volumes (GTVs) were contoured by radiation oncologists. Two types of Clinical Target Volumes (CTVs) and PTVs were created for each patient uniformly based on our institutional guidelines: an adaptive treatment CTV and PTV, and a conventional treatment CTV and PTV. The following relevant OARs were delineated for all patients: body, left & right breasts, heart, left & right lungs, ribs, skin, and spinal canal. Additionally, dosimetric goals were identical for all patients in this study.

The first step in our data pre-processing was conversion of DICOM data to NumPy arrays. The CT array values were clipped to range from -1000 Hounsfield units (HU) to 5000 HU, and then normalized to an absolute range of 0 to 1. Each segmented structure was represented with a binary array in the same shape of the CT array, and assigned a

value of 1 for voxels where the structure is present. Dose arrays were divided by prescription dose so that their values ranged from 0 to approximately 1, with the upper limit determined by the maximum dose in the treatment plan.

A novel aspect of our data pre-processing is the creation of a PTV distance array, which has same shape as the CT array and contains values ranging from 0 to 1. For this array, voxels within the PTV contour are assigned a value of 1.0 and values for voxels outside the PTV gradually decrease towards 0 as the distance from the PTV increases.

An additional novel step in our data pre-processing is the development of a goal array. Conventionally, each OAR would be assigned to its own channel of the input data. This has two major consequences: First, a model trained with such input is inflexible, as it only has capacity for specific pre-trained OARs. Therefore, this limits the generalizability and clinical practicality of the model. Secondly, there is significant redundancy in this type of input data because many of the OAR arrays will only hold non-zero values in a relatively small percentage of its total size. In consideration of these limitations, we desired a single array that conveys all relevant OAR information so that we could minimize the number of overall input channels without sacrificing the quality of the input data. Furthermore, we desired a method that could represent a physician's dosimetric goals in the same shape of the CT so that it could be used as input data for a CNN.

Our proposed solution to these issues, which we refer to as a goal array, serves as an efficient representation of the most pertinent OARs and dosimetric goals. We established rules to fill the goal array based on each OAR's dosimetric goals, so that the goal array conveys maximum preferred dose on a voxel-by-voxel basis. For instance, one dosimetric goal requests that the contralateral breast max dose is less than 0.9 Gy, so voxels within it were assigned values equal to 0.9 Gy. For volumetric-based goals, we solved for a sub-volume of the organ that: 1) satisfies the sparing criteria, and 2) is most distal to the PTV. For the ipsilateral lung, a goal requests that the volume of it receiving 9 Gy or more is less than 10%. Our function would then solve for 90% of ipsilateral lung that is most distal to the PTV and assigning those voxels to 9 Gy. Any voxel of an OAR that was unspecified by dosimetric goals was assigned to an arbitrary value equal to 105% of prescription dose, conveying a desire to minimize high dose. Overlapping objectives were consolidated by taking the minimum value for each voxel. Next, voxels within the body that remained unassigned by any of these rules were assigned to arbitrary values equal to 95% of prescription dose, conveying that prescription dose is undesirable outside of the target. Lastly, voxels outside the body were assigned values of 0. The goal array was then divided by the prescription dose (as the dose array was).

The input data arrays were assembled by stacking the PTV array, PTV distance array, dose array, and goal array, yielding a 4-dimensional array. Next, the arrays were resized to represent $5mm^3$ voxel spacing. Then, the final input data array was created with a randomized patch selection function and a data augmentation function. The patch center was selected by sampling from a Gaussian distribution with the GTV center of mass as the mean, and the patch extent was increased in random directions until it met our specified shape of [112, 112, 64] in the y-, x-, and z-dimensions respectively. We also performed random spatial translation with a shift tolerance of 5 elements per dimension. The remaining data augmentation techniques included a 50% chance of random rotation (with an additional 25% chance of rotating either 0, 90, 180 or 270 degrees) and a 50% chance of random flip.

Our dataset was split prior to model training as follows: The data from 8 patients was withheld, totaling 24 test plans (4 plans per modality). The data from the remaining 20 patients were used during model training, which includes 56 training plans (10 plans per supine modality, 6 plans for the prone modality) and 12 validation plans (2 plans per modality).

Finally, we commenced supervised model training by using the original, human-planned dose distribution as the label. All model training in this study used the AdamW optimizer, an identical fixed random seed, and began with randomly initialized weights. Loss was calculated by comparing the label and the predicted dose. The overall loss was a sum of task-specific loss functions, and each task's loss function was a sum of mean squared error and mean squared logarithmic error. Each model trained for 5,000 epochs with a learning rate ranging from 1e-6 to 1e-4 over one cycle. The regularization task's weights were frozen for all of model training. We also froze task-specific weights if their validation loss failed to improve across 500 epochs.

In addition to the multi-task model, five single-task models were trained. Single-task models were trained with identical network architecture as our proposed multi-task CNN, except that the network only had one task that predicted a dose distribution for a single modality. Dataset splits were identical for the multi-task and single-task trainings, though single-task trainings omitted data from untrained modalities.

3 Results

Mean Absolute Percent Error	Robotic Arm LINAC	MR-LINAC	O-ring LINAC	C-arm LINAC	Cobalt-60 System
Multi-Task Model Average	1.3262 ± 0.1993%	1.4685 ± 0.2808%	1.1135 ± 0.3168%	0.8053 ± 0.3302%	0.8029 ± 0.1490%
Single-Task Model Average	1.5298 ± 0.2534%	1.5106 ± 0.2802%	1.2308 ± 0.2861%	0.8187 ± 0.3567%	1.1029 ± 0.3552%

Table 1: Model performance across the test dataset.

The trained multi-task model and single-task models were used to predict dose distributions across the test dataset. We calculated the Mean Absolute Percent Error (MAPE) for each dose prediction based on its difference

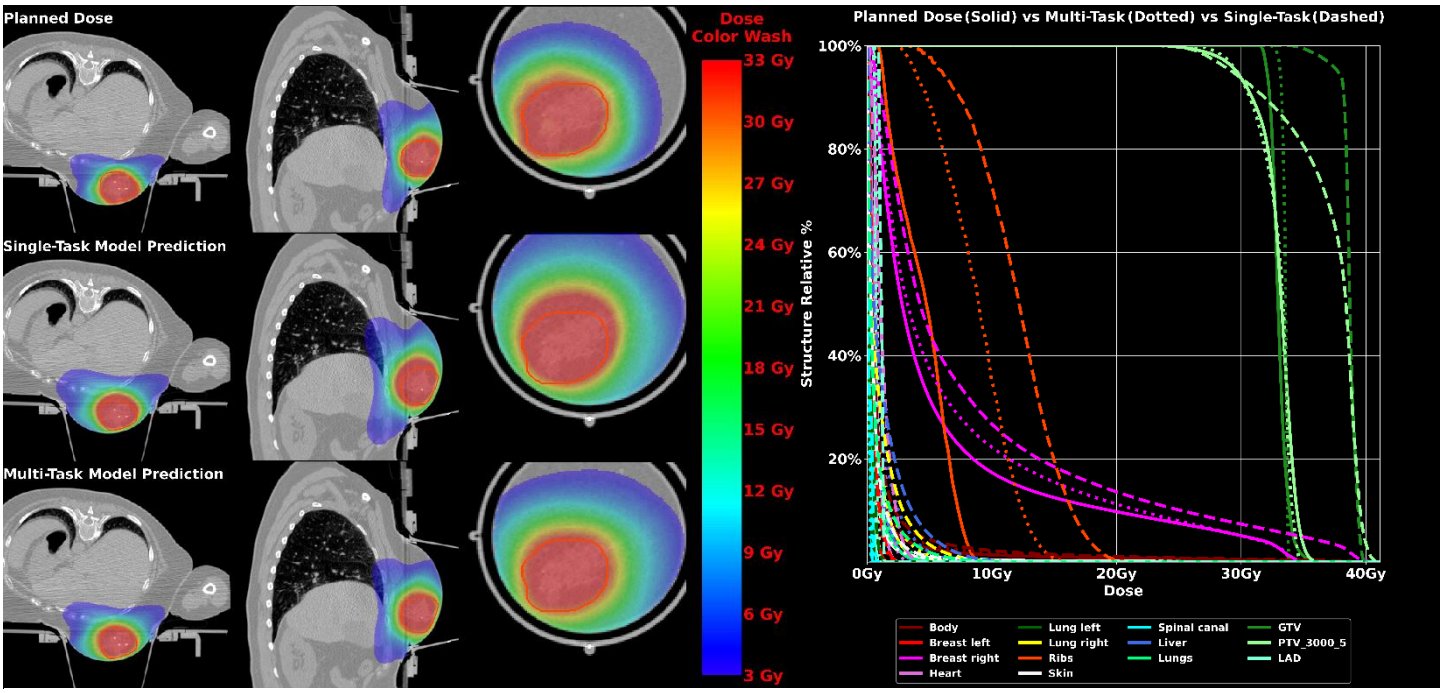

Figure 2: On the left, a patient's dose distributions for the Cobalt-60-based system are overlaid on their computed tomography image, with their planning target volume contoured in red. On the right, dose volume histogram (DVH) values are plotted for all three dose distributions. We aim for the predicted dose to align closely with the planned dose.

with the original human-planned dose distribution. Then, we calculated the average MAPE across the test dataset for the multi-task model and the single-task models as seen in Table 1. The multi-task model exhibited a lower average MAPE across each modality compared to the single-task models. Across the entire test dataset, the MAPE was 1.1033 ± 0.3627% for the multi-task model and 1.2386 ± 0.3872% for the single-task models. We performed a two-tailed Wilcoxon signed-rank test with these 24 paired MAPE values, yielding p=0.0003 and 95% confidence interval = [-0.0865, -0.0712].

In figure 2, we display an example of a prone patient's dose predictions and their corresponding dose volume histogram (DVH) for plans using the Cobalt-60-based system. The DVH demonstrates the multi-task model prediction's improved accuracy versus the single-task model in structures such as the heart, left breast, and PTV. This dosimetric difference can also be observed qualitatively as the single-task model prediction demonstrates excessive high dose outside of the PTV.

4 Discussion

Our study demonstrated superior performance from the multi-task model across the dataset as compared to a traditional single-task model in modality-specific dose prediction. We observed that the modality with the largest number of training plans had the smallest performance gap (C-arm LINAC with 20), and the largest performance gap was in the modality with the least number of training plans (Cobalt-60 system with 6). Based on this, we suspect that the multi-task CNN's shared, modality-agnostic backbone may allow for more rapid adaptation to emerging modalities than a single-task network because it trains shared layers with a larger effective sample size. Furthermore, this design may only require fine-tuning a single, modality-specific layer to add a new modality, or removal of a modality-specific layer for a modality that is phased out of clinical practice. We also suspect that this network can train a model for technique-specific dose prediction.

A trained multi-task model can facilitate quantitative decision-making for physicians and patients. If deployed as a clinical tool, it could be used to compare dosimetric outcomes across multiple modalities. Prior to the treatment planning process, involved parties could weigh the model's predicted dosimetric information alongside the treatment location, appointment availability and/or financial cost on a per-modality basis. For example, patients may consider a specific modality based on geographical proximity to their home if the dosimetric outcome is acceptable compared to a geographically distant but cutting-edge modality.

5 Conclusion

Our study developed a multi-task deep learning model for predicting dose distributions across multiple radiation therapy modalities. This flexible, modality-agnostic tool can aid clinical decision-making and resource allocation. In future works, we aim to improve the model with a larger dataset and investigate the addition of different related tasks like beam angle selection. Longer term, we aim to test site-agnostic dose prediction.

Producing Deliverable Treatment Plans with Deep Learning: A Fully Automated Pipeline Outside the Treatment Planning System

Gerd Heilemann[1], Tufve Nyholm[2], Gregor Goldner[1], Joachim Widder[1], Dietmar Georg[1], and Peter Kuess[1]

[1]Department of Radiation Oncology, Medical University of Vienna, Vienna, Austria
[2]Department of Diagnostics and Interventions, Umeå University, Umeå, Sweden

Abstract **Background**: This study introduces a novel, fully automated one-click planning pipeline for radiation oncology, capable of operating independently of a traditional treatment planning system (TPS) without human intervention.
Methods: An integrated pipeline combining a dose prediction model and a model for generating treatment plans was developed. In this pipeline, we can produce a DICOM RT plan file directly from the segmented CT images of a prostate patient. The plans were analyzed with respect to speed and clinical acceptability based on the recalculated dose distributions.
Results: The pipeline efficiently produced 40 deliverable treatment plans with an average time of (38 ± 6) seconds. All plans met minimum PTV coverage requirements, but a few exceeded maximum dose limits for the bladder and rectum.
Conclusion: This innovative, fully automated pipeline demonstrates potential for rapid and efficient treatment planning in radiation oncology, independent of any TPS.

1 Introduction

Treatment planning in radiotherapy is inherently complex, with plan quality largely depending on the planner's skill, experience, and time investment. This complexity poses significant challenges in an era where demand for radiotherapy is soaring, and advancements in personalized radiotherapy, particularly in online treatment adaptation, are set back by traditional planning workflows.
Deep learning for treatment planning could be a game-changer, offering superior speed, accuracy, and consistency. Numerous models capable of dose prediction [1–3] or predicting the fluence [4] of Volumetric Modulated Arc Therapy (VMAT) plans have been developed. However, a common limitation of these models is their reliance on traditional treatment planning systems (TPS) to convert predicted doses or fluences into DICOM RT plans, that are executable by a LINAC.
Our group has made a significant stride in this area by developing a model that can predict the machine parameters for a VMAT plan directly [5]. Building on this, our current study introduces a pioneering pipeline that combines this model with an existing dose prediction model [3]. This integration culminates in the first fully automated pipeline capable of generating deliverable treatment plans independently of a TPS, achieving this at unprecedented speeds.
The implications of this development are profound. By circumventing traditional TPS constraints, our pipeline not only accelerates the treatment planning process but also brings us closer to the goal of personalized, adaptive radiotherapy. This advancement could potentially streamline workflows, democratize access to high quality radiotherapy, and pave the way for more dynamic treatment adaptation strategies in clinical settings.

2 Materials and Methods

2.1 Patient data

The objective was to develop a model capable of generating treatment plans that meet the latest clinical standards of our department. For this purpose, only treatment plans created using RayStation TPS were initially considered. However, to enrich the dataset, we also incorporated treatment plans developed with the previous TPS, Monaco (ELEKTA, Sweden), for data augmentation and external validation purposes. This study included patients diagnosed with localized prostate cancer, with or without seminal vesicle involvement, between January 2016 and September 2023. A comprehensive overview of the patient cohort and their respective contributions to the study is detailed in Table 1.
All patients underwent computed tomography (CT) imaging with a defined protocol of 2 mm slice thickness. The planning CT mandates a full bladder and a rectal balloon (if not contraindicated). Magnetic Resonance (MR) images were rigidly registered to the CT scans to allow a more precise delineation of the prostate, capsule penetration assessment, and seminal vesicle infiltration. The clinical target volumes (CTV) were determined based on the risk category: the prostate alone for low risk, and the prostate along with seminal vesicles for medium risk. These targets were delineated by a radiation oncologist with over 20 years of experience. Planning target volumes (PTV) were derived by adding a 7 mm margin to the CTV, reduced to 5 mm in cases where gold markers were used. For the purpose of protecting organs-at-risk (OAR) during primary localized prostate radiotherapy, structures such as the rectum, bladder, and both femoral heads were delineated. Before Febuary 2023, experienced radiotherapy technologists (RTT) or physicians performed the contouring of OARs manually. Starting from February 2023, all OAR delineations were conducted using ArtPlan (Therapanacea, France) [6].
Treatment planning was performed using RayStation (Ray-

Description	Number	Used for	Which models
Clinical RayStation plans (2022-2023)	91	Training	Dose prediction, Plan generation
Script-based RayStation plans (same)	61	Training	Plan prediction
Mimicked Monaco plans (2020-2021)	124	Training	Plan prediction
Prostate patients (random from 2016-2020)	40	External validation	Dose prediction + Plan generation

Table 1: Summary of Data Used for Model Training and Validation

Search, Stockholm, Sweden), with a prescribed dose of 60 Gy delivered in 20 fractions (3 Gy per fraction). Detailed clinical goals for planning are outlined in Table 2.

2.2 Models and Training

Architecture: The models were previously published [3, 5]. For this study the models were modified and enhanced. The dose prediction model was extended to produce dose distributions for prostate cancer cases and to incorporate a dose gradient loss to better reproduce gradients observed in the dose distribution (e.g., posterior to spare the rectum). Moreover it was modified to be compatible with the second model, the plan generation. The latter was modified to be compatible with RayStation treatment plans, which is used today for all treatment planning at our department. More detailed information on the models' architectures have been described earlier [3, 5].

Data Augmentation: In order to enhance our dataset, we implemented two distinct augmentation strategies: dose mimicking and script-based plan generation.

1) Dose Mimicking: This method expanded our pool of treatment plans by utilizing clinically approved dose distributions from Monaco plans. Specifically, we used the dose mimicking module in RayStation to generate new plans. This process involved replicating the dose distributions of existing Monaco plans in RayStation, thus producing a set of augmented treatment plans.

2) Script-Based Plan Generation: Using the scripting interface of RayStation, we developed an "offline" auto-planning pipeline within our clinic, which relies on a compiled library of prior plans. This knowledge-based method initializes the optimization process using parameters derived from anatomically similar patients. Through an iterative optimization cycle, the script aims to match the Dose-Volume Histogram (DVH) metrics with those of the anatomically similar cases. While the results of this innovative script-based model have not yet been published, the quality of the generated plans was satisfactory.

These strategies effectively almost tripled our collection of RayStation plans.

Training: The dose prediction model was trained on the 91 clinical RayStation treatment plans. The plan generation model was trained on the same clinical RayStation plans, 124 mimicked plans and an additional 61 script-based plans (see Table 1).

2.3 Fully-automated Pipeline

In our fully automatic pipeline (see Figure 1) for radiotherapy treatment planning, the process begins with preprocessing the DICOM CT image and structure files into matrices. Specifically, the CT images were stored as matrices containing the Hounsfield units in a configuration of 128x128x128 voxels. The DICOM structure data was processed to generate separate masks for the PTV, rectum, bladder, and left/right femoral heads, resulting in a composite shape of 5x128x128x128.

The **dose prediction and enhancement** phase was a critical part of the pipeline. Initially, a dose prediction model [3] was used to generate a preliminary dose distribution from the CT and OAR data in a 128x128x128 format. This dose output was then interpolated to a size of 320x128x128 to ensure compatibility with the subsequent model. The predicted dose undergoes enhancement to improve dose conformality and homogeneity within the targets, while concurrently reducing the doses to the OARs. This was achieved through the application of a series of filters designed to adjust the maximum dose in the PTV and lower the doses in sensitive areas such as the rectum and bladder.

In the **plan generation** phase, the enhanced, predicted dose, along with the CT and structure data, was fed into a second model. This plan generation model, as described in [5], was designed to predict the necessary machine parameters for VMAT plan execution. It generated leaf and jaw positions, as well as monitor units, for all 180 control points of the VMAT arc. Following this, a post-processing step was implemented where the predicted leaf and jaw positions, along with the monitor units, were checked for any potential machine violations, such as minimum leaf gaps and travel speeds between control points. Once validated, this data was stored into a DICOM plan template, which includes the meta-information from the patient's CT and structure DICOM files, ensuring compatibility.

The final stage involved dose calculation and plan review. For this, the generated plans were sent to the TPS, to provide dose calculation with a certified dose engine. The calculated doses were normalized to 57.5 Gy to 95% of the PTV to guarantee minimum coverage. To assist in the review process, the clinical goals were automatically checked, and confor-

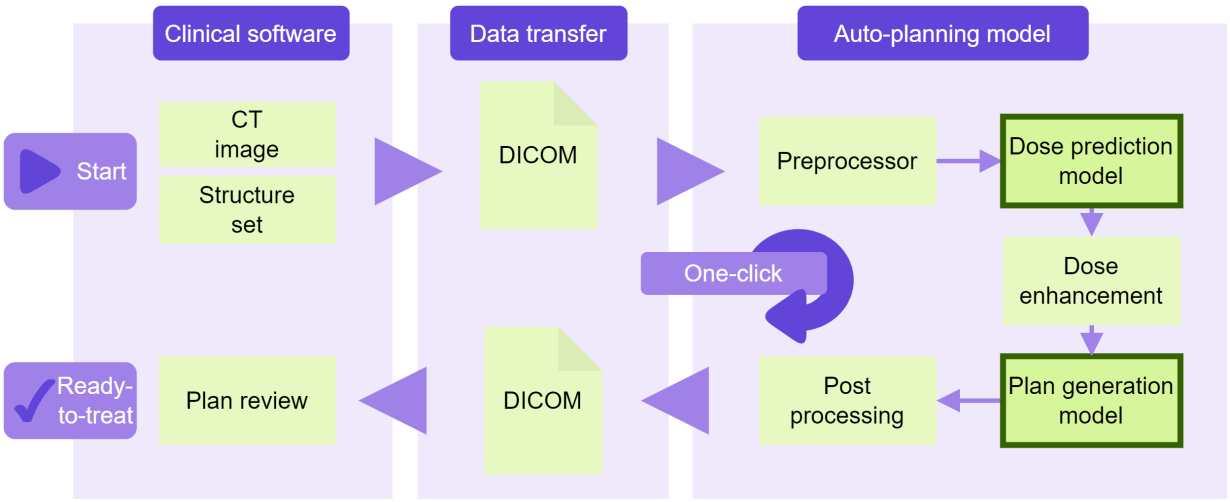

Figure 1: Flowchart of the fully-automatic treatment planning pipeline.

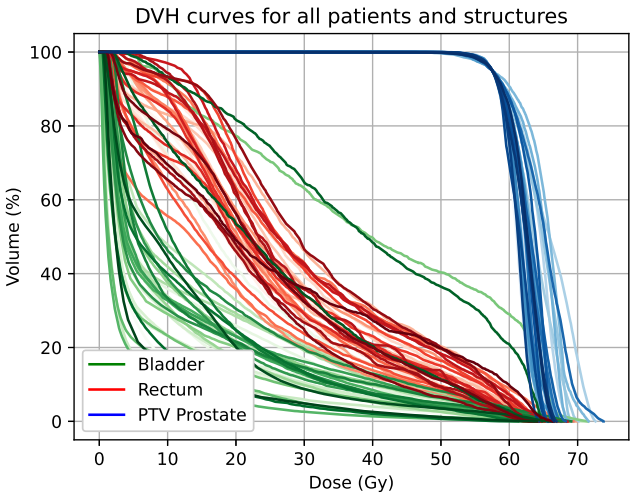

Figure 2: Dose-volume histograms for all external validation patients.

mance was indicated with positive check marks, facilitating a thorough and efficient evaluation of the plan's suitability. This pipeline was tested with an external validation set of 40 prostate patients (see Table 1).

3 Results

Figure 2 shows the DVH curves for all 40 external validation patients. The graph distinctly demonstrates the normalization of treatment plans to meet our minimum coverage criteria. Most treatment plans follow a steep dose falloff with the more than half of the plans dropping to 0% of the target volume below the permitted maximum dose of 66 Gy (21/40 treatment plans).

In the graph one can clearly see how the treatment plans were normalized with respect to satisfy the minimum coverage that we allow.

To evaluate the clinical acceptability, we report how the external validation patients performed with respect to the clinical goals (see Table 2). By design of our normalization each plan complies with the minimum required coverage of the PTV. The bladder maximum dose was exceeded in 7 out of 40 plans (17%), the low dose goals in the bladder were typically achieved. Similarly, no problems were registered in the low dose clinical goals for the rectum. Still, here the V_{20Gy} and the maximum dose were exceeded in 40% and 25% of all evaluated plans, respectively.

The average end-to-end time to produce a treatment plan from a segmented CT with no interaction necessary was 38 ± 6 seconds. The inference was done on the CPU of a regular workstation (AMD Ryzen 7 3700-X 8 Core 3.6 GHz).

ROI	Criteria	Goal	Achieved
Bladder	V_{54Gy}	20%	95%
	V_{48Gy}	40%	98%
	V_{44Gy}	50%	100%
	V_{30Gy}	80%	100%
	$D_{0.01\%}$	66Gy	83%
FemoralHead_L	V_{46Gy}	5%	100%
FemoralHead_R	V_{46Gy}	5%	100%
PTV Prostate	$D_{95\%}$	57%	100%
	$D_{0.01\%}$	66Gy	53%
Rectum	V_{48Gy}	40%	100%
	V_{40Gy}	45%	100%
	V_{30Gy}	60%	100%
	V_{20Gy}	54%	60%
	$D_{0.01\%}$	66Gy	75%

4 Discussion

The pipeline was successful in producing VMAT treatment plans from segmented CT images without the need for any manual interference. The pipeline produced a DICOM RT plan file that is ready to treat without the need for any further

interaction with a TPS. In this study, the TPS was utilized solely for dosimetric verification and review of the predicted plans. However, these functions could potentially be replaced by any secondary dose check and plan review software.
The demonstrated technique of augmenting the training dataset of the plan generation model (model 2) with script based replanning was successfully employed to more than double the amount of training data available. In contrast to standard augmentation techniques like flips, rotations and the addition of noise, this method produced a more diverse set of training data on the same segmented CT images. The key benefit of this technique is that it alters the dose distribution, requiring the optimizer to create a completely new MLC sequence, as opposed to minor modifications to an existing MLC sequence from the training set. We believe such techniques to be very valuable in training the plan generation model which proved to be particularly data demanding. Large improvements could be observed when increasing the dataset from only about 100 available clinical plans to almost 300 plans.
Our original plan generation model was trained on more than 500 clinical treatment plans, originally planned in Monaco TPS. As we pointed out in the study [5] the training dataset was very heterogeneous, with a melange of single fraction doses and primary and post-operative patients mixed together. It is promising, that even for roughly half the number of plans used for training we achieved a comparable level predicting RayStation-like treatment plans.
The dose prediction model (model 1) was trained only on clinically accepted cases. Dose prediction models were shown to work even for smaller sets of up to 100 training data. The augmented treatment plans which originated from the script based replanning were not used because we wanted to guarantee clinical acceptable dose predictions as the basis for the plan generation model (model 2).
The majority of treatment plans produced this way achieved the clinical goals that were used at our department. Some plans failed to comply with the high dose constraints for the rectum. However, these have been shown to be particularly demanding and most often pose the most difficult challenge in manual treatment planning too. Morevover, while the majority of the plans did not exceed the allowed maximum target dose, a notable amount of plans put some hot spots inside the PTV. These were typically within a few percent higher than the acceptable limits, but in a minority of cases significant hot spots were observed (see also Figure 2).
There are some limitations in this study. The treatment plan quality was not always on a clinically acceptable level. This will be addressed as more training data of prostate treatment plans planned in RayStation become available. The pipeline is currently only designed for local primary prostate patients. Dedicated models to produce plans for post-operative patients and for patients with lymph-node involvements are underway. Early tests to train a a generalized model that can cover all these cases at the same time was not successful.
In the current pipeline, more than 2/3 of time is spent on the preprocessing of the segmented CT images. Particularly, creating the mask matrices from the DICOM structure files is very time consuming. The actual dose and machine parameter prediction happened within a few seconds. We believe that this process can be sped up significantly to push the pipeline to produce a plan in under 20 seconds.
The development of this fully automated treatment planning pipeline represents a significant advancement in the field of radiation oncology, particularly in its potential to democratize access to high-quality radiotherapy, e.g., in low-income countries. By simplifying the planning process and reducing the dependency on specialized training and resources, this technology can potentially make advanced radiotherapy treatments more accessible and affordable.

5 Conclusion

Our team has developed what we believe to be the fastest fully automated treatment planning pipeline to date. This pipeline generates deliverable treatment plans independently of traditional TPS. In this study, we successfully integrated our two dose prediction and plan generation models, creating a seamless, fully automated workflow. This one-click solution requires no human interaction. While there were instances where the pipeline did not fully meet the clinical criteria for an acceptable treatment plan, this pioneering methodology showcases promising potential.

Enhancing Domain-Specific Knowledge of LLMs through Retrieval Augmented Multi-Process Prompting (RAMP)

Jace Grandinetti[1] and Rafe McBeth[1]

[1]Department of Radiation Oncology, University of Pennsylvania, Philadelphia, USA

Abstract Despite advancements in Large Language Models (LLMs), their application in specialized fields, such as medical physics, remains challenged by the need for domain-specific knowledge and avoidance of hallucinations. This study introduces a novel framework called RAMP that incorporates Retrieval Augmented Multi-process Prompting techniques to enhance the domain-specific accuracy of LLMs without the need for extensive retraining. By benchmarking on a medical physics multiple-choice exam, we found that our proposed model significantly outperforms standard LLMs and humans in performance, demonstrating improvements by as much as 68% and achieving a high score of 90% on the exam. This method reduces hallucinations and increases domain-specific performance, underscoring the potential for clinical use where accurate information is essential. This generalized technique is easily adaptable to different domains and is independent of LLM models, demonstrating its significant potential.

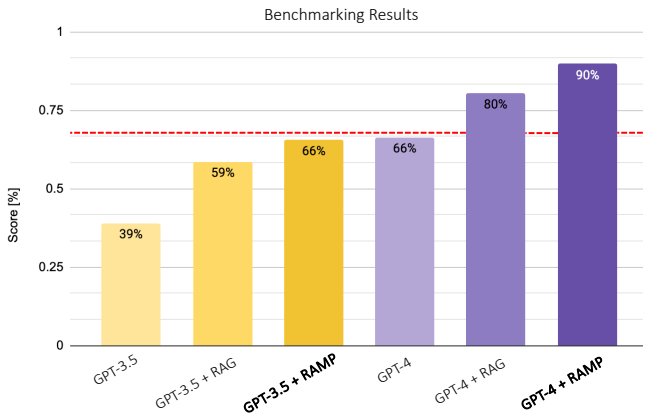

Figure 1: Bar graph illustrating the scores of different model configurations on a medical physics benchmark exam, highlighting the enhanced performance of our proposed RAMP model that achieved a score of up to 90%. The dashed red line represents the average score of 68% achieved by a cohort of medical physicists on a similar exam, serving as a comparative human benchmark [6].

1 Introduction

Natural Language Processing (NLP) models have been experiencing a rapid rise in adoption across many domains due to the Transformer-based Large Language Models (LLMs) [1]. Many leading commercial LLMs have been trained across a vast dataset of knowledge to serve as a "generalist" artificial intelligence (AI) language model, allowing for use in a broad range of specialties. With a generalist approach, these models have performed remarkably well on a range of topics, spanning from English literature to coding, to high-school STEM examinations in physics and biology. For instance, the leading state-of-the-art LLM model, GPT-4 (OpenAI, San Francisco, CA), scored $\sim 90^{th}$ percentile on the Bar Exam, $\sim 99^{th}$ percentile on the GRE Verbal, and a 75% on the Medical Knowledge Self-Assessment Program [2].
However, despite these great advancements, a disparity in knowledge for highly specialized domains (e.g., medical physics, radiation oncology) has been observed due to limited training datasets [3–5]. A study evaluating the performance of GPT-3.5 and GPT-4 on a medical physics exam found that the base models scored only 35% and 67% respectively [6], while GPT-4 similarly scored 68% on a surgical knowledge test [3]. Solutions to create or fine-tune existing models in these domains remain an open challenge. It's been demonstrated that fine-tuning and retraining methods can lead to undesired outputs, loss of prior knowledge, and overall degraded performance [7, 8]. Moreover, LLMs lack access to updated information due to a knowledge cutoff date, struggle with sourcing citations, and often experience hallucinations [9–11]. Falsified or misleading outputs of LLM models can also be especially dangerous in clinical use where medical professionals may use the outputs to guide their decisions, ultimately impacting patient care.

To address this disparity in specialized domain knowledge and to minimize hallucinations, Retrieval Augmented Generation (RAG) has rapidly emerged as a robust method for enhancing LLM models in domain-specific areas without the need for additional training [12]. RAG employs a retriever to locate documents and information corresponding to the user's inquiry, supplying this context to the transformer model during the inference process. This has been shown to significantly reduce hallucinations and provide the necessary contextual information to augment the model's knowledge base without the need for fine-tuning or retraining new models from scratch [13, 14].

Although RAG has demonstrated promising improvements, its current limitations, specifically in handling context length (i.e., number of tokens) and effectively accessing relevant information from retrieved contexts, have posed significant challenges. It has been observed that LLMs struggle with managing information when dealing with extended input contexts, which restricts their ability to handle large databases or extensive documents effectively [15]. In this study, we propose a novel framework that utilizes **R**etrieval **A**ugmented and **M**ulti-process **P**rompting (**RAMP**) techniques to improve the performance of LLM models in the domain of med-

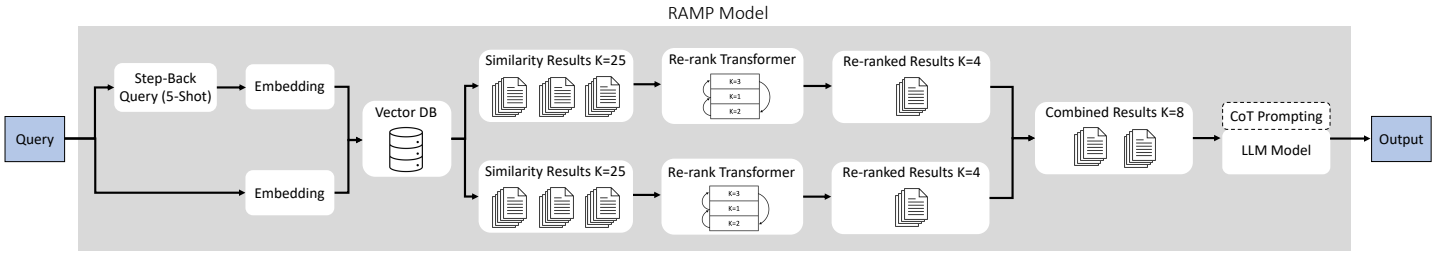

Figure 2: Figure illustrating the architecture of the proposed RAMP model which incorporates Step-Back Prompting, vector embeddings, similarity search in the vector database, a re-ranking transformer, and CoT prompting on an LLM Model for refined output generation. This workflow facilitates the accurate retrieval of pertinent documents, ensuring the model's performance is maximized across all domains in the benchmarking exam.

ical physics. We benchmarked our model using a multiple-choice medical physics exam to compare performance against standard LLM models and a reported average score of a human cohort of medical physicists who participated in a similar exam [6]. This technique is easily adaptable to different domains using various LLM models, highlighting the robust potential of this approach.

2 Methods

The proposed model uniquely integrates RAG and multi-process prompting to enhance performance, starting with Step-Back (SB) prompting to maximize the relevance of retrieved documents. These documents are then refined through a re-ranking transformer to prioritize the selection of those with the highest relevance to the input query for contextual understanding. Finally, Chain-of-Thought (CoT) prompting method is added to further improve reasoning during inferences. Detailed explanations of these individual methods are provided in Sections 2.1 - 2.4.

2.1 Retrieval Augmented Generation

We created a retrieval database by aggregating open-source reports (e.g., AAPM Task Groups and MPPGs), scholarly publications, and textbooks (e.g., IAEA Radiation Oncology Physics) pertinent to medical physics. Our objective was to develop a robust dataset that extensively covers a wide array of fundamental topics and their associated practices within medical physics, with a focus on areas like quality assurance, treatment planning, radiation safety, and medical imaging. A collection of around 50 documents was compiled and converted into text files by employing an open-source Python library [16], contributing to a vector database with a count size of about 10,000. Each document was chunked into vector sizes of ~ 500 and semantically embedded using OpenAI's embedding model. The embeddings were stored in a vector database (Pinecone, San Francisco, CA) where cosine similarity was used to retrieve vector embeddings with the highest similarity indexes.

2.2 Step-Back Prompting

Prompt engineering has proven to be a valuable technique for improving the outcomes of models by adding a layer of instructions that can help guide the LLMs as they make inferences. This has been notably demonstrated in Chain-of-Thought (CoT) prompting where multi-step reasoning is employed to solve intermediate steps from complex queries [17, 18]. A unique application of this CoT prompting is a method proposed by Google's DeepMind known as Step-Back (SB) prompting [19] which creates a secondary "step-back" query and attempts to break down and simplify a question that has multiple components. Expanding on this work, we found that we were able to apply this prompting technique to extract important keywords and rephrase queries in specialized domains, such as medical physics, to improve vector similarity searches. 5-shot prompting examples were also added to improve in-context learning to assist the model with expected outputs.

2.3 Re-Ranking Transformer

Due to the model token limits and degraded performance of LLM models with long contextual inputs, we aimed to minimize the number of retrieved documents. We achieved this by utilizing a re-ranking transformer endpoint (Cohere, Toronto, CA) specifically designed for contextually compressing search results [20]. With this approach, we were able to refine an initial set of 50 retrieved vectors to just 8 highly relevant results, significantly enhancing the speed and accuracy of our inferences. Our findings indicated diminishing returns in the value of providing more than 8 results, as pursuing additional results often led to missed information, notably when dealing with results sized into chunks of approximately 500 tokens. Furthermore, the re-ranking transformer had the added benefit of reducing token usage for API-dependent models like OpenAI's GPT, which can be cost-effective.

2.4 Proposed Model

While SB prompting enhances the retrieval of relevant information, we observed that its application in specialized

Table 1: Table detailing the percentage of correct responses of GPT-3.5 and GPT-4 across seven categories of the 2023 RAPHEX Therapy multiple-choice exam. The models enhanced with our proposed RAMP architecture outperformed the baseline in four out of seven sections, with notable advancements in Treatment Planning and Calculation-Based questions.

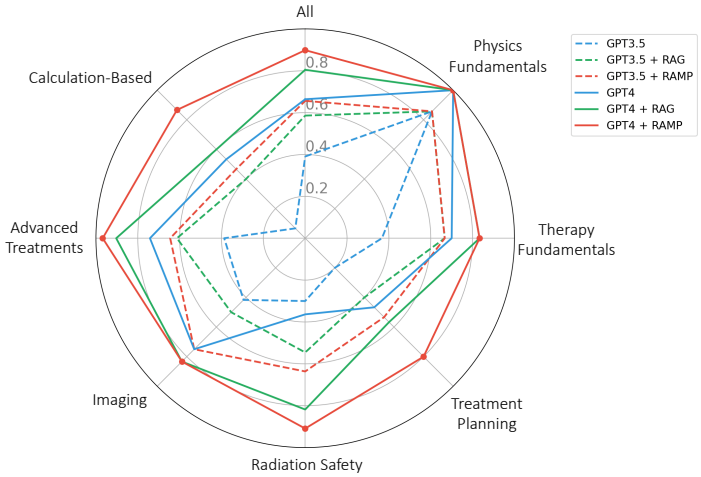

Figure 3: Radar chart depicting the benchmarking results of each model type (GPT-3.5 shown dashed, GPT-4 shown solid) by exam section. Performance percentages are charted where each vertex represents a section category and culminates to 100% at the periphery of the chart.

domains like ours occasionally led to the omission of crucial concepts and keywords necessary for accurate query responses. To mitigate this, we incorporated the original query into the vector database to yield similarity results. This integration of the outcomes from both the SB-prompted and original queries significantly improved the retrieval of pertinent documents. We employed a final CoT prompting technique at the last step to further enhance the model's performance by asking to think carefully step-by-step. It's important to note that we prompted the model to output its reasoning as it solved each problem to minimize guessing and to evaluate where the model may be making mistakes (i.e. retrieval step, incorrect calculation, hallucination, etc.). Fig. 2 illustrates the proposed model where the input query is split for embedding and SB prompting to create a second query. The top 25 similarity results are retrieved for each route which are then re-ranked through the end-point transformer before combining and then passing through the CoT prompted LLM mode. A unique advantage of this model is that it is not LLM model-dependent, so it can be easily implemented with different models.

2.5 Benchmarking Exam

To benchmark LLMs in a way that reduces subjective bias, multiple-choice questions are often used for evaluations. Since there are no existing benchmarking exams in medical physics, we compiled a set of 128 multiple-choice questions, each with 4-5 possible answers, from the RAPHEX 2023 Therapy exam. This was done to guarantee a fair and broad representation of the subject matter, recognizing that crafting a new exam from scratch could unintentionally introduce bias. We omitted questions that couldn't be answered without reference to tables or images, as our model cannot process visual information. A previous study reported that a group of medical physicists at Mayo Clinic Arizona achieved an average score of 68% on a set of RAPHEX questions, some of which were identical and others similar to those in our study. We present these findings to establish a baseline for expected human performance [6].

One drawback to benchmarking with multiple-choice questions is that the method does not inherently penalize correct guesses. Given the potential for using LLMs in clinical settings, it's imperative that the model demonstrates a reliable understanding of the correct answers and is not hallucinating or generating them by chance. To mitigate this issue, we subjected each question to the model five separate times. The model had to answer each question correctly in all five runs, otherwise no points were awarded. This strictly penalizes any incorrect answers and reduces the probability of scoring points through random guessing to less than 0.1%.

3 Results

A total of 6 model variations were benchmarked on the exam: GPT-3.5 and GPT-4, each with and without RAG to serve as a baseline comparison against our proposed RAMP model. The exam's questions were sorted into six categories, with calculation-based questions being doubly classified under their respective topic and the calculation category. The data from Table 1 and Figures 1 (summarized) and 3 (categorized) demonstrate that our proposed model ranked highest in all sections and outperformed the others in 4 out of 7 sections, with the largest improvement in treatment planning, radiation

safety, and calculation-based questions. Overall, improvements increased by approximately 68% using GPT-3.5 and 35% using GPT-4, with GPT-3.5 enhancements nearly matching the performance of the baseline GPT-4 model. Our proposed model also reliably cited the source of information for almost all correct answers, providing additional confidence in its accuracy.

4 Discussion

Significant gains were realized with GPT-3.5, likely due to its narrower training scope compared to GPT-4. Calculation improvements were also notable largely in part due to the CoT prompting and enhanced recall of relevant equations. Furthermore, we observed that a more advanced model like GPT-4 could retrieve pertinent information and process in-context learning with greater efficiency, even though GPT-3.5 showed larger improvements overall. This suggests that integrating RAG and multi-process prompting with more capable models has a synergistic impact, as the foundational knowledge is utilized effectively during the information retrieval and inference processes. Some limitations of this study include a non-comprehensive database due to restrictions on open-source content and information. We expect that we could achieve even better results by extending our dataset to encompass a broader range of knowledge. Moreover, data pre-processing steps to clean the dataset could potentially lead to enhanced precision and the improved sourcing of citations. Finally, this study benchmarked performance exclusively with a single commercial LLM (GPT). Future research would benefit from comparative analysis using models from other developers to provide a more comprehensive understanding of performance across different LLM platforms.

5 Conclusion

In conclusion, we have proposed RAMP: a novel Retrieval Augmented Multi-process Prompting technique that can be easily implemented and deployed on existing LLM models to improve performance in highly specialized domains. From a limited database of open-source materials, we were able to improve the benchmarking performance of the leading GPT-4 model from a score of 66% to 90% in the field of medical physics without the need for fine-tuning or building a new LLM model from scratch. This underscores the technique's robust potential for easy adaptation to various domains, while remaining independent of specific LLM models, demonstrating its applicability beyond medical physics.

An open source PyMedPhys harness for interfacing MOSAIQ® with Claude®

Stuart J Swerdloff, PhD[1] and Simon Biggs[2]

[1]ELEKTA Pty, Wanaka, New Zealand
[2]Anthropic PBC, Wagga-Wagga, Australia

Abstract We introduce tools added to the PyMedPhys project for connecting an anonymized Oncology Information System database, MOSAIQ® , to a Large Language Model, Claude2® for natural language querying. The approach to anonymizing utilizes a custom strategy file provided to the 'pynonymizer' package, and the interface to Claude2® leverages existing capabilities in PyMedPhys and adds a Streamlit based GUI and application logic for querying via Claude2 using Retrieval Augmented Generation of the schema and data dictionary and prompting.

1 Introduction

Large Language Models have achieved significant capabilities and notoriety in the last year. Maintaining the privacy of health information is paramount, and leakage of Private Health Information to a system not within the complete control of the responsible institution must be avoided.
Oncology Information Systems are repositories for both structured and unstructured data that represent many patients' diagnosis, staging, prescription, treatment, and outcomes. Many of the clinical professionals involved in Cancer Care are pressed for the time to provide all the aspects of patient care. Use of Large Language Models to assist in extracting relevant information, correlating data, and generating first draft reports is expected to be of value to the clinicians.
Claude2® is a Large Language Model based on 'Constitutional AI', with a focus on safety, developed by Anthropic.
MOSAIQ® is an Oncology Information System that is used globally at thousands of facilities, developed by ELEKTA.
The current effort aims to place the tools for exploring the possibilities of using LLM as an AI Assistant in Oncology in the hands of cancer clinicians and clinical researchers and leave as much control over the data and prompting in their hands.

2 Materials and Methods

The software and configuration files are available in PyMedPhys [1].
The preliminary step is to anonymise the database that will later be interrogated. Anonymisation is performed using `pynonymizer` (https://pypi.org/project/pynonymizer/ or https://github.com/rwnx/pynonymizer), driven by a strategy file specific to the MOSAIQ® database. The strategy file lists the columns in tables that contain Private Health Information and the strategy for replacing the values (typically using a Faker update). There are approximately 50 columns that contain identifying information.
The database management system is Microsoft SQL Server (2016 or later).
An extract of the strategy file (in YAML format):

```
tables:
  Patient:
    columns:
      Last_Name:
        type: fake_update
        fake_type: last_name
      First_Name:
        type: fake_update
        fake_type: first_name
```

Steps taken to perform the anonymisation of the database:
The starting point was a sample database typically used for engineering development and testing that doesn't contain PHI (all patient and staff identifiers are fictitious), referred to here as "EDB". The "EDB" was backed up to file and named `pynom_msq.bak`, and then restored as `pynom_msq` in to a Microsoft SQL Server instance.
Pynominizer was run, restricted to the `ANONYMIZE_DB` step (given that the editable copy of the database was already present in SQL Server).
The simplest version of this MOSAIQ AI agent has three key components:

- Chat agent for user interaction
- SQL query creation agent which returns queries based on a schema and the conversation history
- A standard database read tool which accepts the queries provided by the SQL query creation agent executes them in read only mode, and then sends the results to the chat agent in order to converse with the user

A version of the above that makes significant improvements upon this simple version is provided within the discussion.
Given the chat agent and SQL query execution components are relatively standard, we will focus on the SQL query generation method here.
In order to direct Claude in MOSAIQ SQL query generation we provide it with both the conversation transcript and the full MOSAIQ SQL schema. In order to provide the schema to Claude in a format that it would expect we asked Claude

how it would design such a schema format. The format we used was:

```
<?xml version="1.0" encoding="UTF-8"?>
<database>
  <table name="ExampleTable">
    <column name="AnID" type="integer" />
    <column name="AnotherColumn"
        type="varchar(50)" />
  </table>
</database>
```

We then used the following SQL query to extract the desired database schema directly from the database itself, and formatted it according to Claude's preference for inclusion within the prompt:

```
SELECT TABLE_NAME, COLUMN_NAME, DATA_TYPE
FROM INFORMATION_SCHEMA.COLUMNS
```

This schema was about 5% larger than the 200k context window for Claude, so a few tables were excluded from the schema for implementation purposes.
In order to direct the SQL agent to produce appropriate queries the following key components of the prompt were utilised:

- System prompt
- Database schema
- Conversation transcript
- Reminder of key requirements
- Forced initial completion

Although there was more to it, the key parts of the system prompt were the following (shortened for brevity):

> You are an MSSQL AI agent. You respond only with valid Microsoft SQL Queries encompassed within <query> tags. You always provide 10 unique and diverse queries.
>
> Some queries that you request may not return a result, and some tables within the schema may not be relevant to your needs. So make sure that each of your queries targets different tables within the database so that you get good coverage over possible solutions and are able to return something meaningful.
>
> ...
>
> All queries assume the following database schema: schema

After the schema has been provided, the conversation transcript is then also included. After all of this a reiteration of the task is given as so:

> You respond only with valid Microsoft SQL Queries encompassed within <query> tags. All queries assume that the database is designed according to the provided schema within the <database> tags that was provided within your system prompt. You are to provide exactly 10 unique and diverse queries. Make sure that each of your queries targets different tables within the database.

And finally we put "words in the assistant's mouth" by starting their response for them, ensuring adherence to our output schema that we subsequently parse to actually undergo the queries ourselves:

> Assistant: <query> SELECT DISTINCT

The assistant will then undergo its textual completion directly after the DISTINCT keyword in order to create its first query and then subsequent queries.
As an evaluation, for this agent, the following questions were asked and the result was then recorded:

- Please find the patient ID that has had the most radiotherapy treatments
- Please find the most common cancer diagnosis that patients have had
- What is the most common number of fractions used to treat patients? Do not give a range, instead, find exactly the most common fraction number.

The agent was only given one shot in each attempt and was not given the opportunity to refine or further verify its answer. For all testing we used the publicly available version of Claude, version 2.1 via the Anthropic Python PyPI package version 0.14.0. The Mosaiq DB utilised was a testing instance that corresponds to the same schema as that used by MOSAIQ version 3.1.3.

3 Results

See tables 1, 2, and 3 for a summary of the results provided by the agent for each of the provided questions. Of note, the only question for which the majority of the answers were the correct one was for the question "Please find the most common cancer diagnosis that patients have had". An example SQL query that the agent created to answer this question was:

```
SELECT TOP 10 tpg.Description AS CancerType,
    COUNT(m.MED_ID) AS NumDiagnosed
FROM Medical m JOIN Topog tpg ON tpg.TPG_ID =
    m.TPG_ID GROUP BY tpg.Description ORDER BY
    NumDiagnosed DESC
```

Case	Count

31587	2
10003	3
31215	1

Table 1: Results for "Please find the patient ID that has had the most radiotherapy treatments"

For the last question regarding fractionation, in some example responses, it becomes clear that in those particular cases Claude misunderstood the question:

> Based on the queries and analysis, the most common number of fractions used to treat patients is 1 fraction per day. This was determined by:
>
> - Calculating the average number of fractions per day across all patient treatments, which came out to be 1 fraction per day on average.
> - Analyzing the number of treatments (fractions delivered) grouped by number of fractions per day. This showed 1 fraction per day was the most common configuration, used for 54 different sequences of treatment fractions.

Another which was more successful both understood the question and was able to explain its processes:

> Based on the queries I tried, 10 fractions is the most common number used to treat patients in the database. This was determined by:
>
> - Grouping the Fractions field from the Site table and counting the number of patients for each fractions value.
> - Ordering the result by the number of patients in descending order.
> - Taking the top result which showed 10 as the most common number of fractions with 109 patients.

4 Discussion

As can be seen from the results, the agent as built above is inconsistent and while it can find answers to some classes of questions, others it fails dismally.
A second, more complicated version of the above, which aims to improve both speed and quality of the SQL query creation agent splits the SQL creation agent up into the following steps:

- Table selection agent, by first only providing the table name schema and asking it to select just a few tables to work within, the context usage is significantly reduced

Case	Count
Agent said it couldn't find a result	21
Malignant neoplasm of prostate	26

The "NULL" diagnosis (no diagnosis entered)	3
Prostate cancer	1
Bladder cancer	1
Malignant neoplasm	1
Answered wrong question	1

Table 2: Results for "Please find the most common cancer diagnosis that patients have had"

Case	Count
Agent said it couldn't find a result	20
0 fractions	1
1 fraction	4
10 fractions	3
14 fractions	1
23 fractions	1
152 fractions	1
Answered wrong question	1

Table 3: Results for "What is the most common number of fractions used to treat patients? Do not give a range, instead, find exactly the most common fraction number"

- Query creation agent that is only given the schema for the tables selected by the table selection agent

Then, due to the significantly reduced token context utilised we would be able to run this two step query creation agent about 10 times in parallel with a voter agent selecting the best and worst queries based on the results, and then feed back the previously successful queries into subsequent multiple reruns of the SQL query creation agent in a reflexion like approach [2]. The result of which being both a reduced total time to execute (due to not having the entire schema passed) and a hypothesised improvement on completion quality. This hypothesis could be further tested by repeating the above evaluations and iterating for an optimum configuration.

5 Conclusion

We present here an open source harness for interfacing MOSAIQ® with large language models. As well as providing a means to undergo anonymisation of the underlying database. We also provide an example approach for the evaluation of the quality of the underlying model and its interfacing agent. In this case although valid and relevant SQL queries were able to be produced, in its current implementation the agent set up was only able to answer some classes of questions, and in those cases it still wasn't able to do so reliably.
Nevertheless the open source approach, the significant room

for improvement in the agent infrastructure, as well as improvements in the underlying language model being predicted through the scaling laws [3, 4] shows potential for large language model interfaces to radiation oncology information systems.

Abstract This study introduces a novel teacher-student architecture utilizing Large Language Models (LLMs) to improve prostate cancer radiotherapy symptom extraction from clinical notes. Mixtral, the student model, initially extracts symptoms, followed by GPT-4, the teacher model, which refines prompts based on Mixtral's performance. This iterative process involved 294 single symptom clinical notes across 12 symptoms, with up to 16 rounds of refinement per epoch. Results showed significant improvements in extracting symptoms from both single and multi-symptom notes. For 59 single symptom notes, accuracy increased from 0.51 to 0.71, precision from 0.52 to 0.82, recall from 0.52 to 0.72, and F1 score from 0.49 to 0.73. In 375 multi-symptom notes, accuracy rose from 0.24 to 0.43, precision from 0.6 to 0.76, recall from 0.24 to 0.43, and F1 score from 0.20 to 0.44. These results demonstrate the effectiveness of advanced prompt engineering in LLMs for radiation oncology use.

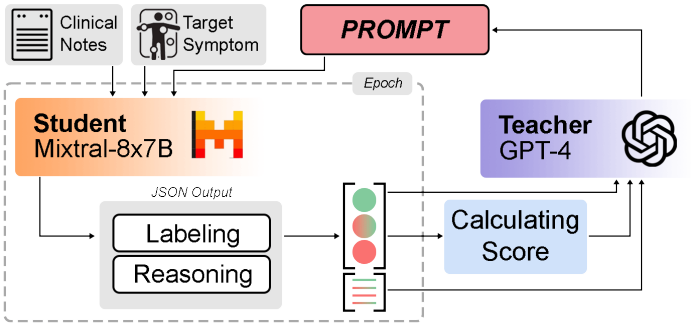

Figure 1: Schematic representation of our proposed method.

1 Introduction

The development of Large Language Models (LLMs) has marked a transformative era in the field of Artificial Intelligence (AI). These advanced models, built on the foundation of extensive data and sophisticated algorithms, have demonstrated remarkable capabilities in understanding and generating human-like text. In the medical domain, specialized versions of these models such as Med-PaLM 2 [1] and HuatuoGPT [2] have been tailored to understand and process medical terminology, patient data, and clinical notes. This focus on healthcare has enabled LLMs to assist in diagnostic processes, treatment recommendation, and patient care, thereby revolutionizing the intersection of AI and medicine [3]. The ability of these models to handle vast and complex datasets has been pivotal in uncovering insights and augmenting the decision-making process in healthcare [4]. However, the effectiveness of LLMs in specialized areas like cancer text analysis is often limited by the availability of relevant training data. Since these models learn and evolve based on the data they are exposed to [5], their performance in domains with scarce publicly available data, such as specific cancer-related texts, can be suboptimal [6, 7]. Further, a major challenge for LLMs in specialized domains is the lack of effective prompt engineering, which is essential for enhancing their performance. Prompt engineering is a process that involves iterative refinement of the input and output formats, as well as the incorporation of domain knowledge and terminology. This process can facilitate LLMs to supplement embedded information in specific domains, and thus increase their applicability and effectiveness in niche fields such as oncology [8]. Recent studies have demonstrated the efficacy of prompt engineering in improving domain-specific inference. Wang et al. [9] showed that combining prompt engineering with paraphrases of rare biomedical words can significantly enhance the performance of pre-trained models in the biomedical domain. Similarly, Alsentzer et al. [10] utilized a large language model for zero-shot interpretable phenotyping of postpartum hemorrhage from clinical notes, highlighting the model's strong performance in extracting granular concepts associated with the condition. These examples underscore the potential of prompt engineering to refine the capabilities of LLMs in specialized medical tasks, offering a promising avenue for the systematic abstraction of critical concepts in fields such as radiation oncology.

Traditional methodologies in prompt refinement have varied, with some relying on manual tuning by experts, while others explore automated techniques. However, these methods often require a balance between human input, computational resources, and specific task requirements [11]. This balance is especially crucial in medical text analysis, where precision and context-specific accuracy are paramount. Recent advancements have been observed in the domain of radi-

*Shared senior author.

ation oncology, particularly in the extraction of key concepts from clinical notes, including the identification of toxicity [12, 13]. Consequently, the development of prompt engineering methodologies for the extraction of key concepts in radiation oncology offers the potential to facilitate large-scale, systematic abstraction of critical concepts in this field.

We introduce a novel, automatic framework for prompt refinement, using a teacher-student dynamic between two LLMs: GPT-4 as the teacher and Mixtral as the student. This novel architecture is shown in Figure 1. This approach is especially pertinent in the clinical domain for key concept extraction, which is reliant on domain specific knowledge. We demonstrate the application of this architecture with prostate cancer radiotherapy toxicity symptom extraction from clinical notes.

2 Materials and Methods

The architecture employs a novel teacher-student framework designed to iteratively refine the prompts used by LLMs for prostate cancer radiotherapy toxicity symptom extraction from clinical notes. The student model, Mixtral, is tasked with the initial extraction of symptoms based on provided prompts. The teacher model, GPT-4, subsequently refines these prompts in a series of rounds and epochs based on the student's performance and reasoning.

The student model, Mixtral-8x7B, operates as the primary extractor of symptoms from the clinical notes. Given a prompt and a target symptom, it classifies the symptom as present, negated, or unknown within the notes. The model's output for each note includes the symptom classification and a reasoning for its decision.

The teacher model GPT-4, receives inputs from the student model's performance across all training notes for a given symptom. These inputs include:

- *Optimal Prompt:* The prompt that has led to the highest level of accuracy in the student's symptom classification.
- *Peak Performance:* The student model's best classification accuracy acquired on the optimal prompt.
- *Decision-making Reasoning:* Insights into the reasoning behind the student model's classification tied to the optimal prompt.
- *Failed Prompt History:* A list of prompts previously tested within the current epoch, which have yielded inferior results compared to the optimal prompt.

Using these inputs, GPT-4 generates refined prompts intended to improve the student's performance in symptom extraction. This refinement process occurs through a sequence of rounds and epochs.

Full optimization encompasses a series of epochs, each consisting of 16 rounds. In every epoch, the teacher model iteratively refines prompts to improve the student model's symptom extraction performance. At each epoch's start, the teacher is updated with the optimal prompt and peak performance metrics from the previous epoch where it has 16 opportunities (one per round) to refine the prompt and exceed the student's current best performance, measured by accuracy. If, in any of the 16 rounds, the teacher model enhances the student's performance beyond its prior peak, the epoch concludes, and the process advances to the next epoch where the teacher is granted a reset of 16 refinement opportunities. The refinement process terminates if the teacher model fails to improve the student's performance in all 16 rounds of an epoch, signaling the achievement of the student's maximum capability within the framework's parameters.

Algorithm 1 Iterative Prompt Refinement for Symptom Extraction on a target symptom

Require: Target symptom, Initial prompt, MaxEpochs, MaxRounds
Initialize Mixtral-8x7B (student model) with initial prompts
Initialize GPT-4 (teacher model)
Set best performance metric to 0
Set optimal prompt to initial prompt for the symptom
for epoch = 1 to MaxEpochs **do**
  for round = 1 to MaxRounds **do**
    Apply current optimal prompt to the student model across all clinical notes
    Gather labels and reasonings
    Calculate performance score
    if performance improves over best performance **then**
      Update best performance and optimal prompt
      Break and proceed to the next epoch
    end if
    Use the teacher model to refine the optimal prompt based on:
    - Current optimal prompt
    - Best performance metrics
    - Reasoning of the student model
    - History of failed prompts
  end for
  if no improvement in any of the 16 rounds **then**
    Terminate refinement for the symptom
  end if
end for

The data consisted of clinical notes from a cohort of prostate cancer patients treated with a radiotherapy (RT) dose of 78 Gy between 2013 and 2020. Clinical notes 6 months post-RT were extracted to focus on long term toxicities. 294 notes with presence of single symptoms were selected. Twelve common post-RT toxicity symptoms: Urgency, Cystitis, Urinary Obstruction, Dysuria, Erectile Dysfunction, Rectal Bleeding, Stricture, Nocturia, Proctitis, Hematuria, Urothelial Carcinoma, and Incontinence were selected. For the training set, we utilized 20 notes per symptom, except for Urothelial Carcinoma, where only 15 notes were available. Correspondingly, the test set comprised 5 notes for each

Average Score	0.51	**0.71**	0.52	**0.82**	0.51	**0.71**	0.49	**0.73**	0.24	**0.43**	0.60	**0.76**	0.24	**0.43**	0.20	**0.44**

Table 1: Symptom extraction test results: Initial (Init.) vs Post-refinement (Post)

symptom, with the exception of Urothelial Carcinoma, which had 4. These notes were labelled with symptom assignment of -1, 0, or 1, signifying its absence, unknown status, or presence, respectively. A separate cohort of 375 clinical notes with multiple symptom within each note were also labelled and used exclusively for validation. Multi-symptom notes ranged from 1 to 10 for the number of distinct symptom mention in each notes, with an average of 5 symptoms mentions per mutli-symptom note. This comprehensive dataset structure and labeling approach provided a robust foundation for evaluating the architecture performance, particularly in demonstrating its scalability and effectiveness in handling complex, multi-symptom clinical notes. Use of clinical notes, and the overall study was reviewed and approved by the institutional review board.

The evaluation methodology utilized accuracy as the primary metric for assessing the student model's performance during the prompt refinement process. To measure the effectiveness of these refined prompts compared to the initial ones, we employed accuracy along with weighted precision, recall, and F1 scores on the test set. These metrics provided a comprehensive view of the refined prompts' performance enhancements over the initial versions. You can find the algorithmic implementation of our method in Algorithm 1.

3 Results

Table 1, summarizes accuracy, precision, recall and F1 scores on both single symptom notes, and multi-symptom notes. Initial and post-refinement refinement results are presented for both categories, with initial performance metrics based on the the initial prompt, and post-refinement performance based on optimized prompt. Improvements across all evaluation metrics is observed. Highlighted entries show performance improvement from initial to post-refined extraction. For single symptom notes, a strong performance increase is observed across all metrics. The average improvement in accuracy from 0.51 to 0.71, precision from 0.52 to 0.82, recall from 0.52 to 0.72, and F1 from 0.49 to 0.73 is observed in single symptom notes. Noteworthy improvements include the symptom "Urgency," where accuracy soared from 0.80 to a perfect 1.00, and precision mirrored this perfect score. Similarly, "Stricture" and "Urothelial Carcinoma" witnessed accuracy enhancements from 0.40 and 0.00 to 1.00, respectively. Performance improvement across all metrics was observed for multi-symptom notes, with average improvement in accuracy from 0.24 to 0.43, precision from 0.6 to 0.76, recall from 0.24 to 0.43 and F1 from 0.20 to 0.44. The improvement was was not as strong as the single-symptom notes. Notable example of "Rectal Bleeding," showcased an increase in accuracy from 0.16 to 0.57 and an F1 score increase from 0.10 to 0.58.

Figure 2 depicts the progression of Mixtral's symptom extraction accuracy across different symptoms over successive epochs, as well as the average and standard deviation of symptom accuracy per epoch. A clear trend of improvement is observed in nearly all symptoms as the number of epochs increases, illustrating the efficacy of our prompt refinement process. Notably, symptoms such as "Urothelial Carcinoma" and "Proctitis" show a remarkable upward trajectory, indicating significant gains from the iterative approach. This demonstrates adaptive learning capabilities of this novel architecture.

4 Discussion

This novel student LLM-teacher LLM architecture demonstrates performance improvement in accuracy, precision, recall and F1 scores for prostate cancer RT symptoms. This novel architecture makes contribution in the following key areas:

- *Automatic Prompt Engineering* This automated method for refining prompts using a teacher-student combination of two LLMs, streamlines the traditionally manual process of prompt optimization.
- *Zero-Shot Learning* This framework enhances LLM performance without additional model training, showcasing the efficiency of our zero-shot learning approach.

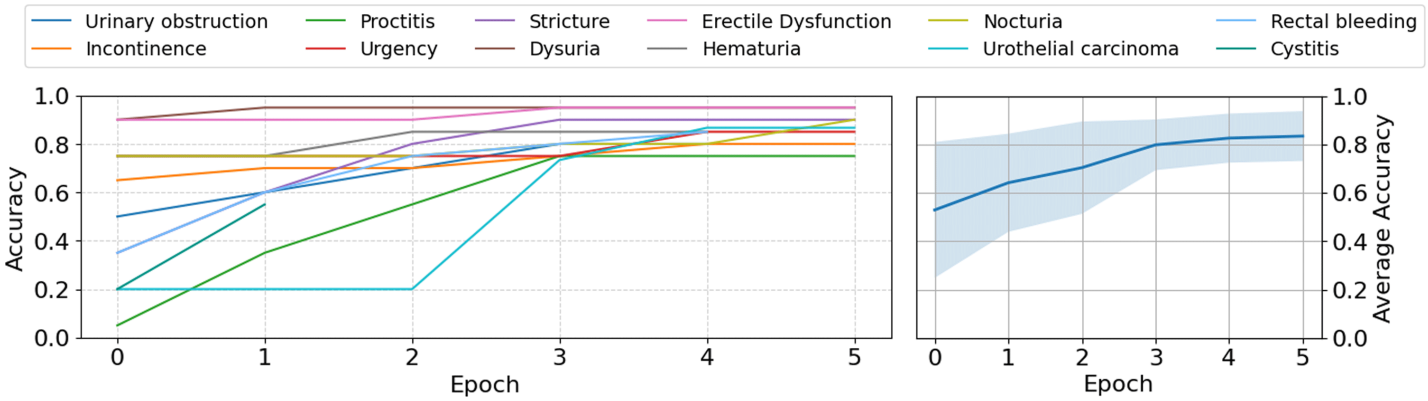

Figure 2: The evolution of Mixtral's symptom extraction accuracy per different symptoms at different epochs.

- *Local Model Improvement for Privacy* The improvement of the student model is conducted locally, ensuring sensitive clinical data, like Protected health information (PHI), is processed securely, addressing major data privacy concerns in healthcare.

The performance improvement across metrics of accuracy, precision, recall and F1 was observed for both single and multi-symptom notes. The prompt-optimization was performed on single symptom notes, and applied across test set of single symptom notes, and multi-symptom notes. This could potentially have contributed to inferior performance improvement in multi-symptom notes. Limited sample size of single symptom notes utilized for optimization may potentially have resulted in over fitting. Higher sample size for optimization, both single and multi-symptom could potentially further improve robustness, and the performance. Hyperparameter selection for both student and teacher models can also have a significant impact on the overall optimization process. Repetition studies were performed to tune hyperparameters of student model to ensure absolute consistency in response over three repetitions. As such, low `temperature` (0.2) and `top_p` (0.1) were utilized for the student model, and high `temperature` (2) and `top_p` (0.9) were used for the teacher model in this architecture. This may have limitations and further experimentation may lead to better results.

5 Conclusion

In conclusion, this novel architecture presents a pathway for self-optimized local LLM agents that can extract key concepts in medical notes with a zero shot learning approach. The complete local inference by the student model is suitable for protecting privacy of healthcare data. This system provides proof-of-concept in the research setting, and is promising for the potential of natural language processing methods to support clinical care.

A BFO-compliant Ontology for Radiation Therapy (RTO)

Mark H Phillips[1], Andre Dekker[2], and Jonathan Bona[3]

[1]Department of Radiation Oncology, University of Washington, Seattle, WA, USA
[2]Department of Radiation Oncology, University of Maastricht, MAASTRO, Maastricht, NL
[3]Department of Informatics, University of Arkansas, Little Rock, AR, USA

Abstract This work describes the development of an ontology for the medical domain of radiation therapy. This effort was undertaken to provide a solid foundation upon which other standards within the field can be developed and applied. Given the uncertainties in vocabularies and concepts, the decision was made to harness the W3C ontology tools which provides numerous advantages. These include interoperability between domains, a serialization that is widely acceptable and computable, and an implementation that allows the use of Descriptive Logic. The ontology follows the guidelines of the OBO Foundry and is based on the Basic Formal Ontology. It was written in the OWL language using the software package, Protege. Examples of the utility of this ontology in the clinical environment of radiation oncology are provided.

1 Introduction

The Open Biological and Biomedical Ontology Foundry (OBO Foundry) has emerged as the home of a large number of ontologies. To be included in this repository, the creators of an ontology must follow certain principles and best practices for creating and maintaining ontologies [1]. The framework established by the OBO Foundry serves a number of useful goals. Perhaps most importantly, it guarantees interoperability between ontologies. In addition, the use of a common format reduces the difficulties in using parts or all of an ontology. Finally, the use of unique IRI's and the commitment to avoiding identical labels of ontology entities insures that ambiguities are minimized.

The topics of the OBO Foundry ontologies span a very wide range, including three "base" ontologies: Basic Formal Ontology (BFO), Core Ontology for Biology and Biomedicine (COB), and Relation Ontology (RO). These greatly help in making sure that ontologies as separate as the Gene Ontology (GO) and Ontology for General Medical Science (OGMS) can use classes and relations from each other. Many of the ontologies are basic biology-oriented, while others serve as repositories of general domain knowledge.

In this work, we described the construction of an OBO-compliant ontology for the domain of radiation therapy (RTO). The motivation for this work is several-fold. First, several technologies are emerging that require, or at least benefit from, a comprehensive knowledge representation of this domain. These include initiatives such as mCODE [2] and IHE-RO [3]. Second, the field of radiation oncology suffers from a plethora of database schemas that include several different Oncology Information Systems (OIS), electronic health record systems (EHR), insurance companies, and national and international research organizations. In the absence of a standard representation of the field, these computer systems either cannot communicate or require extensive, and ever-evolving, software to map variables and concepts. Even that environment is fraught with potential errors since it is difficult to resolve ambiguities and/or redundancies. Finally, the rise of machine learning has highlighted the need for comprehensive structured data that is intelligible across medical and biological domains. For example, the potential to find associations between genetic patterns and oncology treatment outcomes requires a common knowledge representation. Even between medical subfields, such as medical, surgical and radiation oncology, unambiguous and explicit definitions are important.

It should be noted that the RTO takes as its domain "radiation therapy" which is not identical with the larger domain of "radiation oncology". The latter includes a much more comprehensive area of knowledge that is more biology-oriented than radiation therapy, which is more oriented towards the physics/engineering and clinical side of radiation oncology. If an ontology of radiation oncology and/or oncology in general is constructed, it is our expectation that the RTO will be easily integrated, thereby reducing the effort and possible duplication and confusion. Of course, it is not possible to cleanly separate radiation oncology from radiation therapy, and RTO does attempt to make bridges when it is necessary.

2 Methods and Materials

This project was implemented by the American Association of Physicists in Medicine (AAPM) as a task group charged with building an OBO-compliant ontology. (Simultaneously, the AAPM Big Data Subcommittee also began working on a non-compliant ontology in conjunction with the mCODE project; this ontology serves as a foundation for future work harnessing the Semantic Web [4].) Task group membership consisted of AAPM volunteers. In addition, an informatician (J Bona) with experience with OBO Foundry ontologies was recruited. Work on the project was carried out using a github repository and with biweekly meetings carried out over the internet. In addition, discussions with other OBO ontology groups were conducted to resolve issues.

The ontology construction was carried out using the standards promulgated by the OBO Foundry organization. The

ontology was also built using the standards and tools of the World Wide Web (W3C) consortium [5]. This was done to insure the maximum flexibility and applicability of the ontology, as well as being able to leverage the software and tools developed under these standards.
The Ontology Development Kit (ODK) was used to initialize the ontology repository. The software package Protege [6] was used to develop the ontology using the W3C language OWL: "OWL is a computational logic-based language such that knowledge expressed in OWL can be exploited by computer programs, e.g., to verify the consistency of that knowledge or to make implicit knowledge explicit." [7]
Our ontology was built upon the Basic Formal Ontology [8, 9] and the Relation Ontology [10]. These ontologies define the taxonomy of the ontology and the relations between individuals, respectively. They are extremely general, defining entities such as "process" and relations such has "has-part", and do not refer to any concepts specific to biomedical domains. In addition, the evolving standard Core Ontology for Biology and Biomedicine [11] was integrated when possible. This arose as it became clear that there were a number of classes that were so general to the domains of biomedicine, e.g. device, that it was useful to include them in a standard ontology which all interested users could import.
The Task Group relied on the tools built into Github to provide a controlled process for the discussion of issues, the addition to and modification of the ontology as it developed, and convenient means of coordinating between members of the task group as well as interested parties.
The knowledge representation of the domain of radiation therapy can be broken up into overlapping subdomains. This is due to the large degree of overlap between disparate fields such as nuclear physics, medical practice, oncology, computer engineering, and biomedical informatics. One of the main challenges in building this ontology is incorporating ontological bridges between these different domains. Given the OBO principles of re-use of terms within the collective ontologies, this led to the need of reviewing a large number of related ontologies, and when necessary, discussing and collaborating with these groups.
Although the subdomains were not completely orthogonal, we were able to sequentially focus on the following areas.

- basic and nuclear physics;
- production and measurement of ionizing radiation;
- radiation therapy workflow;
- clinical devices specific to radiation therapy.

Finally, an important component of the development of the ontology was the recognition that clinical practice evolves, new technologies are developed and terminology is difficult to control. Therefore, this ontology was built to contain as little of current vocabularies–rather, it tries to encapsulate the most basic concepts with well-defined terms and definitions. More specific classes can be built using the Descriptive Logic methods that are an integral part of the OWL standard. It is expected that users can apply this formal ontology to the their specific needs by using axioms to build specific complex classes from the elemental concepts in RTO.

3 Results

The Radiation Therapy Ontology (RTO) was built and published under the auspices of the OBO Foundry. This version of RTO is a backbone upon which further details and refinements can be made. The classes and properties that were implemented were done so with an eye to several practical applications–namely mirroring the variables used in the Operational Ontology of Radiation Oncology [4], and providing support for a multi-institutional research project on reducing errors in radiation oncology [12].
Following the dictum that classes defined in other ontologies should be used, rather than re-defined, classes were imported from a number of different ontologies, including Basic Formal Ontology, Relation Ontology, Core Ontology for Biology and Biomedicine, Information Artifact Ontology, Radiation Biology Ontology, Chemical Entities of Biological Interest, Ontology for Biomedical Investigations, and Ontology for General Medical Science. In addition, the NCI Thesaurus is sometimes linked to definitions.
The goal of avoiding overly specific classes and vocabulary was achieved to some degree by making use of the concept of defined classes. For example, the concept of Intensity modulated radiotherapy (IMRT) means different things to different stakeholders. As a simplified example, a user could define a class `IMRT` as a subclass of `techinque action specification` and then restrict it as follows:
`has Part min 1 inverse_planned_specification`
and `has Part min 1 multileaf_collimator`
and `has Part min 5 control_point`
where the objects of these three triples are classes already defined.
The other goal was to interface with other clinical/research systems in radiation oncology. For this, we relied on Ontop [13]. Ontop is a Virtual Knowledge Graph system. It exposes the content of arbitrary relational databases as knowledge graphs. These graphs are virtual, which means that data remains in the data sources instead of being moved to another database. Ontop translates SPARQL queries (opens new window) expressed over the knowledge graphs into SQL queries executed by the relational data sources and relies on R2RML mappings. Again, as with the defined classes, this approach allows a maximum of flexibility between established data sources and emerging standards. R2RML has a default mapping scheme or it can be individually tailored as needed.

4 Discussion

The development of a radiation therapy ontology has become necessary in order for the field to be able to leverage the ad-

vances made machine learning as well as biological advances in other biomedical fields. The AAPM has been at the forefront of this effort with a two-pronged approach. First, it has worked with other stakeholders, such as American Society of Clinical Oncology and IHE-RO and HL7 FHIR, to construct an ontology based on the commercial and clinical environment [4]. The second is to work to apply the advantages and power of the Semantic Web to data curation by the creation of a formal ontology, RTO.

One of the persistent problems in making the most of the data we are continually acquiring is the set of conflicting standards, particularly in vocabulary. For example, the term "modality" is a term of art that is commonly used but not clearly defined. DICOM-RT Second Generation uses the term in multiple places with varying definitions depending on the context. The term is also defined in the Operational Ontology for Oncology. The standard defines a value set, none of which matches the DICOM standard. This leads to significant difficulties when trying to query relational databases.

There are several different approaches one can take with this ontology. If one is using Ontop, then R2RML can be used to map the RTO class to the corresponding appropriate column variable in the database. Alternatively, one can add a class specific to the application and then use the equivalence axiom to map one to the other.

As discussed earlier, the use of standards promulgated by the W3 Consortium provides a wealth of possibilities for expanded and novel uses of an ontology in radiation oncology. These include the ability to tap into the expertise of related domains, the reduction in the effort needed to broadcast data from a given domain, and the ability to leverage algorithms based on knowledge graphs and descriptive logic [14–16].

The representation of data in this approach differs from traditional relational databases. The core concept is the "triple"– subject, predicate, object. For example, `J Smith has_role patient`.

Figure 1 represents the way in which the overall concepts of the ontology are modelled for RT. In the database, each of the classes shown in Figure 1 would be instantiated by individuals, represented by an Internationalized Resource Identifier (IRI) which is unique. That is, similar to DICOM UID's, a given `radiation therapy plan specification` for a given patient would have a unique IRI which provides an unambiguous link to the resource.

An important aspect of the approach we have taken to building an ontology is the ability to use inference. The use of a defined syntax and semantics (in this case, RDF/XML) allows one to build a "reasoner" which is software that applies Desciption Logic to infer new facts from the stated ones using the axioms of the ontology. Simple examples include inferences such as "If A is a spouse of B, then B is a spouse of A", "If C is the child of D, D is the parent of C", and "If Patient X is treated on Y therapy device, and Y is a gamma-emitting device, then X is treated using gamma rays." In the latter example, the reasoner builds the latter triple using only

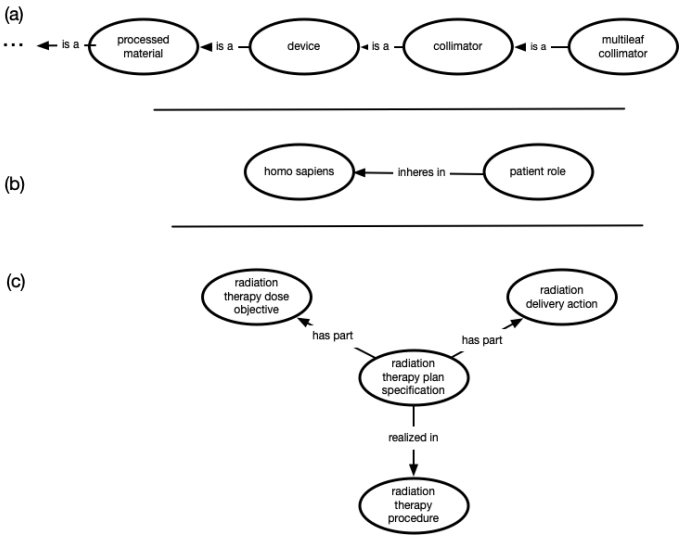

Figure 1: Elements of the ontology expressed as triples. For reasons of space, elements are rendered separately. (a) taxonomy representing a part of a linac; (b) representation of humans as patients; (c) elements that go into defining the use of radiation therapy as a treatment.

the first two without explicit construction.

As discussed earlier, this ability to use inference allows a specific application to define a useful class even though the available data does not explicitly contain that structured data. In this way, the formal RTO ontology can be used to provide building blocks for a wide range of applications and, with relatively minor additions, be tailored for the specific purposes.

The implementation of data using OWL has other advantages as well. For one, the ability of the reasoner to use inference makes it easy to do complex searches that would require difficult SQL joins. For example, searching a database for patients that met a complex set of eligibility criteria for a clinical trial can be simpler, depending on the criteria and size of the database. If one is going to store the data in the triple store approach, it can also be much easier to modify the schema as knowledge evolves and progresses relative to the corresponding effort with relational databases.

Finally, by designing RTO as an OBO-compliant ontology, progress in knowledge in related fields, such as genetics, can more easily be integrated into research and clinical practice of radiation oncology. In this way, the Semantic Web can provide computational tools to explore and understand how to better use radiation to treat cancer.

5 Conclusion

The motivation, methods and advantages of building a formal ontology following OBO Foundry priniciples for the radiation therapy domain has been described. This work was not meant to reduce the effectiveness of other approaches. Rather, it has been carried out in anticipation of its utility in the future development of computational methods utilizing a

wide range of biological and biomedical data. Using OWL and Protege is a reflection that sometimes the model is as important or more important than the data whereas the relational database is useful when data are more important than the model.

Abstract Beyond clinical trials with a limited number of participants, Real-World Data (RWD) has the potential to improve inclusion in healthcare research. In deploying AI like Natural Language Processing (NLP) for healthcare, careful data and process curation is as important as the algorithms themselves. This ensures patient-focused outcomes, effective modeling, ethical use, and real-world clinical relevance. Therefore, stakeholder involvement through methods like Patient and Public Involvement and Engagement (PPIE) is crucial.
This work explores the process and findings from implementing PPIE for using NLP in cancer related free text electronic health records. The identifiable nature of this data presents unique challenges compared to working with easily anonymizable data. The PPIE event was an in-person focus group discussion with cancer survivors and caregivers. Key questions and feedback focused on data use, acceptable consent processes, research communication, and participation. Regarding consent, two-thirds of the contributors preferred a national opt-out approach, while one-third preferred project-specific consent.

1 Introduction

Real World Data (RWD) refers to all medical data collected during routine patient care rather than during clinical trials. Modern cancer care aims to be driven by evidence-based clinical decisions on treatment strategies. This evidence is often generated using clinical trials. It is well known, however, that many patient populations are under-represented in these trials, therefore, trial findings are not always generalizable. RWD can be leveraged to generate evidence in the real-world settings [1]. Unlike traditional clinical trials with narrow selection criteria, Real-World Data allows us to learn from a wider range of patients.
With the advent and adoption of Electronic Health Records, the availability of real-world data from healthcare systems has exponentially increased. In clinical oncology practice, the details of patients' cancer care including diagnosis and treatment, pathology and radiology reports, ambulatory care, medical and family history are often found in free text narrative and scanned documents [2]. It is estimated that up to 80% of electronic medical records are free text written medical notes, meaning that only 20% of RWD is structured (e.g. in tables, coded data). Structured data are algorithm-friendly, easier to anonymize, and process. The conversion of unstructured data contained within free text into a structured format can increase the scope of useful data, reduce missingness and sparseness, thereby enhancing learning from all patients. In this context, Artificial Intelligence techniques such as Natural Language Processing (NLP) are likely to play an important role.

NLP is the subfield of Artificial Intelligence that focuses on sequences like text and speech data. Intuitively, NLP gives computers the ability to understand text and spoken words in a way similar to humans by combining computational linguistics and rule-based modeling of human language with statistical, machine learning and deep learning models[3]. Working with free text written medical notes is an application of real-world data. In this work, we investigated the patient's perspective about the application of NLP to oncology medical notes. Unstructured data within free text presents unique challenges compared to structured data as even anonymization methods do not fully guarantee complete de-identification of personal identifiable information. Details from free text data can still include residual identifiers that can be cross-referenced with external sources. This means we need to work in more secure ways, and we need to check that the way we are working is acceptable and adequately communicated to patients and the public. These important questions can't be answered without engagement with the community the data is about, hence the need for PPIE.

The key aspect is to understand patients' views on the use of free text data for this type of research, their perspective on the data storage and processing methods proposed, how patients can consent to participate in research involving NLP processing of their (potentially identifiable) written medical notes, the type of information to be communicated about the project and the suitable method of delivery of this communication. To explore these aspects, we performed a Patient and Public Involvement and Engagement (PPIE) event.

Patient and Public Involvement and Engagement is the inclusion of End users such as patients, carers or any member of the community who typically will not be included in a health research design process, but their perspective is crucial because they are stakeholders in the research outcomes. PPIE is about working with ordinary people to shape and produce better research and how results are shared [4]. Public involvement in research as research being carried out 'with' or 'by' members of the public rather than 'to', 'about' or

'for' them. It is an active partnership between patients, carers and members of the public with researchers that influences and shapes research[5]. PPIE usually involves the public or specific patient groups[6] as in our case where we focus on patients living with Cancer.

2 Methods

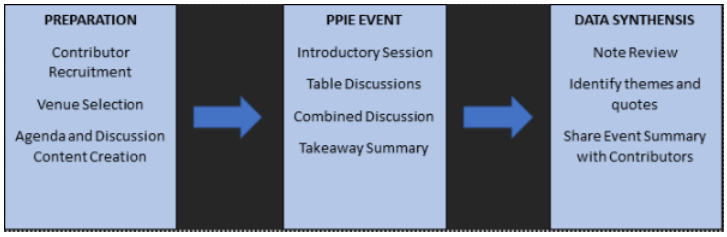

Figure 1: Process flow for a Patient and Public Involvement and Engagement for NLP on medical notes

Here we present an approach to deliver a PPIE event discussing NLP on medical notes mainly focused on three broad headings: 1) Preparation towards the Event, 2) the PPIE Event and 3) Data Synthesis of information gathered from the event. Figure 1 shows the process flow for the PPIE event.

Preparation

In preparation for the PPIE event, we leveraged community support by engaging a local cancer focus network. This community is focused on delivering services and innovative projects that bring patients, researchers, scientists and communities together to enhance health research. The Recruitment of contributors was done by collaborating with the PPIE specialist in the community. The selected Venue was central and accessible. The team then worked with the PPIE specialist to design the event, curate discussion questions and decide on method of event delivery. Table 1 shows the curated key questions

PPIE Event

The PPIE for NLP on medical notes was a 2-hour in-person focus group with 13 participants, nine contributors (Cancer survivors and Carers) and four facilitators (Researchers). Two discussion tables, each with 4-5 Contributors and 2 facilitators, were set up. The key questions were discussed at each table before a combined group discussion to consolidate the individual table discussions. To set context and prepare contributors for table discussions, a team member gave an introductory presentation discussing clinical trial limitations in cancer treatment (underrepresentation, cost, implementation), real-world data advantages (inclusivity, affordability) in addressing these limitations, the roles of structured real-world data, past PPIE findings, the risk of working with written medical notes and key event questions. Printed copies of the presentation were provided per table for reference.

The discussion questions focused on key concepts like data use, research participation, and communication about applying and implementing artificial intelligence techniques such as NLP to cancer medical notes. Contributors documented their insights on post-its stuck on to a large sheet, while dedicated facilitators took notes. The question about how people consent to this type of Research Participation was based on voting. In the UK, National opt-out is patients' choice to block their health data from being used in non-essential research while Study specific opt-out is choice to opt out of specific research project only [7]. The Contributors (9 people) voted YES or NO to National data opt-out versus Study specific opt-out

Concept	Key Questions	Discussion Points/Action
Data Use What is important to consider for our research project?	Contributors' initial views on the use of written medical notes in cancer research	What is important to patients and carers when working with potentially identifiable written medical note data?
Research Participation Is a study-specific opt-out also needed? Vote: Is the national data opt-out or study-specific opt-out most appropriate for our research project?	Contributors' perspective on National data Opt-Out vs. Project Specific Opt-Out for work with potentially identifiable written medical data	Is the national data opt-out appropriate for our research project?
Research Communication How should information be shared?	Contributors' opinions on information that needs to be disseminated about this work	What type of information is important to communicate about our research project?

Table 1: Key questions asked during the PPIE event on NLP for written cancer medical notes

Data Synthesis

After the event, facilitators used thematic analysis on the focus group notes to identify common themes and representative quotes." We then compiled a report summarizing the insights from the PPIE event, which was shared with the contributors via email.

3 Results

During the focus group discussion, contributors' questions and feedback about applying NLP to medical data were documented. Based on our findings, we have synthesized the key questions about the concepts with exemplar quotes from participant notes related to each concept.

Table 2 presents key data use concerns from participants, like patient inclusion, data accuracy/completeness, and anonymization with supporting quotes from contributors. Table 3 displays contributor feedback and comments on how consent for this type of research should be obtained. It in-

Data Use Themes	Exemplar quotes
Inclusion	How are you going to ensure inclusion of people from different ethnic backgrounds? Sometimes minority patients are excluded from medical research. "How are you going to ensure inclusivity, sometimes patients don't get a choice"
Data Accuracy	How accurate is the data? Some contributors inferred that data accuracy is more important than privacy. Lack of confidence about what is written, inferred, and recorded in medical notes, i.e., is the text data correct? Concerns over bias in source data, e.g., when written medical notes don't give the full picture. "Quality of data entered" "My GP has very detailed notes on me electronically. I am not concerned at all" "The data is as good as the recorder"
Data Completeness	How is data about patients treated at multiple centres included – would all the related and historical medical records be included in this work? Why is the focus of the study on only cancer data and not others like mental health? Will handwritten data be used in the study? "Risk of incorrectly transcribing (Handwritten) Data 'GARBAGE IN GARBAGE OUT!'" "Previous cancer history is important would be missed? = partial results/accuracy"
Data Usage	Could the structured data be used to go back to the patient to check accuracy of the data? "If something historical is discovered that may affect patient prognosis, do you get in touch to address it? – I would hope so!"
Masking/Anonymization	What is the balance between anonymization and missing important details in the dataset "What if important information is masked"

Table 2: Questions and exemplar quotes about data use from the contributors during the PPIE event on NLP for written cancer medical notes

Research Participation Themes	Exemplar quotes
Voting Result	National Opt-Out: 6/9 Project Specific Opt-Out: 3/9 One contributor mentioned that hospitals often do audits, and there is no extra need to ask for opt-out in those contexts

Table 3: Contributors' opinion on research participation consent during the PPIE event on NLP for written cancer medical notes

cludes the results of voting on if a National Opt-Out is sufficient or a Project Specific Opt-Out should be implemented and Table 4 shows specific questions and verbatim quotes related to communication about this research. Contributors asked questions about various

4 Discussion

In discussions about the application of NLP, it is far more common to find research related to the algorithms, performance and related technical concepts compared to those related to the real-world users such as those with experience with cancer and radiotherapy as in our work. Beyond the algorithms, hype and techniques, Artificial Intelligence models such as those used in Natural Language Processing are as good as the data used in training. Human experience transcends collected data and to design practical and useful solutions for people, it is valuable to involve them in the

Research Communication Themes	Exemplar quotes
Consent	Does this study include international patients? Will opting out of the research affect a person's treatment progress and standard of care? "Just say "research to improve future patient care" nothing more complex"
Inclusion	Is there provision for non-English speakers? Digital-based solution excludes some patients Why is the study covering only a few years as treatments can change – will data be out of date? Why is this study only at the Christie? "How will the research ensure inclusivity of people with protected characteristics" "2020 - 2014 Old DATA not Current"
Data privacy and security	What is the provision against data leaks in this project? What is the procedure to mitigate data exposure? Commercial use concerns "Is missed personal data screening a big risk because it's partial and less specific / individual i.e., don't worry"
Research info dissemination	Leaflets Support groups QR Codes Online Website On Screen on TVs Multilingual "Communication - Information on what the research is about What is being collected How it is going to be used What will the outcome be or goal Who will be involved. Cohort of patients? What to do if you want to be involved? / How not to be involved? Who to ask if you have questions"

Table 4: Questions and exemplar quotes about research communication from contributors during the PPIE event on NLP for written cancer medical notes

process and this is one of the cases for PPIE in healthcare research.

There is literature documenting both in person and online PPIE Events for different health research such as Vitamin B12 deficiency[1], availability of public database of statutory notification of adverse events from residential care facilities (RCFs)[6], optimal Vitamin D Status [8] and lived experiences of people with long COVID [9].To the best of authors knowledge, there is no literature documenting the PPIE process and findings for NLP in cancer medical notes. Some of the key insights about the research questions from the stakeholder perspective PPIE for NLP on real world cancer medical notes. The findings on the 3 key concepts discussed, their implications and project design adjustment made based on this event are;

Data use: Contributors prioritized balancing information availability with data privacy, not opting for absolute privacy as would have been assumed. Many contributors indicated they were also comfortable with less masking and anonymization of identifiable information if it is authorized researchers working with their data. The initial data use timeline (how old the medical notes must be before use) proposed was at least 2-year-old such that mostly non active patients were included, the contributors did not agree with this, the majority considered it a type of exclusion from beneficial research, the team is adjusting for a more inclusive data use timeline.

Research Participation: Following an introductory session, participants voted on the preferred consent model. Two thirds of the contributors favored National Opt-Out (pre-existing database of non-research objectors), while one third preferred Project-Specific Opt-Out meaning consent should be sought for the specific research. The team aligned with the majority vote on this.

Research Communication: Before proceeding to the Research Ethics Committee, to effectively communicate our work to patients and ensure appropriate and relevant information is accessible. We are going to include some of the contributors in our project information (posters, digital copies) review process. We have planned a subsequent video meeting showing what we have so far and clarifying if it is well communicated.

One limitation of this work is the number of contributors: only nine (9) from the same local area participated in the PPIE event. This suggests an opportunity for future work with a larger and more diverse group. Additionally, while the contributors were active, the short focus group format may not have captured all participant perspectives comprehensively.

5 Conclusion

In this work, we shared our process and findings from a Patient and Public Involvement and Engagement Event on applying Natural Language Processing to real-world cancer medical notes. Data Privacy remains important, but contributors prioritized balancing information availability with protecting privacy. Regarding the preferred consent model, two thirds (66.6%) favored National Opt-Out compared to one third (33.3%) for Study Specific Opt-Out. Contributors also emphasized the importance of clarity and inclusion in the research communication method. These insights have enriched our perspective and strengthened the research design as the project on applying NLP to cancer medical notes proceeds with ethical approval.

An AI-Driven Radiation Therapy Workflow Management Platform

Doori Rose[1], Grace Chow[1], Laura I. Cervino[1], Joseph O. Deasy[1], Sharif F. Elguindi[1], Gregory Niyazov[1], Jean M. Moran[1], Darian Pazgan-Lorenzo[1], Ellen Pinto[1], Lakshmi Santanam[1], Niral M. Shah[1], Pengpeng Zhang[1], Anyi Li[1]

[1]Department of Medical Physics, Memorial Sloan Kettering Cancer Center, New York, USA

Abstract Our team has engineered PlanQ, an innovative AI-powered radiotherapy workflow management platform, designed to streamline clinical decision-making and enhance operational efficiency within high-volume radiation therapy settings. PlanQ, with its flexible and modular design, integrates data across diverse systems and formats, offering real-time multimodal data curation, while incorporating practitioner insights as definitive inputs. By leveraging a sophisticated language model and natural language processing, PlanQ adeptly interlinks disparate clinical incidents, facilitates the examination of historical patient treatment information, and gauges re-irradiation hazards. Additionally, the platform centralizes the visualization and oversight of clinical workflows, and an AI-driven Operational Research model adeptly prioritizes planning schedules for a large team based on complexity and urgency. Empirical results indicate PlanQ's efficacy in diminishing coordination workload by 70%, reducing planning tasks by 10%, and saving an hour daily in plan verification efforts. The platform's language model demonstrates a remarkable 95% precision in synthesizing isolated clinical occurrences, ensuring immediate workflow transparency.

1. Introduction

A significant obstacle in radiotherapy emerges from the dispersion of patient data across disparate locations, providers, and systems. This issue is particularly pronounced within larger healthcare institutions, where crafting a digital patient profile often entails manual integration of data from numerous sources, leading to a process that's both time-intensive and susceptible to errors(Lustberg, et al. 2017).

Data on patients is frequently segmented across multiple systems. Simply amassing this data in one spot doesn't inherently synthesize a cohesive digital profile. The true utility of the data manifests when it's synthesized, reflecting the dynamic nature of a patient's health status that continuously evolves throughout their treatment. Adapting patient information in real-time to reflect these changes, and converting the data into a universally accepted format applicable for various radiotherapy scenarios(Field, et al. 2021), presents another layer of complexity.

Effective radiotherapy treatment relies on a well-orchestrated care team, where fluid communication, coordination, and immediate access to an updated digital patient profile are crucial for successful outcomes and error prevention. Real-time updates to the patient's status within their digital profile are vital for the care team to promptly adjust treatment plans. Yet, with frequent reliance on email for communication, tracking patient updates becomes challenging, particularly in high-volume settings, leading to communication overload and potential risks in patient care.

Our project introduces an AI-enabled system(Vandewinckele, et al. 2020) designed to streamline the management of radiotherapy workflows. This system forges connections between diverse clinical events and crafts a continuous digital narrative for each patient, enhancing clinical decision-making. Deployed in high-volume radiation therapy centers, the platform aims to improve workload efficiency and adapt to a broad spectrum of clinical scenarios.

2 Materials and Methods

The cornerstone of PlanQ platform is the harmonization, integration, and capturing of federated patient data to construct comprehensive digital profiles. We have developed a versatile connector layer capable of interfacing with a multitude of established vendor systems. By leveraging advanced distributed big data technologies, our system can interface with over 13 hospital-wide systems and seamlessly integrate common RT vendor systems such as MIM, Aria, and Mosaiq. Our integration process creates a robust foundation for each patient's digital profile by combining data from various modalities, including pathology and radiology reports and diagnostic and simulation DICOM images. PlanQ processes this data through a multi-stage ingestion approach, incorporating both nightly batch updates and real-time event-driven updates, ensuring that all care team members have access to the most current and comprehensive patient profiles from any location and device.

The pivotal step lies in curating the data to map out the interconnected patient journey, which is essential for clinical decision support. Our sophisticated curation engine employs patient matching, data normalization, cutting-edge medical language models, and knowledge graphs to analyze and vectorize multimodal patient data. This process includes extracting structured reports from unstructured simulation orders and prescriptions, using the widely embraced Fast Healthcare Interoperability Resources (FHIR) standards to store and standardize longitudinal patient information.

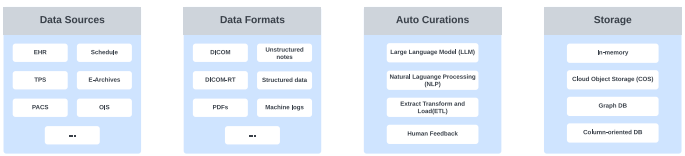

Figure 1. Highlights of PlanQ features: Its heterogeneous architecture adapts to various vendor systems and multimodality environments. The auto curation algorithms and infrastructures enable the near-real-time ingestion and curations from enterprise-wide data sources

PlanQ introduced an assistant feature that relies on expert human guidance to fine-tune the algorithm's curation process, ensuring the identification and inclusion of all relevant

patient data elements, such as historical RT treatment records, to create a high-quality digital profile. The patient events are organized into a 'subway map' visualization, providing a clear and continuous update on each treatment phase, giving the management team a comprehensive overview of clinic performance. This centralized system for documents, records, and team communication streamlines interactions and clarifies the treatment planning process.

PlaQ is built as a scalable and modular entity that accommodates data from an array of vendor systems and environments. Data curation occurs in real time, adhering to FAIR data principles, with human feedback anchoring the veracity of the curation process. Using an expansive language model and natural language processing, it connects disparate clinical events, sifts through and interprets past treatment data, and assesses the risk of re-irradiation. The platform consolidates the visualization and oversight of the clinical workflow, offering a singular, integrated viewpoint. Furthermore, we have integrated an AI-enhanced Operational Research model to refine the scheduling process, adjusting for the varying complexities and priorities within a team of 70 planners.

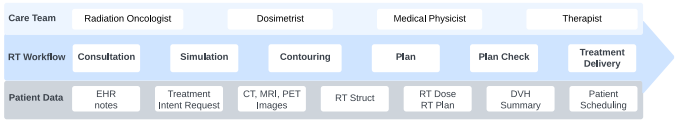

Figure 2. Disconnected patient data and communications between multiple clinical teams make RT workflow challenging. PlanQ integrates and curates data in real-time and makes the data accessible through cloud computing, improving the coordination between care teams and supporting clinical decisions

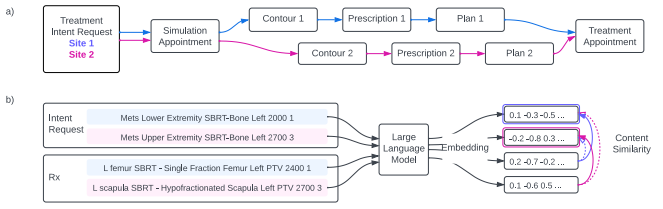

Figure 3. a) The intelligent curation module uses AI to connect the unstructured, non-standard clinical notes at the site level when multiple sites are treated at the same or different timelines.
b) We use an LLM trained in a medical knowledge base to link clinical events described with non-standardized medical terminology. We extract features from treatment intent reports and prescriptions using a sentence transformer, store the vector embeddings in an in-memory database, and calculate the vector similarities to link the evens at the site level

3 Results

Trials and implementation of PlanQ have demonstrated enhanced operational efficiency in the management of radiotherapy workflows. Notably, we have documented a 70% reduction in the effort required for treatment planning coordination, a 10% decrease in planning tasks, and a daily time saving of one hour for planning verification activities. Through PlanQ's effective data curation, retrieving historical radiation records has become more efficient, saving valuable time for physicians, planners, and physicists and reducing the risk of re-irradiation. The sophisticated Large Language Model (LLM) utilized by PlanQ exhibits a 95% accuracy level in synthesizing and associating separate clinical events, which grants immediate, real-time access to the radiotherapy planning process for all clinical teams involved. The platform's vendor-agnostic design ensures its compatibility and flexibility across a diverse array of radiotherapy workflows and clinical environments.

4 Discussion

Figure 4. Screenshots of PlanQ
a) Multiple sites treatment intents
b) Patient journey with Rx (LLM)
c) Prior irradiation records (NLP classifier)
d) DVH summary
e) Patients view from various of sources

PlanQ is an AI-enhanced, ready-for-clinic informatics platform specifically designed to streamline the complexities of managing radiotherapy workflows. PlanQ effortlessly conforms to vendor-neutral systems and multi-modality clinical settings with its versatile architecture. At its core, PlanQ constructs a comprehensive, visual timeline of each patient's treatment, anchored in the FAIR data principles, weaving together disparate data streams to aid instantaneous clinical decision-making. This integration provides a longitudinal view of the clinical workflow and detailed patient information.

PlanQ refines the accuracy of treatment plans and enhances the synergy between therapists, planners, physicists, and physicians. In essence, PlanQ not only streamlines communication but also redefines the landscape of clinical informatics, establishing a new paradigm for patient-focused radiotherapy management.

5 Conclusion

The PlanQ platform is a clinic-ready AI-driven enterprise-wide radiotherapy workflow management and clinical decision support system, showing promising results in improving efficiency and accuracy in treatment planning workflow. Its adaptability makes it a powerful and user-friendly tool to handle the complexities of radiotherapy workflows and support clinical decision-making in a variety of setups.

Abstract We previously developed a mechanistic hidden Markov model (HMM) to predict the lymphatic tumor progression in oropharyngeal squamous cell carcinomas. To extend the model to other tumor subsites in the head and neck defined by ICD-10 codes, we develop a mixture model combining multiple HMMs. The mixture coefficients and the model parameters are learned via an EM-like algorithm from a large multi-centric dataset on lymph node involvement. The methodology is demonstrated for tumors in the oropharynx and oral cavity. The mixture model groups anatomically nearly subsites and yields interpretable mixture coefficients consistent with anatomical location. It allows the prediction of differences in lymph node involvement depending on tumor subsite.

1 Introduction

Head and neck squamous cell carcinomas (HNSCC) frequently spread through the lymphatic system [1, 2]. Current diagnostic imaging modalities are unable to detect microscopic lymph node metastases [3, 4]. To avoid nodal recurrences, large volumes in the neck, which are at risk of harbouring occult disease, are irradiated electively. Guidelines about which lymph node levels (LNLs) to irradiate [5] are currently not based on a patient's individual risk, but on the overall prevalence of nodal disease as reported in the literature [1, 2].

To personalize the prediction of the risk for occult disease, given a patient's individual diagnosis, we first published a large, multi-centric dataset that reports per patient which LNLs were clinically/pathologically involved [6, 7].

And subsequently, building on this work, we published an interpretable hidden Markov model (HMM), trained with this data, to predict the risk for occult nodal disease, given an individual patient's diagnosis [8].

Such a personalized risk prediction may allow clinicians to safely reduce the elective clinical target volume (CTV-N) and thus reduce side-effects that degrade the patient's quality of life without compromising treatment efficacy [9].

Here, we extend the previous work by incorporating the primary tumor location (specified as ICD-10 code) into the model of lymphatic tumor progression, focusing on tumors in the oropharynx and the oral cavity. HNSCC patients with primary tumors at different subsites show different patterns of lymphatic spread [1, 2]. So far, this could be handled by training different models for broader categories of tumor locations, e.g. oropharynx and oral cavity tumors. However, this approach does not describe differences in lymphatic spread between different subsites within the oropharynx and oral cavity. To address this issue, we present an approach using mixtures of HMMs. The intuition is that the lymphatic spread of a tumor that lies anatomically at the boarder of oropharynx and oral cavity (e.g. tumors in the palate) may be described by a mixture of different models. Tumor subsites used in this work are sketched in figure 1.

2 Materials and Methods

Each LNL $v \in \{1, 2, \ldots, V\}$ considered in our model is represented by a binary random variable X_v representing the true state of that level (0 for "healthy" and 1 for "involved"). A patient's state of lymph node involvement can be represented in a random vector $\mathbf{X} = (X_1, X_2, \ldots, X_V)$. When a patient is diagnosed with HNSCC, we only observe the clinical lymph node involvement based on imaging, which we denote as another binary random variable Y_v. To compute the personalized risk of occult disease $\mathbf{X}$, given a diagnosis $\mathbf{Y}$, we apply Bayes' law:

$$P(\mathbf{X} \mid \mathbf{Y}) = \frac{P(\mathbf{Y} \mid \mathbf{X})\, P(\mathbf{X})}{\sum_{\mathbf{X}^\star} P(\mathbf{Y} \mid \mathbf{X}^\star)\, P(\mathbf{X}^\star)} \tag{1}$$

In the above equation, the term $P(\mathbf{Y} \mid \mathbf{X})$ is given by the sensitivity and specificity of the diagnostic procedure. The term $P(\mathbf{X})$ represents the prior probability of involvement, which depends on the probability of the tumor to spread

through the lymphatic system. The main task of the HMM is to model $P(\mathbf{X})$ and the main contribution of this paper is to incorporate the primary tumor subsite into the model of $P(\mathbf{X})$.

2.1 Hidden Markov Model for Lymphatic Progression

A patient's state of lymph node involvement $\mathbf{X}[t]$ evolves over discrete time steps t. Let us enumerate all 2^V possible states, representing all combinations of LNLs. In this paper, we consider ipsilateral LNLs I, II, III and IV, which amounts to 16 possible states. The HMM is specified by a *transition matrix*:

$$\mathbf{A} = (A_{ij}) = P\left(\mathbf{X}[t+1] = \boldsymbol{\xi}_j \mid \mathbf{X}[t] = \boldsymbol{\xi}_i\right) \tag{2}$$

whose elements A_{ij} contain the conditional probabilities that a state $\mathbf{X}[t] = \boldsymbol{\xi}_i$ transitions to $\mathbf{X}[t+1] = \boldsymbol{\xi}_j$ over one time step. The transition matrix is specified and parameterised via the graphical model shown in figure 1. The red arcs in the graph of figure 1 (right panel) are associated with the probability that the primary tumor spreads directly to a LNL (parameters b_v). The blue arcs describe the spread from an upstream LNL – given it is already metastatic – to a downstream level (parameters $t_{v\to v+1}$). Now, let $\boldsymbol{\pi}$ be the *starting distribution*

$$\boldsymbol{\pi} = (\pi_i) = P(\mathbf{X}[0] = \boldsymbol{\xi}_i) \tag{3}$$

denoting the probability to start in state $\boldsymbol{\xi}_i$ at time step 0. Assuming that every patient started with all LNLs being healthy, we set π_i to zero for all states except the completly healthy state $\boldsymbol{\xi} = (0,0,0,0)$, which has probability one.
Using the quantities introduced so far, the probability $P(\mathbf{X}[t] = \boldsymbol{\xi}_i)$ to be in state $\boldsymbol{\theta}_i$ in time step t can now be conveniently expressed as a matrix product:

$$P(\mathbf{X}[t] = \boldsymbol{\xi}_i) = (\boldsymbol{\pi} \cdot \mathbf{A}^t)_i \tag{4}$$

This evolution implicitly marginalizes over all possible paths to arrive at state $\boldsymbol{\xi}_i$ after t time-steps. Additionally, we must marginalize over the unknown time of diagnosis using a time-prior $P_T(t)$. This finally defines the probability distribution over all states of lymph node involvement used in equation 1.

$$P(\mathbf{X} = \boldsymbol{\xi}_i \mid \boldsymbol{\theta}) = \sum_{t=0}^{t_{\max}} P_T(t) (\boldsymbol{\pi} \cdot \mathbf{A}^t)_i \tag{5}$$

where $\boldsymbol{\theta} = \{b_v, t_{v\to v+1}\}$ denotes the set of all model parameters (7 in our case). Fortunately, the exact length and shape of this distribution has little impact as previously shown [8]. We set $t_{\max} = 10$ and $P_{\text{early}}(t)$ to a binomial distribution with parameter 0.3. Further details on the HMM can be found in Ludwig, Pouymayou, Balermpas, et al. [8] and Ludwig [10].

2.2 Mixture of HMMs

We now assume that primary tumors at different subsites have different patterns of lymphatic spread, corresponding to different model parameters $\boldsymbol{\theta}$. Training a separate model for every possible subsite (ICD-10 code) would require a sufficiently large dataset for every tumor site. However, anatomically nearby locations are expected to show very similar patterns of LNL involvement. Therefore, we consider a mixture model. Let us assume that we have a dataset $\mathbf{D}$ that is specified via the number of patients N_{is} that were diagnosed in LNL involvement state i and had a primary tutor in subsite s. Let us further assume that we want to describe this dataset using a mixture of M HMMs, each with a different set of model parameters $\boldsymbol{\theta_m}$. As the generative model of the data, we assume that a patient with subsite s is generated with probability π_{sm} from model m. The likelihood of the dataset can then be written as

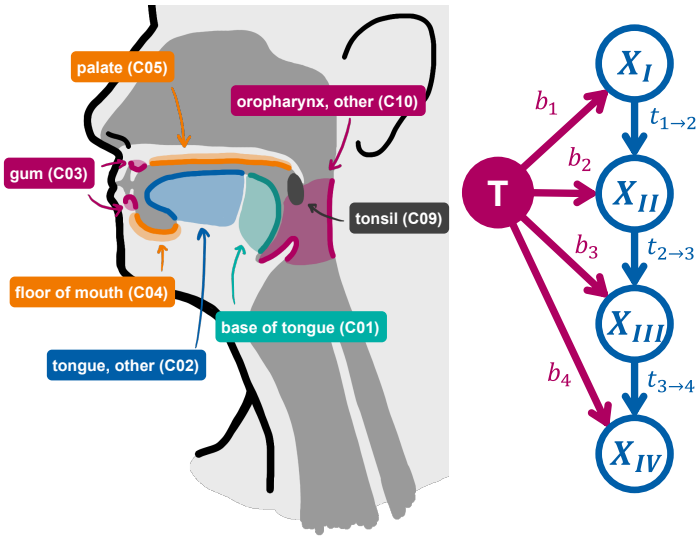

Figure 1: On the left: Anatomical sketch of the tumor subsites and corresponding ICD-10 codes considered in this work. The subsite "other parts of mouth" (C06) was not drawn. On the right: Parametrized graphical model of the lymphatic network considering four LNLs. Blue nodes represent the hidden states of LNLs X_v, while the red one is the tumor. Arcs represent possible routes of metastatic spread, associated with a probability.

$$P(\mathbf{D} \mid \boldsymbol{\theta}, \boldsymbol{\pi}) = \prod_s \prod_i \left[\sum_{m=1}^{M} \pi_{sm} P_m(\mathbf{X} = \boldsymbol{\xi}_i \mid \boldsymbol{\theta}_m) \right]^{N_{is}} \tag{6}$$

We now have two types of parameters, the probabilities of tumor spread for the different models, $\boldsymbol{\theta_m}$, and the mixing coefficients π_{sm}. Assuming a uniform prior in the interval $[0,1]$ for all parameters, the posterior distribution over the parameters $P(\boldsymbol{\theta}, \boldsymbol{\pi} \mid \mathbf{D})$ is given by the likelihood in equation 6 except for a normalisation constant. In this work, we use Markov chain Monte Carlo sampling (MCMC) via the `emcee` Python package [11] to sample model parameters from the posterior distribution. However, $P(\boldsymbol{\theta}, \boldsymbol{\pi} \mid \mathbf{D})$ itself is a multi-model distribution because one can permute the different models. To address this problem, we revert to an *expectation-maximization (EM)* algorithm where we iterate two steps until convergence of the mixing coefficients. In the E-step, we sample model parameters $\boldsymbol{\theta_m}$ using MCMC for given mixing

coefficients π_{sm}. In the M-step, we maximize the likelihood with respect to the mixing coefficients for given samples of $\boldsymbol{\theta_m}$

2.3 Multi-Centric Data

For the analyses in this work, we used five datasets from four different institutions, resulting in 1242 patients in total.

1. 287 oropharyngeal patients from the University of Zurich in Switzerland
2. 263 oropharyngeal patients from the Centre Léon Bérard in France
3. 289 oropharyngeal and oral cavity patients from the Inselspital Bern in Switzerland
4. 239 oropharyngeal and oral cavity patients from the Centre Léon Bérard in France
5. 162 oropharyngeal patients from the Hospital Vall d'Hebron in Spain (not yet public)

The data sets 1-4 are publicly available in the form of CSV tables [7, 12] and may be interactively explored in our **Ly**mphatic **Pro**gression e**X**plorer LyProX. For each patient, the primary tumor subsite is reported (among other patient and tumor characteristics) and each individual LNL is reported as metastatic or healthy, according to the available diagnostic modalities (in part pathology after neck dissection, otherwise clinical involvement).
In figure 2, we plot the prevalence of involvement in the four ipsilateral LNLs I, II, III, and IV stratified by the primary tumor's subsite. The figure illustrates the variations in LNL involvement between subsites within the oral cavity and oropharynx categories. The number of patients for each subsite is indicated in figure 3.

3 Results

We demonstrate the methodology for a mixture model with $M = 2$ components, considering the ipsilateral involvement of LNLs I, II, III, and IV and the primary tumor subsites

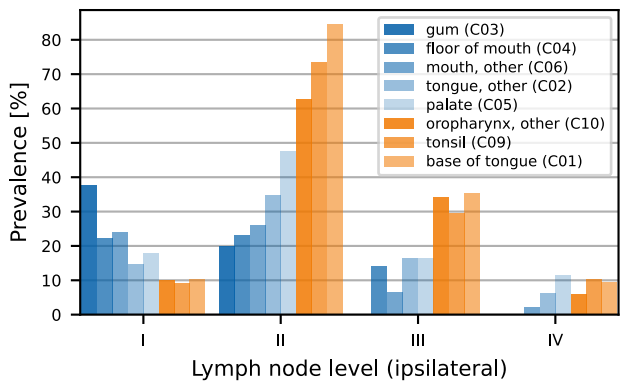

Figure 2: Prevalence of ipsilateral LNL involvement stratified by subsite. The subsites are sorted in ascending order by their prevalence of involvement in LNL II. Oral cavity subsites are plotted in shades of blue, oropharynx subsites in shades of orange.

shown in figure 2. In figure 3 we show the resulting mixture coefficients π_{sm}. The interpretation of this result is as follows: tumors of the base of tongue (C01) are fully described by component A, and tumors of the gum (C03) are fully described by component B. These two subsites are the most distinct regarding the involvement of LNLs I and II, and the result is thus intuitive. Component A may be interpreted as a model for oropharynx-like tumor spread, and component B as a model for oral cavity-like tumor spread. All other subsites are described as mixtures. tumors in the tonsil (C09) have LNL involvement similar to base of tongue tumors and are mostly assigned to component A. Instead, tumors of the palate (C05) are to similar degree assigned to components A and B, which is consistent with the anatomical location and the observation that the LNL involvement is in between oropharynx and oral cavity-type patterns (figure 2).

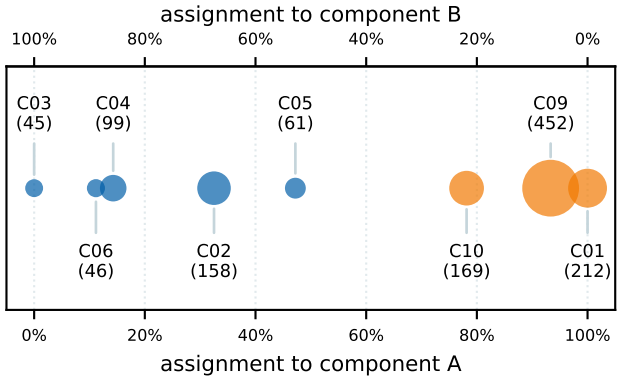

Figure 3: Assignment of each subsite to each of the two components. The further left a subsite, the more it is assigned to component A, the further right, the more to component B. The size of the marker (area) corresponds to the number of patients in the subsite.

The figure 4 illustrates the model's predictions of the overall prevalence of lymph node involvement in LNLs I, II and III (filled histograms) for selected subsites, obtained by summing the probabilities of states where the respecive level is involved. The mixture model is compared to two independent HMM models trained for oral cavity and oropharynx (by pooling the respective subsites). The mixture model and the independent oropharynx model perform similarly for tonsil tumors (C09), which is the largest patient group, dominating the independent oropharynx model and the component B in the mixture model. However, the mixture model better predicts the higher prevalence in level II for base of tongue and palate tumors.

4 Discussion

We have previously developed a model of lymphatic progression of HNSCC using HMM, which allows us to estimate the probability of occult lymph node metastases in clinically negative LNLs. Mixture models are a suitable method to incorporate the primary tumor location into the model, which allows us to account for differences in lymph node involvement for different subsites. Future work will extend the work

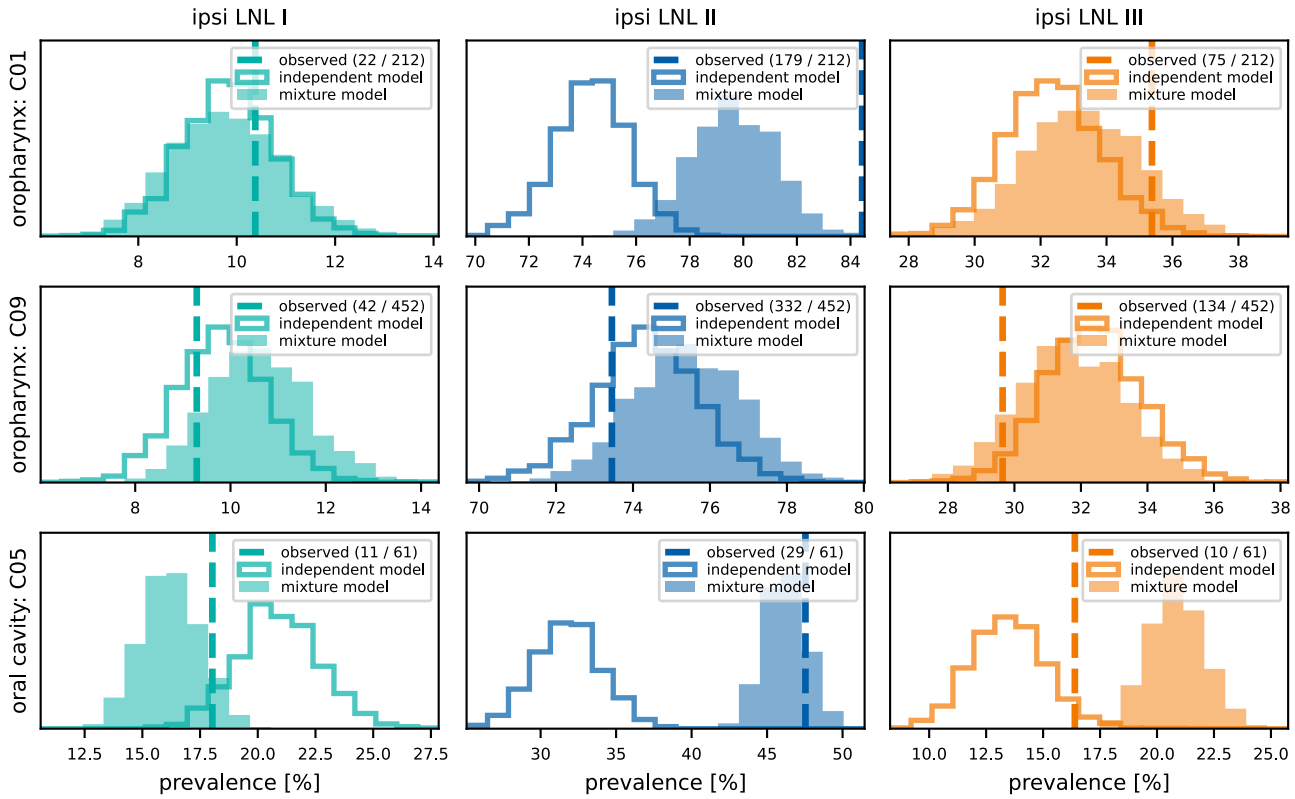

Figure 4: The prevalence of involvement as seen in the data (vertical dashed lines), predicted by an independent model for the oropharyngeal or oral cavity patients (outlined histograms), and predicted by the mixture model (filled histograms). Each row correpsonds to one subsite and each column to one LNL.

to tumors in the hypopharynx and larynx and optimize the number of model components.

Data Collection Platform for Radiation Oncology Clinical Use and Medical Research in a Multivendor Setting

Diego García[1], David Brito[1]

[1]Department of Radiotherapy, Sociedad de Lucha Contra el Cáncer, Guayaquil, Ecuador

Abstract

Purpose: To develop a data collection platform for radiation oncology clinical use and Clinical Research, and to evaluate its implementation in a healthcare setting. This is accomplished by retrieve and display data obtained from Mosaiq (Elekta, Sweden) and Aria (Varian, USA) on a user-friendly interface, use the data to organize the workflow, build data collection forms and to generate automated reports and dashboards.

Introduction: In radiotherapy, is important to have an accurate an efficient way to access the relevant information about the patient's treatment course, to contextualize it on the workflow of the Department and to extract clinical parameters for Clinical research. This is critical in a mixed environment with various record and verify systems in place, as they do not communicate with each other in a native way. Here we present a locally developed platform to integrate data from Mosaiq, Aria and our local Electronic Health Record system (EHR) and display it in a user-friendly web interface.

Methods: Our system (Armoniq) was developed on a local server running PHP and MySQL to handle database queries and display the results, based on Data FAIR principles (Findable, Accessible, Interoperable and Reusable). The main conditions are that the system must have user authentication, to prevent unauthorized access and only read queries are allowed (SQL SELECT), to avoid data manipulation outside the native systems.

Results: The radiotherapy workflow module was deployed in mid-2017. So far, we have recorded the timeline of approximately 12500 cases, improving the dosimetry staff response time and replacing paper records. On the other hand, the data collection module has 186 variables meant to be used in 4 clinical retrospective studies. On average, the server handles 1500+ daily requests by 143 active users.

Conclusions: The platform provided a centralized and standardized system for data collection, storage, and retrieval, which improved the quality of patient care, streamlined the clinical workflow, and contributed to medical research in other areas of the clinic. The platform facilitated the collection and management of patient data for research purposes, while also serving as an essential tool for daily clinical practice.
Non-standardized data registration highlights the importance of standardization in healthcare data management. This work can serve as a model for other healthcare facilities seeking to improve their data management and contribute to medical research.

1 Introduction

The challenges faced by radiation oncology facilities worldwide include deficits in personnel and equipment, leading to compromised patient care and hindering medical research advancement. Insufficient qualified personnel and a scarcity of linear accelerators contribute to increased workloads, longer waiting times, compromised treatment planning, delayed interventions, and reduced treatment capacity, impacting the overall quality and accessibility of radiation therapy services. Furthemore, in a multivendor setting, interoperability problems and the absence of standardized tools exacerbate inefficiencies in data consolidation and obstruct strategic decision-making. The varied data formats across different systems impede a unified approach to optimizing resource and personnel allocation, equipment acquisition and treatment strategies.

In the dynamic field of radiation therapy and oncology, where accessing patient treatment information is crucial, the locally developed platform aims to transcend system incompatibility by seamlessly integrating data from disparate Record and Verify systems, such as Mosaiq, Aria, and the local Electronic Health Record system. The platform provides a user-friendly web interface, harmonizing data sources and empowering clinicians and researchers with a unified and comprehensive view of patient information, advancing patient care and scientific innovation.

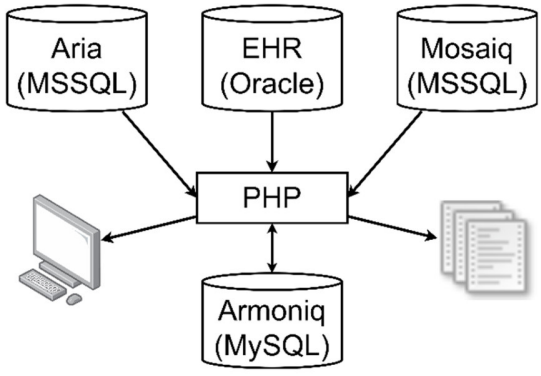

Fig 1. Basic software architecture diagram. Our server uses PHP to read data from external systems, save to a separate database and generate reports

2 Materials and Methods

The development of a comprehensive data collection platform, named Armoniq, was executed on a local server running PHP and MySQL (Fig.1). This infrastructure was chosen to efficiently handle database queries and display results. Armoniq was designed with adherence to the core tenets of the FAIR principles, ensuring that data within the system is easily findable, accessible, interoperable, and reusable.

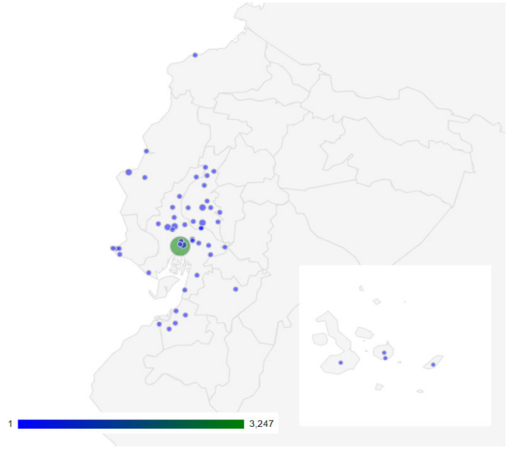

Fig. 2 Geographic distribution of the patients treated in the Radiation Therapy Department..

The main conditions governing the system's functionality include robust user authentication mechanisms to prevent unauthorized access, a critical consideration in handling sensitive patient data within the radiation oncology department. Furthermore, the system strictly allows read queries (SQL SELECT) exclusively, mitigating the risk of unintended data manipulation outside the native systems. This restriction enhances data security and integrity, aligning with best practices in healthcare information management.

This locally hosted system was seamlessly integrated into the radiation oncology department, replacing traditional paper records, and serving as a versatile tool for workflow management, task coordination, patient check-in, follow-up, and data mining from the two different Oncology Information Systems (OIS). The implementation underwent rigorous evaluation, incorporating feedback from healthcare providers and researchers, ensuring that Armoniq not only addressed the identified challenges but also complied with security protocols and enhanced decision-making processes within the multivendor context of the department.

3 Results

The implementation of the radiotherapy workflow module in mid-2017 marked a transformative milestone in the radiation oncology department. To date, the system has meticulously recorded the timelines of approximately 12,500 cases, providing a comprehensive and accessible repository of patient data. This deployment significantly contributed to the enhancement of dosimetry staff response times, streamlining the treatment planning process, and replacing traditional paper records with a more efficient and secure digital solution.

Simultaneously, the data collection module within Armoniq demonstrates its versatility as a powerful research tool. With a robust framework comprising 186 variables carefully designed for application in four distinct clinical retrospective studies, this module empowers researchers with the depth and breadth of information needed to drive advancements in the field of radiation oncology. The flexibility of the platform enables researchers to extract valuable insights, contributing to a growing body of knowledge within the department.

In terms of system usage, Armoniq has become an integral part of the daily operations, with the server consistently handling over 1,500 requests each day. This high demand is met by the active engagement of 143 users who rely on the platform for various tasks related to patient care, workflow management, and data analysis. The substantial user base and daily requests underscore the system's reliability and efficiency in supporting the multifaceted needs of the radiation oncology department. The successful integration and sustained utilization of Armoniq highlight its pivotal role in not only addressing the challenges posed by deficits in personnel and equipment but also in facilitating a data-driven approach to decision-making and research initiatives within the department.

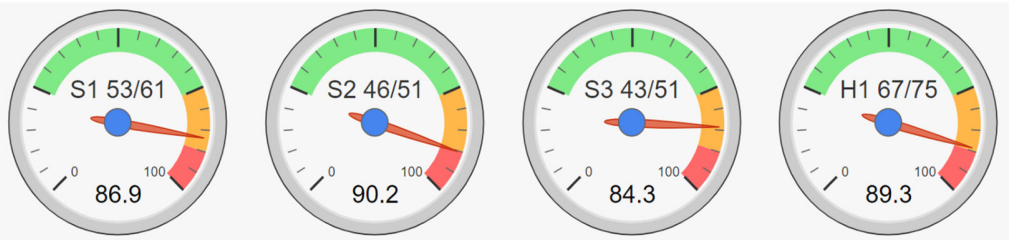

Fig. 4 Daily linac workload. The gauge shows the machine, number of activities planned / number of available schedule slots and the equivalent percentage of use

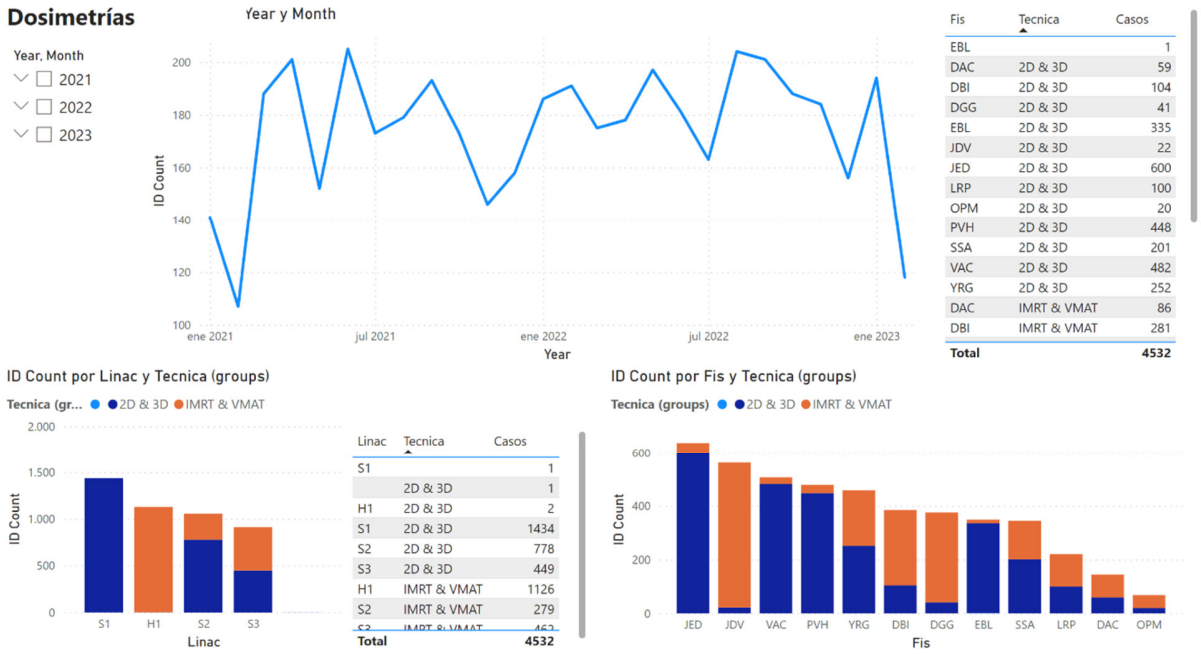

Fig. 5 Screenshot of the interactive dosimetry dashboard made using MS Power BI. The number of calculated plans can be filtered and ordered by dosimetrist, technique and linac. We use this data on the decision-making process for acquiring linacs and hire new personnel.

4 Discussion

While this work has demonstrated the positive impact of the data collection platform on patient care, clinical workflows, and medical research within the radiation oncology department, the platform is facing extinction due to external pressures from administration. This raises concerns about the sustainability and resilience of such initiatives in the face of broader institutional changes. The imposition of a single OIS by external vendors, driven by commercial strategies, and recent decisions to dismantle the platform highlight the vulnerability of healthcare systems to external influences, where short-term administrative goals may overshadow the long-term benefits of integrated and standardized data management solutions.

The discussions surrounding the potential extinction of the platform underscore the need for comprehensive evaluations of decisions impacting healthcare data infrastructure, considering not only immediate financial considerations but also the enduring value of interoperability, standardization, and continuity in patient care and research efforts. As the landscape of healthcare data management continues to evolve, this experience serves as a valuable lesson, emphasizing the importance of sustained commitment to data standardization and interoperability for the greater benefit of patient outcomes and scientific progress.

5 Conclusion

The implementation of the data collection platform brought about transformative changes in the radiation oncology department, providing a centralized and standardized system for data collection, storage, and retrieval. The positive impact of this platform extended across multiple facets of healthcare, demonstrating improvements in patient care, streamlined clinical workflows, and a noteworthy contribution to medical research within various areas of the clinic. By serving as a repository for patient data, the platform not only enhanced the efficiency of daily clinical practices but also emerged as a valuable tool for advancing medical research endeavors. This integration of patient data for research purposes underscores the platform's versatility, offering a dual benefit of supporting both clinical operations and research initiatives.

Despite challenges arising from non-standardized data registration across various OIS, Armoniq facilitated extensive data mapping and integration efforts. The challenges posed by non-standardized data registration further emphasize the critical need for standardization in healthcare data management. The absence of standardized practices creates obstacles not only in daily operations but also hampers the potential for meaningful research outcomes. Standardization is paramount for ensuring the accuracy, consistency, and reliability of healthcare data,

which is fundamental for evidence-based decision-making and the advancement of medical knowledge. The experiences encountered in addressing non-standardized data registration highlight the importance of establishing robust data management practices as an integral component of effective healthcare systems.

[4]Department of Radiation Oncology, Saint-Luc University Hospital, Belgium

Abstract Artificial Intelligence (AI) is gaining momentum in medical fields like radiation therapy. Models to delineate structures and predict optimal dose trade-off for patients are developed by the research community. Although some of these models are starting to be implemented clinically, an end-to-end workflow with a user-friendly graphical interface to visualize the result of successive AI models and to support decision of treatment indication is still prospective.

To address this problem, we present PARROT, a free and open-source web platform that facilitates the use of AI delineation and dose prediction models and the visualization of the models outputs. The treatment decision support shows clinical evaluation tools to compare dose distributions, among which normal tissue complication probabilities (NTCP) models.

1 Introduction

Artificial Intelligence (AI) is gaining momentum in medical fields like radiation therapy. Models to delineate structures and predict optimal dose trade-off for patients are developed by the research community. Although some of these models are starting to be implemented clinically, an end-to-end workflow with a user-friendly graphical interface to visualize the result of successive AI models and to support decision of final treatment indication is still prospective.

To address this problem, we introduce PARROT which stands for Platform for ARtificial intelligence guided Radiation Oncology Treatment. PARROT is a user-friendly, free and open-source web platform which allows users to visualize DICOM files, run AI models in a single mouse click, display and evaluate predictions easily. Several trained state-of-the-art dose prediction and contour segmentation models are available. Moreover, users can add their own models from the embedded code editor. The app consists of a front-end built in React JavaScript including the graphical interface with DICOM viewer, a selection panel of AI models, an editor of contours predictions and evaluation tools. The back-end is built with Flask to handle the predictions of AI models.

Download instructions are available on our website https://huggingface.co/spaces/AI4MIRO/parrot.ai and the source code can be found on the Gitlab repository https://gitlab.com/ai4miro/parrot.

2 Materials and Methods

The interface is organized in four screens, Figure 1.

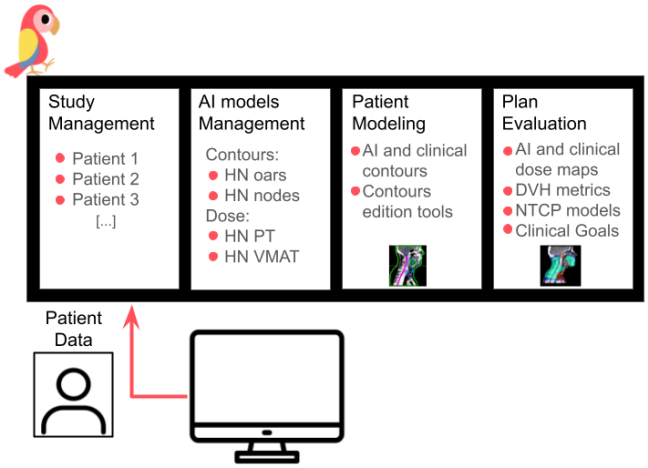

Figure 1: Overview of the PARROT platform.

2.1 Study Management

Users can import patient data from this screen to a Orthanc daemon—a lightweight, standalone DICOM server [1]. It runs locally and therefore ensures the confidentiality of patient files. The interactions with the Orthanc daemon are done through its RESTful API [2]. The list of patient data present in the Orthanc server is displayed with summarized information (Figure 2). Users can load the data into the app by clicking on the Load button. The left icon displays more complete information from DICOM tags (Figure 3) and users can delete a patient study from the server with the red arrow on the right.

2.2 AI Models Management

Eight segmentation models and six dose prediction models are made available and listed on the screen (Figure 4). These models are trained from state-of-the-art architectures such as nnUNet [3], SwinUNETR [4] and HDUNet [5] (Table 1). On the left hand side of each line, a standardized description of the model is available. The PDF description file contains details about the architecture with a link of the original research

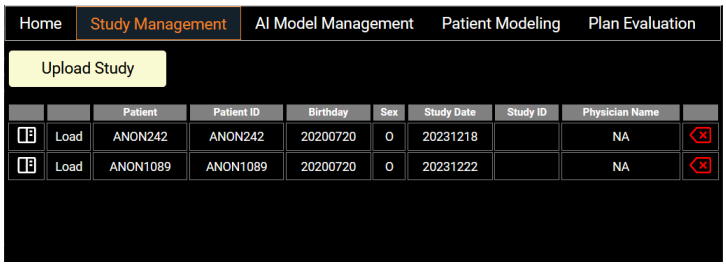

Figure 2: Study management screen.

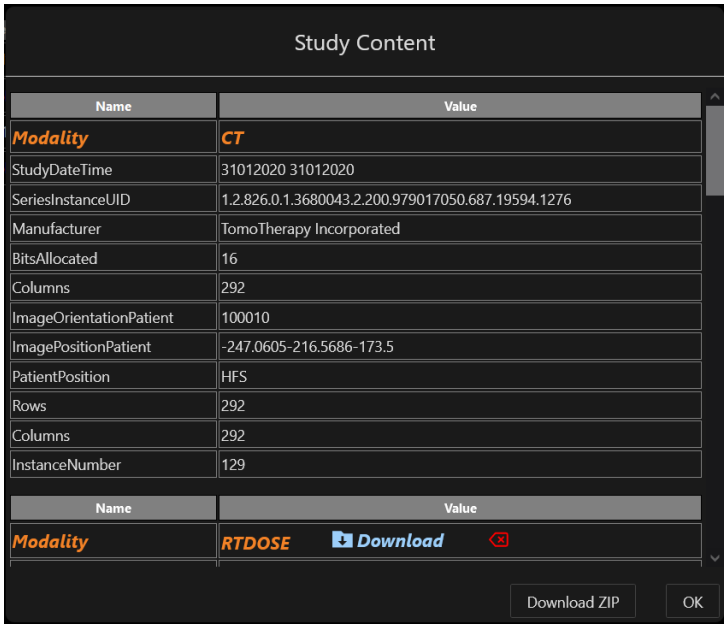

Figure 3: Content information of the study stored in DICOM tags.

article, details on the training process including dataset, and performance on our test set (Figure 5).

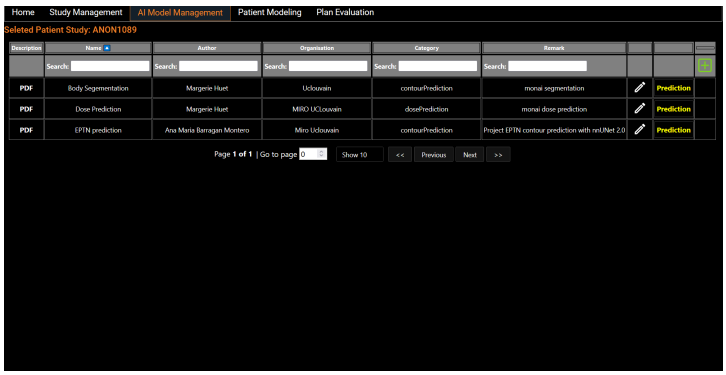

Figure 4: AI Models Management screen. A list of the embedded AI models are displayed.

To run a model prediction, the user simply clicks on the yellow Prediction button on the right hand side of the model line. This will open a Python scripting editor to run the code (Figure 6). Users can select a Python environment with a set of libraries from the drop-down menu in the upper right corner. By hovering on an item, a description of the libraries it contain is displayed. Once the prediction is done, users can upload the result to the study to visualize the output in the Patient Modeling screen (Figure 8). Users

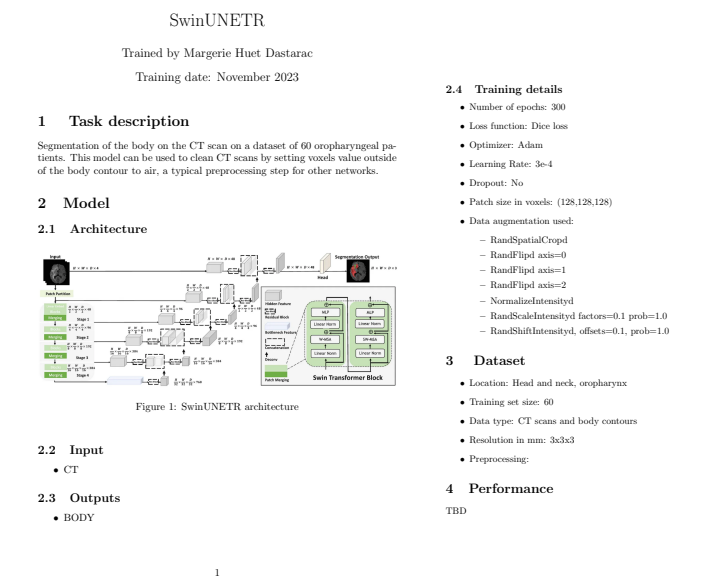

Figure 5: Example of PDF with description of a specific model provided in PARROT.

also have the flexibility to run their own models by loading their processing and inference scripts in the Python scripting editor. On our website, we provide a description and examples using the API to retrieve the patient information loaded on PARROT and upload the result.

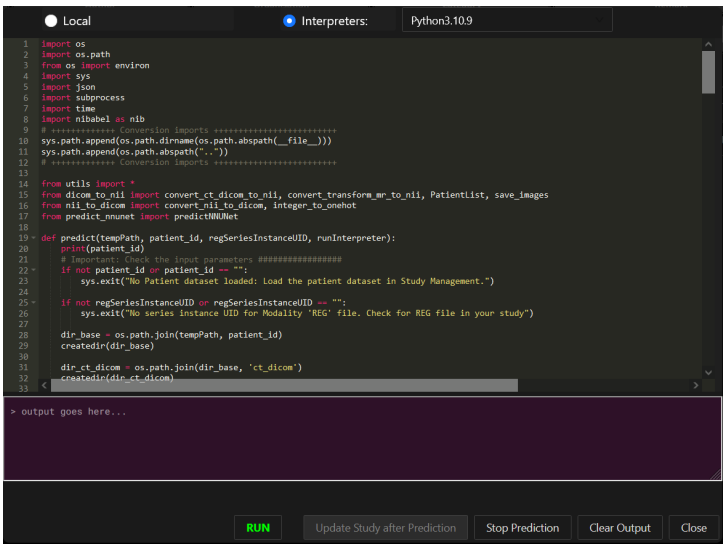

Figure 6: Python scripting editor. Users can edit their script, run and display output from this window.

We distinguish two categories of models: the segmentation models and the dose prediction models. A key difference between the two categories is that segmentation models require only the anatomy of the patient (CT scan or MRI image) whereas dose prediction models also require binary masks of tumor volumes (TV) and organs at risk (OARs). For the latter, we implemented a dialog that allows users to map structures present in the current patient data and the

input required for the AI dose prediction model, Figure 7.

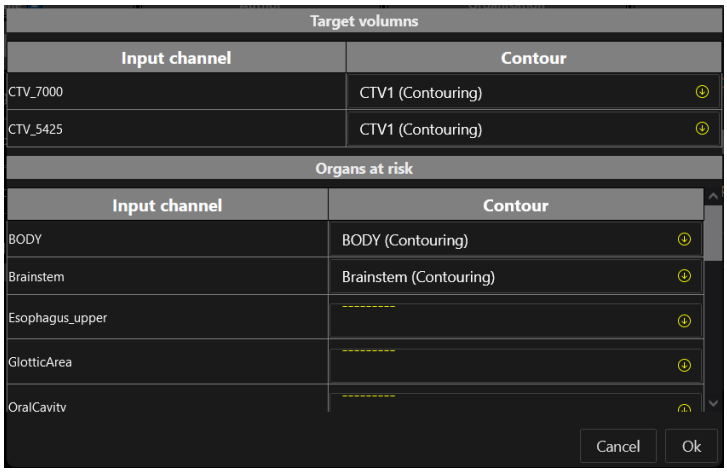

Figure 7: Mapping dialog between structures present in the current patient data and required inputs of the model. The left column displays the input channels required for that specific AI model and the right column a drop-down list of the contours available in the loaded patient study.

2.3 Patient Modeling

This screen allows an interactive visualization of contours, whether uploaded by the user or generated by AI models in the previous tab. Similarly to the visualization of treatment planning software, users can scroll through the anatomy and contours of the patient, zoom, pan and change window range and levels. Users can edit contours with the different tools that can be seen Figure 8. The platform maintains a detailed history of modifications, and users can provide descriptive labels for refining AI models.

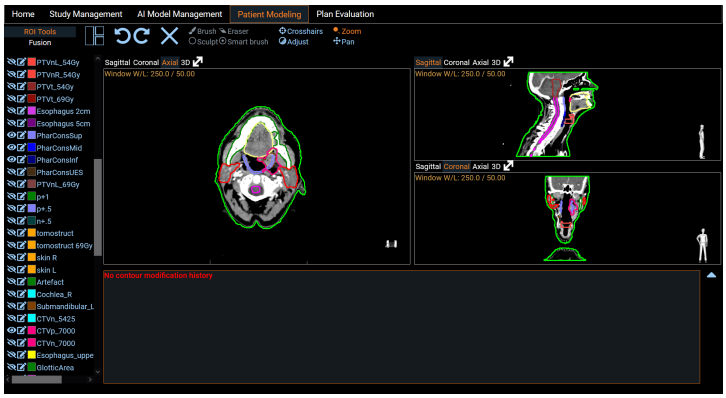

Figure 8: Patient Modeling screen.

2.4 Plan Evaluation

A comprehensive display of two dose distributions comparison is presented on the last screen. The two dose distributions can originate from the importation step or result from the inference of AI models. We provide a set of tools for comparison, such as dose-volume histograms (DVH) curves, dose statistics, and the fulfillment of clinical goals. Clinical goals can be uploaded following an Excel template so that it fits any clinical requirements of the users institutions. The platform incorporates treatment indications based on NTCP protocols. It has been shown in multiple studies that predicted dose distributions yield meaningful output when used with NTCP models for treatment selection decision support [6, 7]. Two NTCP protocols, validated by the clinical community have been integrated, one for head and neck cancer patients (with four NTCP models for xerostomia grade $\geq$ II and grade $\geq$ III and dysphagia grade $\geq$ II and grade $\geq$ III)[8] and one for esophagus cancer patients to estimate pulmonary complications probabilities [9]. This is a useful decision support tool for the clinical community.

Figure 9: Plan Evaluation screen.

3 Results

Three main use cases that can benefit from PARROT are the following.

3.1 Visualization of state-of-the-art AI models on patient of local institute

The integration of a novel AI model within a clinical setting necessitates a careful and meticulous analysis of the tool. It is imperative to conduct thorough testing using a local patient database to compare the performance of the model in its initial testing conditions and the specific context of the new healthcare institution. The PARROT framework facilitates seamless visualization of predictions, eliminating the need for manual coding.

3.2 Curate own AI segmentation models with the contour editing tools

Utilizing the features available on the viewer screen, clinicians have the capability to rectify contours produced by AI models and annotate the rationale behind the modifications. This process helps to identify systematic errors and limitations of the AI models, guiding efforts to curate the training set and retrain the model.

Segmentation		Dose prediction	
Location	Architecture	Location	Architecture
Head and Neck Nodes	nnUNetv2	Head and Neck PT	HDUNet
Head and Neck OARs	nnUNetv2	Head and Neck VMAT	HDUNet
Prostate OARs	nnUNetv2	Prostate IMRT	HDUNet
Breast OARs	nnUNetv2	Breast PT	HDUNet
Brain OARs	nnUNetv2	Esophagus IMRT	HDUNet
Brain Tumor	SwinUNETR	Esophagus PT	HDUNet
Esophagus OARs	nnUNetv2		
Body	SwinUNETR		

Table 1: List of provided AI models.

3.3 Decision support between PT and XT treatments

The dose evaluation screen of PARROT serves as a decision support tool for choosing between PT and XT treatments. Users can have a seamless overview of DVH curves, dose metrics, clinical goals reached and indication of NTCP models. In the current version, AI dose prediction models and corresponding NTCP models are provided for oropharyngeal cancer patients (PT versus VMAT) and esophageal cancer (PT versus IMRT).

4 Discussion

We believe that PARROT can have a positive impact on the safe integration of AI models in the clinic. On the one hand, PARROT can facilitate model comparison, sharing, and benchmarking by the research community. On the other hand, it can foster the dissemination of AI models to the clinics, standardizing and improving the medical practice. In addition, it can be a valuable tool to foster consensus between experts when updating or creating new contouring and planning guidelines. In the future, we would like to extend PARROT to integrate different methods of uncertainty quantification both for segmentation and dose prediction models. These uncertainty estimation tools can be used to curate AI models and datasets and flag out-of-distribution patients and therefore indicate clinicians that the AI model should not be used for that specific patient.

Currently, the platform supports CT and MR images, and automatically applies a registration field whenever a REG DICOM file is uploaded. But future releases will allow PET scan to be viewed and used by AI models.

5 Conclusion

PARROT is a a free and open-source web platform that facilitates the use of AI models in the radiation therapy field. The web platform allows users to visualize DICOM files, run AI models (contour segmentation and dose prediction models) in a single mouse click, display and evaluate predictions easily. PARROT offers clinical evaluation tools to compare dose distributions and support treatment decision. Among these tools, users can find dose-volume histograms curves, dose statistics, validation of clinical goals and outputs of normal tissue complication probabilities models. We believe that PARROT can have a positive impact on the safe integration of AI models in the clinic.

Dose evaluation on daily CBCTs for breast cancer patients

Peter Stijnman[1], Maureen Groot Koerkamp[1], Anette Houweling[1], Cornel Zachiu[1], and Bas Raaymakers[1]

[1]Department of Radiotherapy, University Medical Center Utrecht, Utrecht, Netherlands

Abstract In this work, an interfraction dose evaluation workflow based on daily CBCT data for breast cancer patients is shown. Using deformable image registration a synthetic CT is created from the planning CT and the daily CBCT and the contours delineated on the planning CT are propagated to the synthetic CT. This synthetic CT is used to calculate the daily delivered dose, from which a trigger system can be built to flag patients who might receive suboptimal treatment. Currently, the workflow has processed 456 patients with a total of 5157 fractions. The population-based data suggests that overall the delivered treatment meets a very high standard (i.e. 97.3% of patients receive an average CTV coverage higher than 95%). However, there are some patients for whom the treatment could be improved based on the patient-specific information that this workflow supplies. Furthermore, any uncertainties in the clinic about the impact of anatomical changes on the delivered dose can be verified with this workflow.

1 Introduction

The recent trend in radiotherapy is to move from a single treatment plan that is used throughout multiple fractions to an online adaptive treatment [1]. The result would be a better-tailored treatment that takes into account the daily patient anatomy. To achieve this goal, the treatment plan has to be re-optimized every day. This is a computationally expensive procedure and requires expertise at the treatment machine to run the online adaptive workflow and approve the newly optimized treatment.

As a stepping stone between planning a single treatment plan and performing fully online adaptive radiotherapy, we propose a workflow where the CBCT imaging, acquired for position verification, is used to calculate the planned dose on the daily anatomy to find patients that might receive suboptimal treatment, similar work has been shown in [2].

The benefit of the proposed approach is that it is relatively inexpensive to check if the current treatment plan still adheres to the prescribed dose constraints. These constraints can easily be checked at the treatment machine and a decision can be made to either go ahead with the treatment or to make a new treatment plan for the patient. The calculated daily delivered dose can provide more useful information about the treatment quality compared to only the anatomical information the CBCT provides.

2 Materials and Methods

Patient data is gathered using a daily SQL query on a server containing the CBCT DICOM-files. The CBCTs are filtered on the series description tag to only obtain the breast cancer patients. The number of breast cancer patients that are treated within our hospital on a daily basis is around 45.

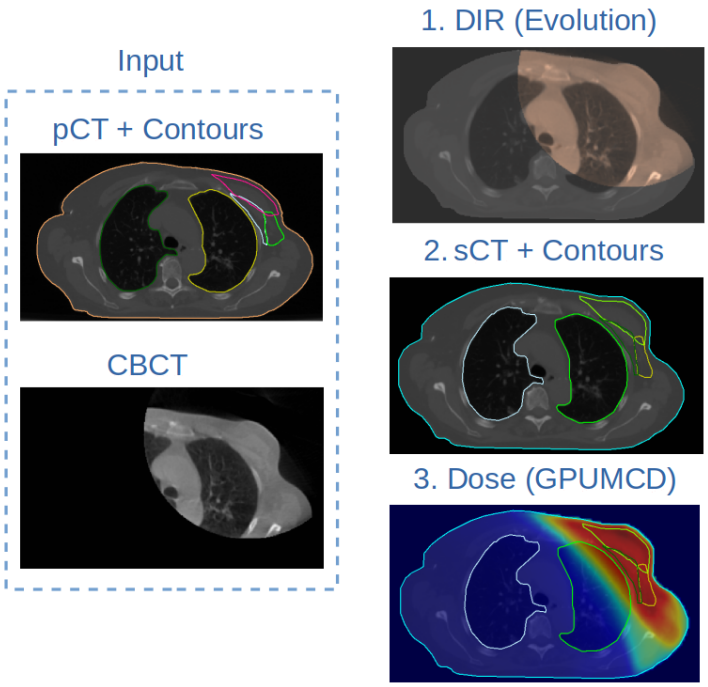

Figure 1: A schematic overview of the workflow. The planning CT with any relevant delineations and the daily CBCT are used as input. The first step is to perform a deformable image registration inside the CBCT FoV and a rigid image registration outside. The second step is to propagate the delineations. Finally, we can use the synthetic CT and the planned treatment to calculate the daily delivered dose.

A schematic overview of the workflow is shown in Figure 1. Before the treatment start, the daily CBCT is matched to the planning CT (pCT) in order to align the daily anatomy to that of with the anatomy as seen on the pCT. Using this matched CBCT and the pCT a daily synthetic CT (sCT) is created using deformable image registration, because the CBCT units are not intended for dose calculation. Since the CBCT only contains part of the anatomy, we perform the deformable image registration of the pCT to the CBCT only within the field of view (FoV) of the CBCT. Outside of the FoV of the CBCT the pCT is rigidly registered and stitched to the deformable registered pCT as a best estimate of the patient anatomy outside the CBCT FoV. Any air pockets that remain at the periphery of the sCT but are inside the newly generated body contour on the CBCT, are filled with a -120 HU value, corresponding to fatty tissue. This generated sCT is used

for the daily dose calculation. For both the deformable and rigid image registration Evolution, an in-house developed implementation, is used [3].

Using the deformation vector fields that are obtained from Evolution we propagate the contours that were delineated on the pCT to the sCT. For this patient group, we propagated the clinical target volumes (CTV) (i.e. breast and lymph node targets), gross tumour volumes (GTV), heart, and lung contours. For the dose calculation, we created a new body contour based on the sCT. Using this body contour the propagated CTVs are also adjusted to ensure that they are adapted to any changes in the body contour. This is done by first expanding the CTV in both the lateral and anterior direction with 1 cm and then cropping the expanded CTV on 0.5 cm below the body contour. For the lymph node and CTV boost contours no expansion and only the crop on the body contour is performed.

With the sCT and propagated contours available and the treatment plan unchanged, the daily delivered dose can be calculated. This is done using the GPUMCD dose engine from Elekta AB, Stockholm, Sweden. An application to call this dose engine from the command line has been developed in-house and was tested against dose calculations performed with the Monaco treatment planning system from Elekta AB. The dose is calculated with a variance of 3% on a 3 mm isotropic grid.

From the calculated daily delivered dose and the propagated contours the dose volume histograms (DVHs) can be computed. This is achieved by first interpolating the dose onto a 1 mm isotropic grid. The dose is then grouped in 2000 bins to obtain the DVHs that are comparable to DVHs obtained from Monaco. This information, together with the volume of the the contour, the prescribed, minimum, mean, and maximum dose within the contour is exported to a .csv file. From this file, any DVHs statistics can be calculated, for example the mean dose and the V95% are the most relevant statistics for the CTVs and the mean dose, V5Gy, and V10Gy for the organs at risk (OARs).

The DVH curves and statistics are written into a patient-specific report, making it is easy to track the daily delivered dose over the history of the treatment. Based on predetermined thresholds, for example, a CTV V95% coverage below 95%, a trigger can be implemented for clinicians to inspect the daily delivered dose or view any trends over the delivered fractions.

3 Results

At the time of writing, the interfraction dose for a total of 456 patients has been calculated, totaling 5157 fractions over 4 and a half months. On average it takes 6 minutes to perform the workflow for a single fraction. The majority of the time is spent on propagating the contours to the sCT, predominantly, because this has not yet been optimized for runtime.

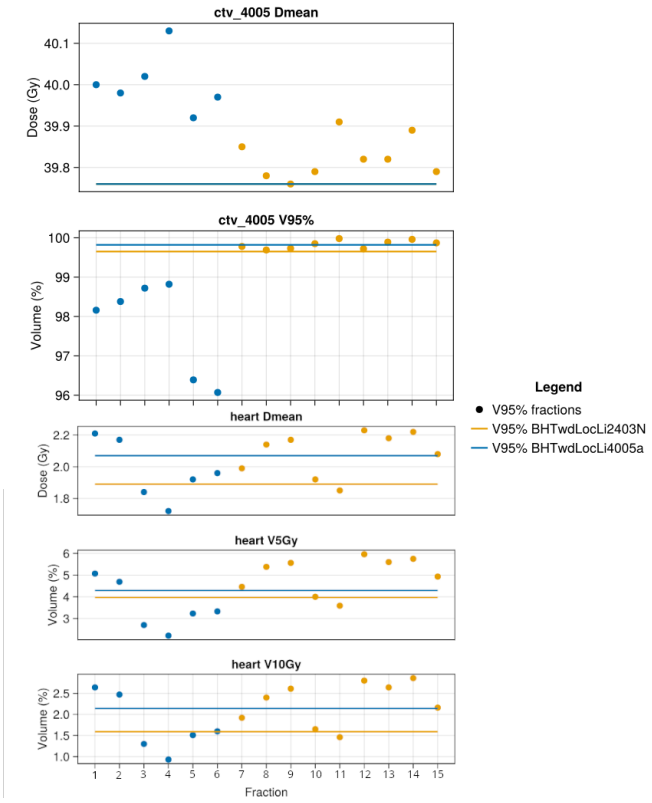

Figure 2: The mean dose and V95% for the CTV, and the mean dose, V5Gy and V10Gy per fraction for the heart of a single patient. The dots represent the separate fractions, while the lines represent the same values based on the planning CT and are used for comparison. This patient had a new treatment plan after 6 fractions to improve the CTV coverage.

To showcase the trends that can be observed from the daily dose, we highlight the CTV coverage and the heart dose for a single patient in Figure 2. This patient received a new treatment plan after 6 fractions because the CTV coverage was deemed too low to be clinically acceptable. From fraction 7 onwards the new treatment plan was started. As can be observed from Figure 2 the CTV coverage is improved drastically for this new treatment plan, while the heart dose is not significantly changed compared to the first treatment plan.

Rather than viewing the data for a single patient, we can also make an overview of the entire breast cancer patient population. This is especially valuable information for assessing the treatment quality and plan robustness that is delivered within the hospital. Such an overview is shown in Figure 3. From Figure 3, it can be observed that for the large majority of the patient population, a sufficiently high median CTV coverage is achieved on an interfraction basis. For the patients where this was not the case, a big reason was the lower number of fractions. The fractionation of the prescribed treatment ranges from 5 to 20 fractions. When the first 2 fractions of a 5 fraction treatment do not have desirable CTV coverage the mean coverage will be heavily impacted.

Another interesting aspect that we can investigate is the robustness of different radiation plan types. As an example, patients where lymph node structures are irradiated are treated

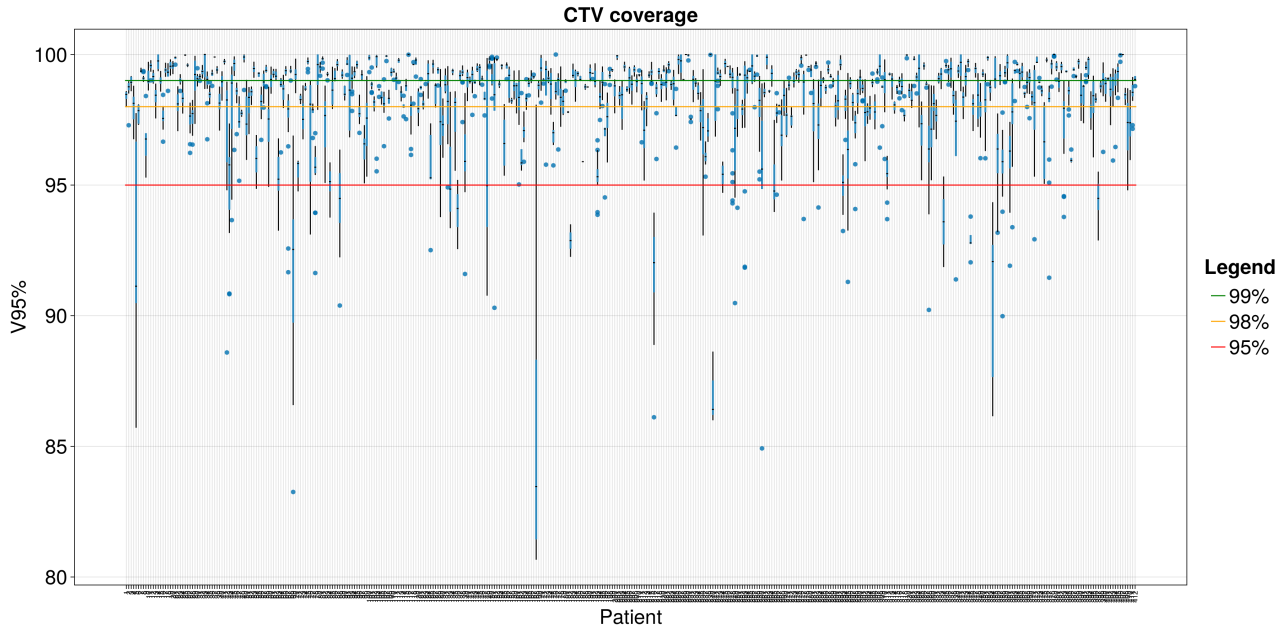

Figure 3: An overview of the CTV coverage for the patient population. Each boxplot represents the CTV V95% coverage for a single patient, showing the median, IQR, and the outliers. The green, yellow, and red lines are to indicate the 99%, 98%, and 95% coverage levels respectively. The target for the clinic is to have coverage above 95%. Currently, we check fractions below this threshold to evaluate potential causes for the lower coverage.

with a full volumetric modulated arc therapy (VMAT) plan type, while patients who do not receive radiation of lymph node structures are treated with a combination of tangential radiation fields (∼80% dose) and VMAT (∼20% dose) since it is a more robust method and the delivery time is shorter. The patients for both treatment plan types can be split into 4 groups: 1) this workflow would warrant a check and the clinic did not make a new treatment plan; 2) where this workflow would warrant a check and the clinic did make a new treatment plan; 3) no trigger, but more than one treatment plan; and 4) no trigger and no new treatment plan. If we were to trigger a check with this workflow based on a CTV V95% coverage lower than 95%, we would obtain the results that can be observed from Figure 4.

What we observe from Figure 4 is that the treatment for most patients goes as planned and no changes need to be made. We observed a similar result based on the data from Figure 3. For some patients, we do observe that a new treatment plan was made while our workflow would not trigger a check for that patient. In these cases, often the reason for a new treatment plan was discomfort in positioning the arms above the head. Furthermore, there are some cases where our workflow would trigger a check of the plan quality while the clinical workflow did not notice a need for a new treatment plan. This can be because of a few reasons, however, it should be noted that a single fraction with a CTV V95% coverage lower than 95% is quite a strict threshold. Patients from groups 1 and 3 are the most interesting cases for an evaluation, because there might be patients that receive a suboptimal treatment that are not caught by the clinical workflow.

Finally, Figure 5 indicates an example where a difference in

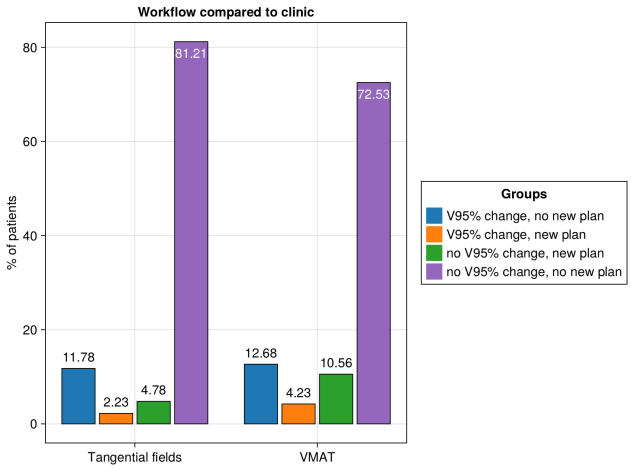

Figure 4: Clinically triggered replanning compared to workflow-initiated check for breast cancer patients with and without lymph node irradiation. We divided the patients into four groups. Either both the workflow and clinic agree and a new treatment plan needs to be made or both agree that the current treatment is sufficiently effective. Or the workflow and the clinic do not agree. The trigger for the workflow-initiated check is a primary CTV coverage lower than 95% of the prescribed dose.

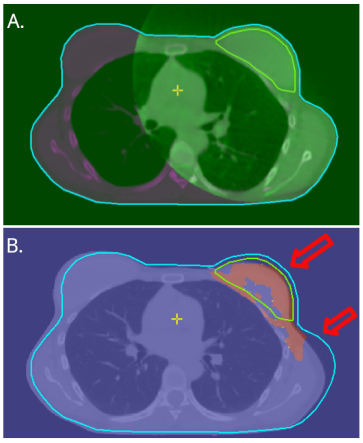

Figure 5: An example of a difference between the daily anatomy and the pCT resulting in a difference in CTV coverage. A.) the daily sCT with the CBCT overlapped in a copper tint with the new body and CTV contours. B.) the pCT with the daily delivered dose clipped on 95% of the prescribed dose overlapped and the same contours as A.). The red coloured areas indicate where the dose is higher than 95% of the prescribed dose and blue areas are below this threshold. The red arrows indicate locations where the body contour has been increased.

the daily anatomy results in underdosage of the CTV. For this patient no new plan was made as this discrepancy between the daily anatomy and the pCT was predominantly there only on the last two out of fifteen fractions. However, this type of anatomical difference has been observed with multiple patients.

4 Discussion

The impact of the developed workflow on the clinic is multi-faceted. Primarily, a better-informed decision to make a new pCT to check if a new treatment plan is required can be made. Mainly because rather than basing this decision on the daily anatomical differences, the daily delivered dose can be incorporated in this decision. Furthermore, because the dosimetric impact of the daily anatomical changes is now known, the radiotherapy technicians who are performing the treatment might inquire clinical physicists and radiation oncologists fewer times, and as such, saving time and unburdening them.
Another impact of the developed workflow is the ability to obtain dosimetric information on a large population. This information can be used to investigate potential sources of errors inside the clinic, either with the patient setup or the plan quality for different plan types.
Ultimately, the biggest impact would be to detect patients with this workflow that would receive suboptimal treatment and have gone unnoticed through the clinic otherwise. Especially for hypofractionated treatments, since being able to check the daily delivered dose and acting upon any under or overdosing will have a large impact.
Currently, there are still some edge cases that this workflow does not handle properly. Examples of such cases are tissue expanders that create an artefact on both the pCT and the daily CBCT. This artefact is delineated for a density override on the pCT, but is not properly propagated onto the sCT. Another example is patients where the target volumes do not entirely fit inside the FoV of the CBCT. This can result in issues with constructing a proper body and target contour. However, these issues can easily be identified through visual inspection of the propagated contours, sCT, and calculated dose.
As for the computation time per fraction, on average about 6 minutes, this can be significantly reduced. The deformable image registration and the dose calculation are already properly optimized, however, propagating and adjusting the contours (i.e. cropping the CTVs) still take several minutes. This is the result of utilizing generic software tools that read and write from disk unnecessarily often for this rather than a custom-made solution that does a single pass over all the contours.
Another improvement of the workflow we are investigating, is the extension to other treatment sites. We already expanded towards head and neck cancer patients, however, the definitive workflow for those patients is still being developed.
Finally, in future work, we continue to move towards a daily adaptive treatment on the CBCT linacs. Utilizing the information that is obtained from this workflow to perform a re-optimization of the treatment plan on the daily anatomy to improve the efficacy of the treatment for each fraction.

5 Conclusion

In this work, we proposed an interfraction dose calculation workflow using CBCTs for breast cancer patients. The daily delivered dose that is calculated using this workflow can be used as additional information to ensure the radiation treatment is effective. This effectiveness can be evaluated on a patient-specific level or on a population level, to draw conclusions for different treatment plan types or to obtain insights into what anatomical changes could cause significant dosimetric changes. Finally, the next step for this workflow is to extend it towards other treatment sites than solely breast cancer.

Harnessing Radiotherapy Data for Quality Care and Outcome Research

Rishabh Kapoor[1,2], William Sleeman IV[1,2], and Jatinder R Palta[1,2]

[1]Department of Radiation Oncology, Virginia Commonwealth University, Richmond, VA, USA
[2]National Radiation Oncology Program, Veteran Health Administration, Richmond, VA, USA

Abstract The our work presents the development and validation of the Health Information Gateway and Exchange (HINGE) software platform, designed to harness radiotherapy data for quality care and outcome research in oncology. HINGE addresses challenges associated with healthcare data, including volume, variety, velocity, veracity, and value, by offering scalable architecture, diverse data format handling, real-time processing, data quality prioritization, and insightful data analysis. Key design features include data standardization, integration with EHR, Treatment Planning System (TPS), and Treatment Management System (TMS), and a user-friendly interface with disease-specific templates. The platform underwent validation using a comprehensive dataset, showing promising results in reducing physician burden and enhancing data accuracy. Challenges encountered in building HINGE, such as consensus among physicians, clinical workflow variations, and system integrations, were overcome through collaboration and iterative improvements. The platform's deployment architecture ensures reliability, security, and performance, with ongoing evaluation for VA compliance. Overall, HINGE represents a significant advancement in facilitating data-driven decision-making in radiation oncology.

1 Introduction

Manual abstraction, collation, curation, and subsequent analysis of healthcare data for quality and outcome assessment of patient treatments are onerous, expensive, and impractical. Advances in computer storage, computing power, and the ability to electronically mine data from disparate sources (e.g., demographics, genetics, imaging, treatment, clinical decisions, and outcomes) have the power to enable big data research in radiation oncology. Developing an ecosystem to make routine clinical data "Artificial Intelligence (AI) ready" will allow us to generate new knowledge from large scale analysis of historical patients' treatments and outcomes to improve care for the future patients. A fundamental barrier in reaching this vision is the lack of strategic development of IT infrastructures that facilitate data aggregation out of clinical systems via federated or centralized infrastructures for data access. Another barrier is to organize and standardize knowledge and information in a way that is computer understandable with standardized vocabularies, established taxonomies and interoperability standards.

We designed and built an IT infrastructure; Health Information Gateway and Exchange (HINGE) software platform that address the challenges associated with the 5 Vs of healthcare data - Volume, Variety, Velocity, Veracity, and Value [2]. In terms of Volume, the scalable architecture of HINGE allows it to handle the vast amounts of data generated in healthcare, including data from EHRs, Treatment planning and dosimetry and Treatment Management Systems in real time. Regarding Variety, the HINGE software is designed to handle diverse data formats, including structured, unstructured, and semi-structured data. When it comes to Velocity, the IT infrastructure supports data processing and analysis when the data are sent over to the HINGE central server for analysis. For Veracity, the HINGE software prioritizes data quality and reliability using the mapping techniques with established ontology and data standardization efforts of professional societies. Finally, in terms of Value, the HINGE software infrastructure focus on extracting meaningful insights and knowledge from healthcare data. This is done by efficient data analysis and mining techniques like ontology-based search tools that are designed to gather data for cohort analysis, machine learning, outcome assessment, and informed decision making..

2 Materials and Methods

The HINGE software, designed for radiotherapy data management, employs several key design features. In terms of data standardization, it facilitates Extract, Transform, and Load (ETL) processes for disparate clinical, treatment, and process data by deploying 'smart' disease-specific templates in its user interface. These templates enable structured data entry, utilizing disease-specific nomenclatures, and include critical data elements for quality assurance analyses.

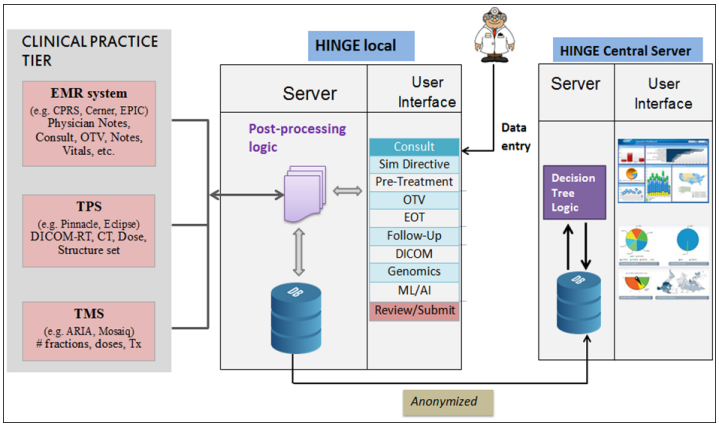

Figure 1 Overview of the architecture of Health Information Gateway and Exchange (HINGE) software platform.

The software integrates with various data sources, including VHA's EHR (VISTA), through an external interface that fetches patient details, ensuring seamless data interoperability. For treatment planning system (TPS) integration, HINGE utilizes the IHE-RO standard, importing DICOM-RT data and adhering to TG-263 standardized nomenclature for target and organ-at-risk structures [1] (Figure 1). To connect with treatment management systems (TMS), a Docker container named HINGE-Broker is implemented, accessing TMS databases and exposing a web API for remote queries. The data retrieved from TMS populates HINGE templates, providing a discretized view of treatment delivery data (figure 2). The software ensures ease of use for physicians through disease-specific templates, designed with UI/UX

considerations to reduce clicks, facilitate lateral data entry, and automate calculations. Validation checks, error messages, and disease-specific fields enhance data entry accuracy. For EHR integration, HINGE utilizes HL7 FHIR standards, playing a crucial role in interoperability profiles such as IHE-RO and CodeX [4]. These profiles allow the extraction of treatment summary information from radiotherapy treatment management systems, integrating it seamlessly with EHRs. The data elements interfaces from the TMS to HINGE templates is shown in Figure 2.

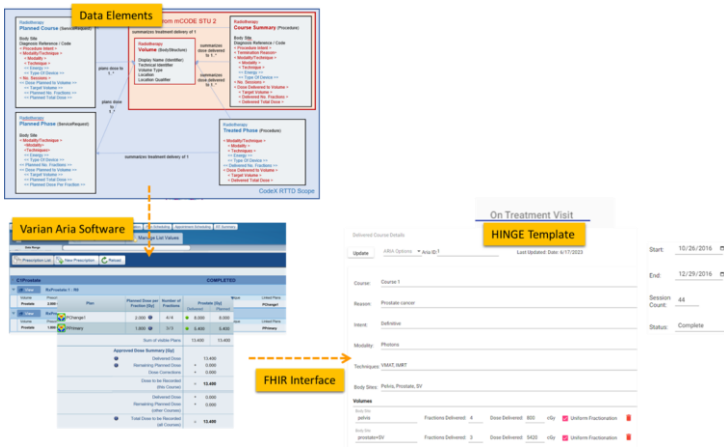

Figure 2: Consensus treatment summary data elements defined with CodeX and IHE-RO effort is implemented in the Varian Aria software and interfaced to the HINGE software via the FHIR interfaces

HINGE Information Technology and Deployment Architecture: The HINGE web applications are deployed on the VA cloud platform hosted by Amazon Web Services (AWS), utilizing ECS containers and Fargate services. MongoDB serves as the backend database for template data storage, Angular web application framework powers the front-end user interface, and AWS S3 is employed for storing medical imaging and treatment planning objects in DICOM format. The architecture, depicted in Figure 3, employs EC2 instances for MongoDB and incorporates essential data backup solutions, two availability zones, and a load balancer system across developmental, pre-production, and production environments. Continuous cybersecurity measures, including vulnerability analysis and remediation, ensure security. The overall cost for hosting and cybersecurity measures is estimated to be less than half a million dollars (FY 2022). This architecture provides a robust and scalable foundation, leveraging AWS services to support reliable, secure, and high-performance operation for radiation oncology practitioners and researchers.

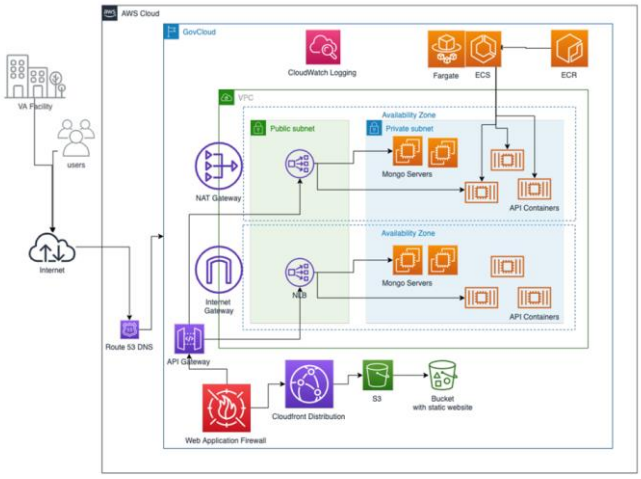

Figure 3: High-level cloud architecture for the HINGE platform

3 Results

The validation of the HINGE platform involved a meticulously collected dataset of 1660 patient clinical and dosimetry records from 40 VA Radiation Oncology clinics, tailored for a pilot study focusing on prostate cancer, non-small cell lung cancer (NSCLC), and small cell lung cancer (SCLC). Each patient's record, comprising 80-100 clinical data elements, was entered into disease site-specific HINGE templates. Leveraging an auto-population feature from electronic medical records, physicians experienced minimal data entry requirements, with the completion of templates and generation of textual narrative notes for initial consultations or follow-up care taking less than 10 minutes based on preliminary analysis. The HINGE platform intelligently populated relevant template sections, utilizing comprehensive patient data from electronic medical records. This streamlined process aimed to reduce the burden on physicians, allowing them to focus more on patient care and decision-making. [3]

To analyze and score the data, the platform employed decision tree logic within a dashboard software (shown in Figure 4). Visual representations, including plots, graphs, and charts, provided insights into the performance of each VA practice for various Clinical Quality Measures (CQMs). [4] In-depth manual checks validated the accuracy and functionality of the decision tree logic, with meticulous analysis and visualization tools used to identify and address discrepancies or issues. The platform underwent further refinement through workshops with VA Subject Matter Expert physicians. Training sessions and iterative improvements based on physician feedback enhanced the quality of templates and generated discrete data. This collaborative approach ensured alignment with the specific needs and workflows of the VA healthcare system.

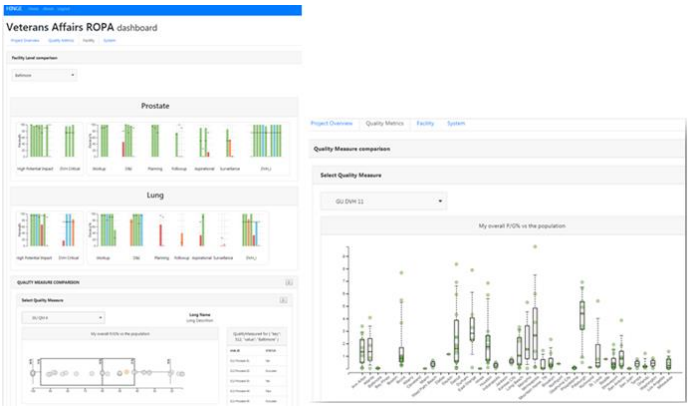

Figure 4: Screen capture of the HINGE dashboard application showing data from 40 VA practices

4 Discussion

The development of the HINGE software for comprehensive radiation oncology data management encountered and successfully addressed several challenges. Achieving consensus among VA subject matter expert physicians posed a significant hurdle due to diverse preferences and practices. The solution involved relying on VA quality measures aligned with evidence-based guidelines and fostering extensive communication to identify and prioritize essential data elements. Variation in clinical workflows across disease sites and clinics necessitated designing adaptable templates, aligning with accrediting bodies' requirements. Integration challenges included harmonizing data syntax and semantics from diverse systems, addressed through an HL7 FHIR interface for EHR integration. Standardizing data from Treatment Planning Systems (TPS) proved challenging, resolved by adopting TG-263 naming conventions and exploring machine learning for automation. The lack of radiation oncology-specific ontologies prompted the deployment of disease-specific templates, mapped to standard ontologies for interoperability. Template usability and user experience were crucial, demanding iterative feedback loops and usability testing to balance comprehensive data capture with user-friendly interfaces. Overcoming these challenges underscores the HINGE software's effectiveness in facilitating robust radiation oncology data management.

5 Conclusion

While the HINGE platform has made significant progress in establishing a robust data collection framework, it is currently undergoing evaluation for compliance with VA cybersecurity standards based on the NIST framework. This rigorous assessment encompasses infrastructure, data protection measures, access controls, encryption protocols, data backups, disaster recovery planning, incident response planning, and vulnerability management. Once deemed compliant, the platform will be deployed within the VA system, providing a secure tool for data entry, analysis, and decision support in radiation oncology.

HINGE notably reduces the burden of data collection, ensuring data integrity by eliminating manual transcription, enhancing traceability, and minimizing errors. The system's versatility extends to creating decision support models for clinicians, fostering improved patient care quality and safety. In the context of value-based healthcare, HINGE quantifies care quality and value, utilizing standardized templates. While alternative approaches, like natural language processing (NLP), face challenges due to the lack of universal standards in radiation oncology documentation, HINGE excels in structured data extraction. Future HINGE releases will integrate Patient Reported Outcomes (PRO), extending data capture to community providers for comprehensive big data outcome research. The paper concludes by advocating collaborative efforts across stakeholders and funding agencies to replicate HINGE's success in other medical domains, emphasizing the importance of defining structured data collection methodologies and clinically meaningful measures for continuous quality improvement.

TrajectoryLog.NET: Applications of an Integrated Trajectory Log File Analysis API

Matthew Schmidt[1], Frank Marshall[1], Sarah Cradick[1], Justin Mikell[1], Phillip Wall[1], Nels Knutson[1], Tom Mazur[1], and Yao Hao[1]

[1]Department of Radiation Oncology, Washington University in St. Louis School of Medicine

Abstract: Machine log file analysis has shown effective utility within a quality assurance program for both periodic linear accelerator testing and patient-specific plan verification. Limitations of existing machine log analysis implementations include the lack of integration with treatment planning system application programming interfaces and incompatibility with emerging ring delivery system linear accelerator platforms. An application programming interface (API) has been developed, TrajectoryLog.NET, to overcome these limitations. This API was benchmarked against a standard python trajectory log file analysis tool and employed in the creation of two analysis applications – a Respiratory Gating QA Analysis tool and a patient specific delivery parameter report. In benchmarking, all parameters were within 5.0 x 10^{-5} deg and 5.0 x 10^{-6} cm for rotational and translational axes of motion respectively. The API was also used to determine the agreement in gantry angle and MLC position between gated and non-gated QA and in determination of the dose rate hysteresis in a gated beam being an average of 5.5 control points (110 ms).

1 Introduction

Many delivered radiation therapy treatments employ a sophisticated combination of dose delivery with varying Multi-Leaf Collimator (MLC) positions in Intensity Modulated Radiation Therapy (IMRT) or variable dose rate, gantry position and speed, and MLC position in Volumetric Modulated Arc Therapy (VMAT) [1]. With the adoption of modulated treatment planning and delivery, robust quality assurance (QA) programs commonly include treatment-specific measurements in addition to periodic geometric and dosimetric linear accelerator (LINAC) QA tests [2]. Both periodic and treatment-specific QA of a dynamic treatment delivery can include dosimetric measurements on an array or phantom, software calculation-based evaluations, log-file analysis or a combination of any of these methods [3].

Analysis of machine log files (trajectory logs) have been utilized in the evaluation of pre-treatment QA, ongoing during treatment QA, and periodic LINAC QA [4,5]. Modern linear accelerators have the capacity to write a trajectory log describing the beam delivery with control points (CP) spaced every 20ms. Current implementations to the use of trajectory logs for LINAC and patient-specific IMRT QA have limitations in both integration with commercial software solutions and workflow automation. Modern treatment planning systems and QA software implement application programming interfaces (APIs) to facilitate powerful custom analysis application designs and streamlined workflows for the evaluation, reporting, and trending of QA data [6,7]. Our institution implements daily trajectory log file analysis, but differing axes of motion have rendered the application incompatible with Ring Delivery System (RDS) LINAC analysis.

To address these limitations and to extend our institutions current solution to facilitate trajectory log analysis for (RDS) LINACs, a Trajectory Log file reader has been developed and distributed as an open-source API.

2 Materials and Methods

TrajectoryLog.NET is an open-source API built and compiled in C# as a .NET class library. The primary function of the API is to consume and interpret binary Trajectory log files in accordance with the standardized format provided by the linear accelerator vendor (TrueBeam V2.7, Varian Medical Systems, Palo Alto, CA) [8]. The TrajectoryLog.NET API currently exposes the following methods in its early inception:

a) EnableDebug: Allows the client to stream the reading and interpretation of the trajectory log binary as a standard output message.
b) DisableDebug: Disables the debug output.
c) LoadLog: Reads the trajectory log and returns a strongly-typed TrajectoryLogInfo class object. *Requires formal parameter for the file name <string>*.
d) ToCSV: Exports trajectory log file as a comma separated value (CSV) file. *Requires formal parameter for the trajectory log <TrajectoryLogInfo>*.
e) ToPDF: Prints standard PDF output for trajectory log analysis. *Requires formal parameter for the trajectory log <TrajectoryLogInfo>*.
f) BuildFluence: Returns 2 dimensional array of fluence from the MLC positions. *Requires formal parameters for the MLC positions <List<float[]>> and the MLC Model <MLCModelEnum>*.

To validate the interpretation of the Trajectory log files with this API, 77 trajectory log files were acquired from a C-arm LINAC (N=35) and RDS LINAC (N = 42) to test the conversion of 3D-conformal radiotherapy (3DCRT) (N = 8), IMRT (N = 32), and VMAT (N = 37) plans. The API exported the trajectory log results in CSV format and each trajectory log file was compared at each CP with a popular open-source python-based trajectory log analysis toolkit, Pylinac [9].

QA software analysis tools leveraging TrajectoryLog.NET were also developed to meet clinical needs that highlight both the TPS integration advantages and enabling log-file based patient-specific QA for RDS LINACs. First, a software application was developed to analyze images and deliveries with and without Respiratory Gating influenced beam delivery. The application evaluates the impact of gat-

ing on machine output and performance via integrated images and trajectory logs acquired from those gating and non-gating plans. The output variations are reported via a gamma analysis index [10] facilitated through the Portal Dosimetry API (PDSAPI V15.6, Varian), while trajectories for gantry angle position, dose rate, and MLC position are plotted within the application for review.

A second application was developed to report the comparison of the RDS trajectory log file actual treatment delivery with the control point parameters from the TPS (Eclipse V15.6, Varian). This application generates a report comparing planned and delivered trajectories, utilizing a comparison of various axes of motion and fluence comparisons from MLC positions.

3 Results

Of the 77 analyzed treatment field trajectory logs, the gantry angle position, collimator angle position, positions of all 120 MLC leaves (57 leaves for RDS machine configuration), and the meterset value were compared to the log file interpretation from Pylinac for each 20ms control point interval during the treatment. All rotational values (collimator and gantry angles) were within 5.0 x 10^{-5} degrees. Linear (MLC) axes were all within 5.0 x 10^{-6} cm and the meterset values were within 5.0 x 10^{-5}MU. The deviation in gantry angle, meterset, and the central MLC leaves are plotted below to identify any drift in the data from incorrect byte counting or data-type precision differences in the file conversion [Figure 1].

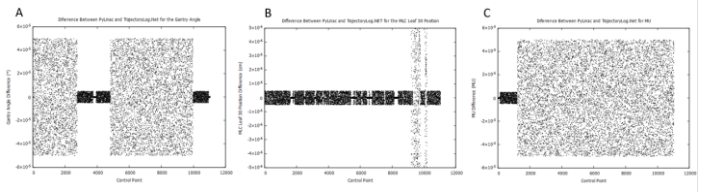

Figure 1: Trajectory log actual value differences when interpreted by TrajectoryLog.NET and Pylinac for (a) Gantry Angle position, (b) Center MLC leaf position, and (c) MU at each control point.

The user interface for the Respiratory Gating QA Analysis application is seen below [Figure 2].

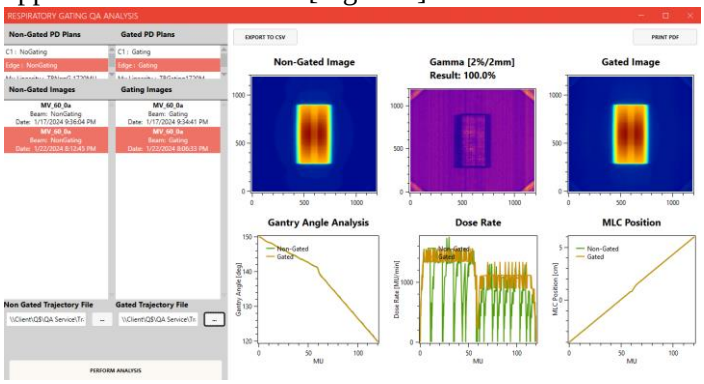

Figure 2: Respiratory Gating QA Analysis utilizing TrajectoryLog.NET for MLC Analysis

The application reported gamma index passing rates are between 87.2% and 100.0% using a 1%/1mm dose difference and distance-to-agreement criteria and 98.0% to 100.0% with 2%/2mm [Table 1]. The gamma analysis is reported with a global dose difference and an region-of-interest defined as the image within a dose threshold of 5%.

	Passing Rate [%]	
TrueBeam 1	1%/1mm	2%/2mm
1/12/2024	98.2	99.5
1/17/2024	87.2	98.0
1/24/2024	92.9	98.1
TrueBeam 2		
1/17/2024	100.0	100.0
1/24/2024	100.0	100.0
TrueBeam 3		
1/17/2024	100.0	100.0
1/124/2024	100.0	100.0

Table 1: Gamma analysis results for 2 Truebeam linear accelerators when acquiring integrated imaging with and without a gated beam.

The Respiratory Gating QA Analysis application can also print an analysis report PDF and export CSV data for further investigation. From this exported data, the gantry angle position of the gated delivery remains within 0.02 degrees of the non-gated, and the central MLC position remains within 0.01 cm. The dose rate of the gated field requires an average of 5.5 control points (110 ms) to return to within one standard deviation of the non-gated field dose rate.

Figure 3 shows the analysis report PDF prototype for a patient-specific log analysis for pre-treatment QA. The report compares various motion axes and reconstructs a fluence from plan parameters and the MLC actual positions during treatment.

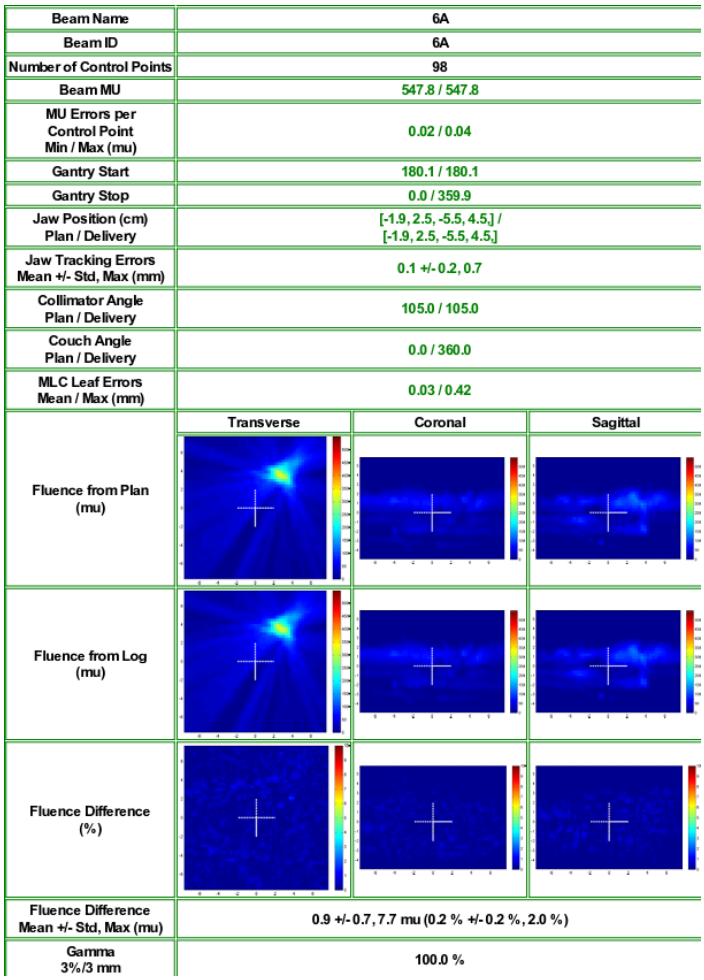

Figure 3: Trajectory log report implementation for patient-specific pretreatment QA and ongoing delivery verification.

4 Discussion

While numerous Trajectory Log analysis tools currently exist, complete integrations with commercial TPS and RDS systems have yet to be explored. Small variations exist within the solutions tested for interpreting trajectory log files, but based on the magnitude of these variations, the cause is more likely a consequence of different implementations of the CSV writing methods as opposed to differences in the data-types between python and C# floating point precision (16-bytes vs 4-bytes for python and C#, respectively). With the increased implementation of workflows leveraging TPS APIs, performing this analysis within the same software framework allows for enhanced integration with clinical tools. This .NET Framework solution is available open-source with installation and use instructions at https://github.com/WUSTL-ClinicalDev/TrajectoryLog.NET, and installed within the nuget package management system for streamlined implementation into Visual Studio.

Two separate applications leveraging the TrajectoryLog.NET API show the APIs immediate utility in both periodic linear accelerator QA and patient-specific QA. Both applications still require further investigation. The Respiratory Gating QA Analysis application would benefit from further exploration of various trajectories and baselining of expected dose rate hysteresis (as seen in the center plot in Figure 2) as the gating window is entered.

Initial implementation of patient-specific trajectory log QA analysis has several benefits to our institution's current solution. With integration of the log analysis into the same framework as the TPS API, DICOM file export is no longer required since the reference trajectories can be acquired directly from planned control points. This simplified workflow also allows for the report implementation as an *on-demand* evaluation during weekly chart checks. Additionally, utilizing an independent API allows for new machine configurations, such as RDS and future linac models, to be included in the API without impacting the client application.

5 Conclusion

TrajectoryLog.NET is a new application programming interface for the consumption and interpretation of binary machine logs acquired during treatment delivery. Trajectory log analysis is a valuable component to quality assurance for various scenarios and can be implemented in an automated fashion with custom software. To show the benefits to integrated trajectory log file interpretation, two sample applications have been developed to evaluate trajectory parameters during a gated delivery and perform basic parameter validation between planned and treated parameters for a new RDS LINAC configuration.

PARADIM: a platform to support research at the interface of AI and medical imaging

Yannick Lemaréchal[2], Gabriel Couture[2], François Pelletier[1], Pierre-Luc Asselin[1], Ronan Lefol[1], Samuel Ouellet[1], Leonardo Di Schiavi Trotta[1], and Philippe Després[1,2]

[1]Département de physique, de génie physique et d'optique, Université Laval, Québec (Québec), Canada.
[2]Centre de recherche de l'Institut universitaire de cardiologie et de pneumologie de Québec-Université Laval, Québec, Québec, Canada.

Abstract This paper describes a digital infrastructure designed to support AI research in medical imaging, with a focus on Research Data Management best practices. The platform (PARADIM, Platform for the annotation, reuse and analysis of medical images - *Plateforme d'Annotation, de Réutilisation d'Analyse D'Images Médicales* in French) is rooted in the FAIR principles, through strict compliance with the DICOM standard, and aims at fulfilling several needs arising from the research community at the intersection of AI and medical imaging: robust data curation procedures, responsible data access and effective data governance, robust de-identification and annotation pipelines, and streamlined data operations (e.g. model training, analysis). The platform, built from open-source components, is designed to facilitate and automate the execution of large-scale, computationally-intensive pipelines (e.g. automatic segmentations, dose calculations, AI model training). PARADIM fills a gap at the interface of AI and medical imaging, where data and digital infrastructures were historically not given the attention and resources they deserve.

1 Introduction

Considerable resources have been allocated to advancing AI in recent years. Meanwhile, investments have been relatively scarce in elements fueling AI, namely data and the fabric that supports it, digital infrastructures. Research and development efforts towards data and infrastructure appears essential for AI to fulfill its promises. This paper describes a digital infrastructure designed to support AI research in medical imaging, with a focus on Research Data Management (RDM) best practices. The platform (PARADIM, Platform for the annotation, reuse and analysis of medical images - *Plateforme d'Annotation, de Réutilisation et d'Analyse D'Images Médicales* in French) is rooted in the FAIR principles [1], through strict compliance with the DICOM standard, and aims at fulfilling several needs arising from the research community at the intersection of AI and medical imaging: robust data curation procedures, responsible data access and effective data governance, robust de-identification and annotation pipelines, and streamlined data operations (e.g. model training, analysis). The development of PARADIM is inspired by the data-centric AI movement – stating that models are mature but quality data to train them are lacking – and by MLOps/DataOps approaches where research activities are integrated as much as possible in the operations of the healthcare enterprise. The platform, built from open-source components, is designed to facilitate and automate the execution of large-scale, computationally-intensive pipelines (e.g. automatic segmentations, dose calculations, AI model training). It is also well-suited for federated learning approaches, where models (but not data) are exchanged across institutions [2]. The platform stems from work presented at the 19th ICCR, which featured the use of Orthanc [3] as a research DICOM server [4].

2 Materials and Methods

2.1 Overview

The PARADIM architecture is presented in Figure 1, showing the main technological components of the platform as well as high-level functionalities. The components are deployed in two distinct environments (blue and orange zones in the figures), corresponding to network areas belonging to the medical institutions on one hand and to other service providers on the other (in this case VALERIA, institutional Research IT services at Université Laval). From a legal perspective, at least in the jurisdiction PARADIM is deployed in (Québec, Canada), data containing Personal Health Information (PHI) can only reside in the medical network area; they must be de-identified before they can be transferred outside this domain. The de-identification component of PARADIM (Karnak) therefore lives in this area. De-identified images are then transferred to the main PARADIM ecosystem (orange frame in Figure 1) where they are stored in a DICOM server (Orthanc) [3]. An authentication/authorization layer (Kheops) manages access to images, either through a web portal (identities managed by institutional AzureAD) or through an API (revocable tokens). This component (Kheops) is the main entry point to images, by humans or machines, and allows the creation of image collections that can be enriched with annotations, typically by medical experts contouring regions of interest. The rest of the platform is dedicated to data operations (e.g. model training), which are orchestrated by a custom-built job dispatcher handling containerized applications. Components are deployed in an institutional OpenShift (RedHat) Kubernetes environment, and the majority of them offer a web-based interface and REST API functionalities that are used for orchestration and connectivity.

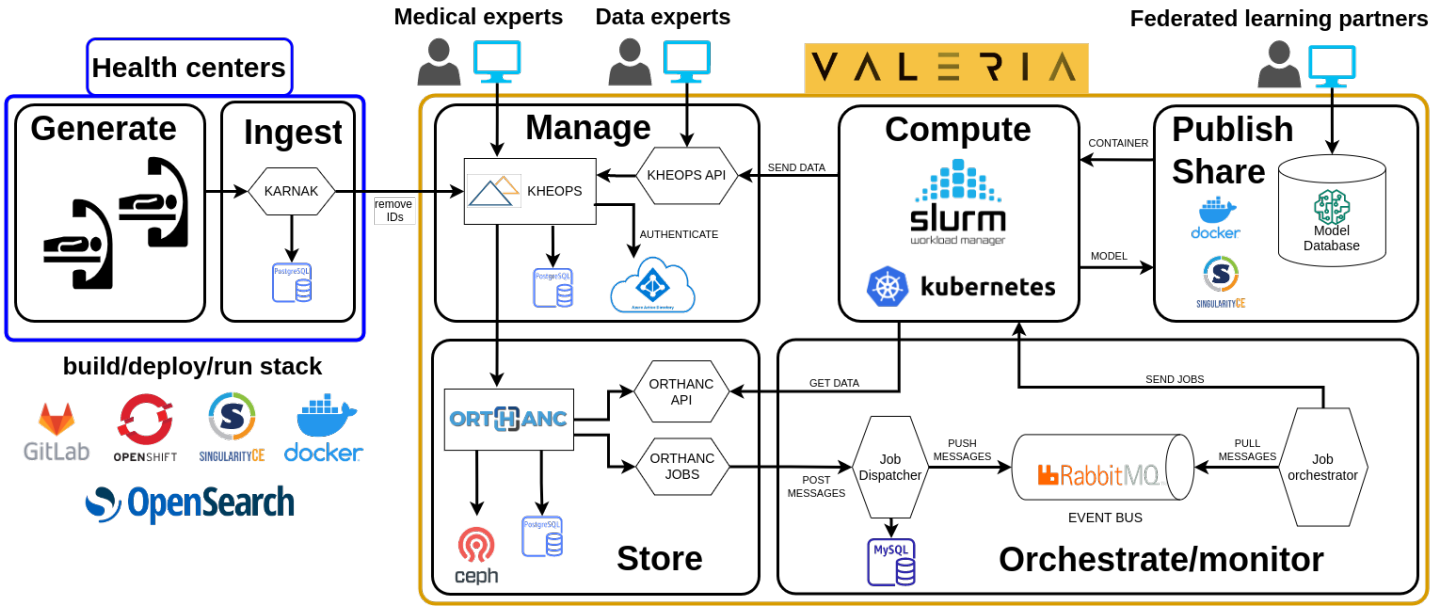

Figure 1: High-level system architecture of PARADIM.

3 Data de-identification

The Karnak software developed by the Osirix Foundation [5] is used in PARADIM as a DICOM de-identification gateway. Karnak provides several functionalities related to data ingestion and de-identification, which is not trivial considering the large number of DICOM tags that can contain PHI. De-identification, as offered by Karnak, typically consists in applying the default de-identification profile defined in the DICOM standard and to add customizations (e.g. keep the original value of a particular field, replace with a fixed value, or shift dates by a random number of days). It is also possible to apply a mask to images, which is useful to remove information engraved in images. De-identification profiles can be defined and reused in Karnak, depending on the requirements of each project (some project might actually need PHI to conduct research activities [6]). Karnak can generate new IDs for patients (based on hash+salt) or use a list provided by users mapping identities. The Clinical Trial Study DICOM module is used to document project information upon ingestion of images in PARADIM (including ERB approval number and type of consent associated with images). This marking of images on ingestion facilitates long-term management with respect to ERB and/or legal approvals.

3.1 Storage backend

Basic data management functionalities in PARADIM are provided by an Orthanc server [3], which natively manages DICOM instances and can be customized and extended in a modular way. In PARADIM, the Python plugin is used to notify the arrival of new studies and series, and to add new endpoints to the existing API. The DICOMweb plugin provides an unified interface to communicate with Orthanc, while the PostgreSQL plugin is used to store the main DICOM tags in a robust database for increased performance. Additional elements were added to the main DICOM tags list to interface with external components such as the OHIF viewer [7]. The AWS S3 plugin was configured to use the Ceph (RedHat) storage provided by our institutional research IT services. DICOM instances stored in Orthanc are immutable; additional information such as annotations, segmentations or derived information are stored in distinct DICOM objects within a study.

3.2 Data governance

Orthanc is well-suited to act as a DICOM data store but has limited functionalities to implement data governance rules, including user management, authentification and authorizations. For these purposes, the Kheops software component developed by the Osirix foundation was used [5]. Kheops uses an album system to constitute image collections, allowing DICOM studies to belong to several albums. Album parameters and metadata generated by Kheops are stored in a dedicated PostgreSQL database. Each album is managed by a data steward who controls access and rights, including adding and removing data or users, and the permission to share or download data. In PARADIM, identities are managed through our institutional AzureAD instance providing single sign-on (SSO) and multifactor authentification (MFA) functionalities. Revocable access tokens can be generated within Kheops to allow services to access specific data collections. Kheops therefore acts as an auth/autz layer on top of Orthanc, with functionalities mainly related to the curation of image collections. An NGINX reverse proxy was set in front of Orthanc to receive network requests and set up Cross-Origin Resource Sharing (CORS) rules that will limit sharing to certain authorized external applications only, including Kheops.

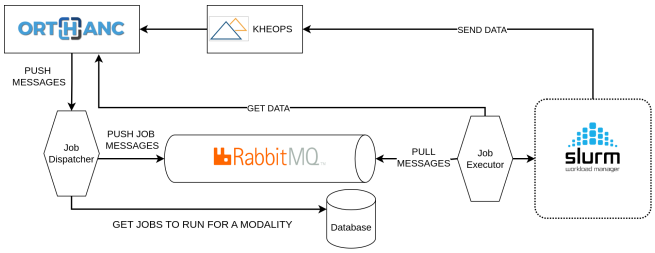

Figure 2: Job dispatching and execution in PARADIM.

3.3 Data analysis

Given the relative complexity of curating data and training AI models, it is important to rely on robust, traceable and ideally automated methods to generate results, even more so that research activities at the interface of AI and medical imaging require significant and expensive computational resources. PARADIM was designed with this in mind, and provides functionalities to automatically trigger compute jobs, and capture execution artefacts (e.g. logs) and metadata on all data operations, from annotations to versions of software used in analysis. These traces are kept in DICOM SR objects and stored along data within studies.

PARADIM users are required to provide their code in application containers that respects the Open Container Initiative specifications. These containers are stored in a private registry, and require only two parameters for execution: one input and one output directories. Internally, user-provided containers are converted to Apptainer images. PARADIM enforces the use of the DICOM format as input and output for all applications. Code snippets and utility functions packaged in libraries (PyOrthanc [8], PyGRPM [9]) are provided to users to ease the capture of execution artifacts and to convert to other formats (e.g. NifTI) if necessary, as some libraries natively require them.

For job execution, two software components were developed: a job dispatcher and a job executor. The first one is connected to the Orthanc API, which triggers contextual messages upon the reception of new images (e.g. a new lung CT study was received). These are sent to a message bus (RabbitMQ) acting as a buffer preventing the overload of compute instances. Messages accumulated in the bus are consumed one by one by the job executor, which 1) gets the relevant patient, study or series associated with the SeriesInstanceUID 2) generates a Slurm script containing the appropriate parameters for job execution. The data and the Slurm script are sent to compute resources and the job executor notifies the job dispatcher that a new job was submitted. Figure 2 illustrates the process.

In addition to jobs triggered by new images received on the platform, it is also possible to launch job manually, either from the command line or through a GUI developed with Streamlit.

3.4 Deployment environment

Components of PARADIM were deployed on our institutional OpenShift (RedHat) platform, using a DevOps-type continuous development and release approach orchestrated by GitLab. Files in YAML format define the different Kubernetes resources to deploy as well as the required resources. It also includes the number of replicas to deploy to ensure high availability, as well as the network configuration, such as the ports to open. All applications can be scaled except the RabbitMQ component to avoid concurrent access problems. Resources can be quickly redeployed or terminated using the GitLab task scheduler. Probes were developed to periodically enquire the state of applications. In case of failure, notifications are sent by email using the SysDig tool provided by our institution. Sensitive variables and information, such as database access, are managed with the GitLab Secrets Manager and dynamically inserted into configuration files during deployment.
Deployed instances, called pods in the Kubernetes nomenclature, are accessible inside the platform through services, and from outside through routes. For example, Orthanc has no external route, and Kheops accesses it through a service. However, Kheops is open to the external network (and users) through routes. The platform lives inside the institutional network, accessible either from campus or via a VPN connection. In all cases, connections are made with the TLS security protocol, with institutional certificates.

4 Results

This section presents use cases of PARADIM, for which the platform was instrumental in automating tasks or in capturing expensive information such as image annotations.

4.1 Annotation pipeline

One of the first use of PARADIM was the capture of image annotations by medical specialists. This information can be considered expensive, in terms of time and expertise, and it is crucial to preserve it on the long term, along with contextual details (e.g. who, when, how). Annotations often act as ground truths in AI project and in this regard they deserve robust methods for preservation and documentation. The current annotation pipeline in PARADIM is based on the use of 3D Slicer [10] and its QuantitativeReporting plugin [11]. 3D Slicer is used to fetch data from the platform (through authenticated DICOMweb transfers), to capture the name of the operator (stored in the ContentCreatorName DICOM attribute), to perform lesion contouring tasks, and to encode everything in DICOM objects containing as much metadata as possible (e.g. dates, software versions). This pipeline was successfully used at our institution to create lesion segmentations on CT for a cohort of approximately 2000 patients in lung cancer. It allows us to keep track of who made the

annotations, when, and in which context. Considering that machines are poised to increasingly perform this type of task in the future, keeping a record on the origin of information is of paramount importance. For the particular case of lung lesion contouring in CT, capturing the annotator identity led us to unveil discrepancies in contouring methods used by different individuals – an important information that can have an impact on results generated.

4.2 Automated tasks

AI models are rapidly becoming commodities that can be consumed from various outlets (e.g. HuggingFace, MONAI), and integrated into complex pipelines. PARADIM facilitates this process and provides functionalities to automate it. As a proof of concept, the TotalSegmentator model [12] was integrated in a pipeline triggered each time a CT study of the thorax is received on the platform. This automatically created DICOM RTSTRUCT objects in the study, with rich metadata (e.g. execution log, software version). A database keeps track of objects created by a particular model, so that subsequent calls will not generate calculations unless the model version (in the container registry) is different. This MLOps/DataOps approach allows for large scale computational endeavours and continuous monitoring of model performance.

4.3 Monte Carlo calculations

Another use case, different from AI-based tasks, is the automatic recalculation of dose maps for brachytherapy cases [13]. The code was provided in a Docker container, stored in the registry, converted to an Apptainer format, and made available in the job dispatcher database. Each RTPLAN modality delivered on the platform triggers a calculation using this container (which also requires RTSTRUCT and CT images to generate results). The entire recalculation pipeline can be re-triggered manually on demand. This kind of automation streamlines the production of results and fosters the transition from research to the real world, through robustness and reproducibility. From a user perspective, the complexity related to storage and computing resources dispatching is masked.

5 Discussion

PARADIM fills a gap at the interface of AI and medical imaging, where data and digital infrastructures were historically not given the attention they deserve. Several improvements are planned for the future, including a fully web-based annotation pipeline (3D Sclicer client currently required), an interface with tools to extract semantic information from radiology reports and better support for whole-slide imaging in digital pathology. Scaling resources on-demand to external providers (cloud bursting) is also planned to deal with large computational tasks.

6 Conclusion

The PARADIM platform was designed to store, manage, enrich and responsibly access medical images in a data science context. It relies on the DICOM standard for maximal interoperability, and facilitates the execution of complex pipelines. It is used by several research teams for various tasks, and keeps track of as much information as possible on data operations, aligned in this regard with the FAIR principles of research data management.

pyCERR – A Python-based Computational Environment for Radiological Research

Aditya P. Apte, Aditi Iyer, Eve LoCastro, Sharif Elguindi, Jue Jiang, Jung Hun Oh, Harini Veeraraghavan, Amita Shukla-Dave, Joseph O. Deasy

Department of Medical Physics, Memorial Sloan Kettering Cancer Center, New York, USA

Abstract A Python-native, GNU-GPL copyright software framework, pyCERR, for commonly used radiological image data formats is presented in this work. It enables researchers to organize, access and transform metadata from high dimensional, multi modal datasets to build cloud-compatible workflows for Artificial Intelligence (AI) modeling in radiation therapy and image analysis. pyCERR provides an extensible data structure and a Viewer to allow for rapid prototyping. Various modules are provided to facilitate analyses including metrics for comparing image segmentation, Image Biomarker Standardization Initiative compliant radiomics, radiotherapy Dose Volume Histogram-based features, convolutional neural network-based models for image segmentations, normal tissue complication and tumor control models for radiotherapy and deformable image registration. pyCERR integrates with Jupyter notebooks, GitHub, the Napari viewer, and cloud services. In summary, pyCERR provides an end-to-end radiological image analysis framework to facilitate reproducible research and seamless integration with cloud platforms and clinical systems.

1 Introduction

A computational Environment for Radiological Research (CERR) platform[1], developed in MATLAB programming language has been widely used and adapted for various medical physics applications over the past decade due to its robust and easy to use data structure and visualization capabilities. These include prototyping Intensity Modulated Radiation Therapy (IMRT) optimization algorithms[2], outcomes modeling [3, 4], film dosimetry QA[5], quality assurance of RT and imaging data by leading quality assurance centers[6], CNN-based training and inference[7]. CERR's flexible data structure has been extended by several plugins such as segmentation benchmarking software developed by AAPM TG 211 [8]. While CERR has been tremendously useful in clinical research, it is limited by the requirement of MATLAB license for development. This is especially crucial in cloud-environments where open-source programming languages offer ease of use as well as readability of the underlying codebase. Python has emerged as the language of choice for research, serving as a glue language for various software libraries. Python's scientific computing and visualization libraries now offer functionalities that are on par or better than MATLAB and its toolboxes for medical image processing.

pyCERR maintains the flexible, readable data structure and graphical user interfaces of CERR platform while providing relevant tools in a Python programming environment, enabling access to cutting edge AI modeling and image processing libraries for local and cloud friendly workflows.

2 Materials and Methods

The components of pyCERR can be broadly categorized as (1) Data container (2) Visualization and (3) Analysis modules.

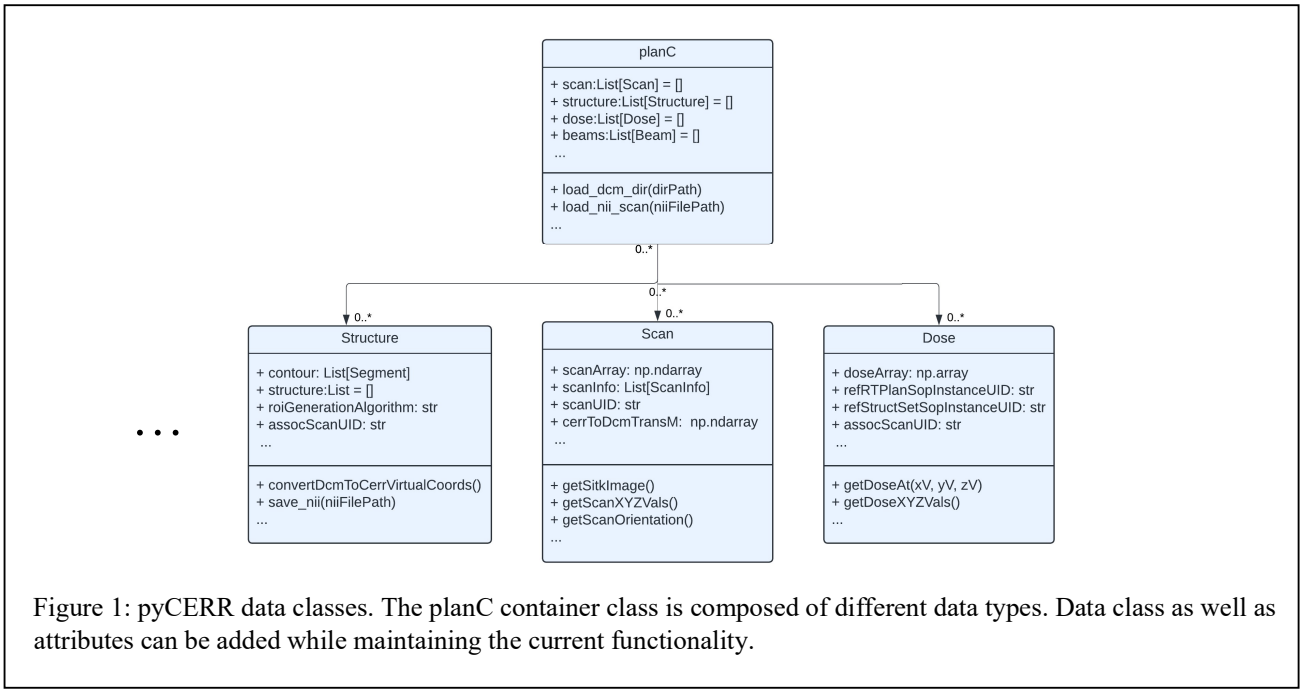

Figure 1: pyCERR data classes. The planC container class is composed of different data types. Data class as well as attributes can be added while maintaining the current functionality.

Data container: The central idea of pyCERR is to provide consistent data structure for metadata from different file formats. The plan container class planC houses data classes containing attributes for various data types. These include (a) Scan for imaging data such as CT, MR, PET, (b) Structure for image segmentation, (c) Dose for RT dose, (d) Beams for RT Plans as well as derived data types such as deformable registration. Figure 1 shows schematic of data classes including some of their attributes and routines for data access and transformation.

Modules are provided for importing and exporting imaging data between DICOM and NifTI formats as well as conversion to SimpleITK[9] Image object. Pydicom[10] is used to read and write DICOM, Nibabel[11] to write to NifTI and SimpleITK to read ITK-compatible formats such NifTI, MHA, NRRD. Data attributes in planC container can be readily accessed for analyses, edited and saved to DICOM and NifTI file formats.

pyCERR currently imports metadata from DICOM RTSTRUCT and SEG segmentation modalities, scan modalities CT, MR, PET and radiotherapy dose modalities RTDOSE and RTPLAN. pyCERR also supports import of Scans, Segmentations and Doses stored in various research friendly formats such as NifTI, NRRD, MHA etc. to planC container. Segmentation is stored as polygonal contours and is converted to as binary mask and vice-versa. pyCERR provides utilities to convert PET images to SUV units using normalizations such as Body Weight, Body Surface Area, Lean Body Mass [ref] approaches. pyCERR supports time series dynamic scan sequences such as DCE MRI as well as diffusion weighted imaging. Image volumes are organized by time or b-values. MRI images are converted to real world units using vendor-specific private tags.

Visualization: Multi-dimensional image viewer Napari[12] is perfectly suited for pyCERR's multi-modal data structure. As Napari is written in Python programming language, it saves users from passing data back and forth between viewers in other languages such as ImageJ[13] and 3D Slicer[14]. Napari ecosystem consists of fast-growing list of plugins geared towards image analysis. These include microscopy datasets and Segment Anything Model[15]. To our knowledge, pyCERR is the only software platform that enables visualization of radiotherapy data in Napari. The viewer module in pyCERR provides routines to visualize scan, segmentation, and dose data types. Currently, pyCERR provides widgets to window scans and to segment them by leveraging Napari's labeling tools.

Analysis modules: Organization of imaging data in plan container enables efficient access to the underlying data elements and their relationships for building modules for analyses. Modules for data transformation, radiomics, dosimetry features, segmentation evaluation and outcomes explorer are included with pyCERR. Data transformations include tools for post-processing results of image segmentation such as smoothing contour polygons, connected components filtering, resampling and copying segmentation and doses from one scan to another. Radiomics module in pyCERR provides IBSI1 compliant scalar features and IBSI2 compliant filters. Feature and filter computation is entirely Python-based and makes use of vectorized code using Numpy arrays for speed. Filter response of IBSI2 filters is stored in planC which facilitates visualization and analysis. pyCERR provides dose volume histogram (DVH) based features such as Vx, Dx, MOHx, MOCx.

3 Results

pyCERR package is distributed under an open-source, GNU GPL license at https://github.com/cerr/pyCERR. pyCERR can be installed from the GitHub repository by using Python package installer pip. Tests for various modules including IBSI compliant feature calculation, conversion of data between various formats are distributed with pyCERR. These are run at every code update to GitHub repository. Notebooks demonstrating various use cases are provided at https://github.com/cerr/pyCERR-Notebooks to provide a starting point for analyses. Following are some common use cases:

(1) Copying segmentation from ome image to other: In image analysis applications involving feature extraction, AI and multi-modal images, segmentation from one modality is used on another scan in the same physical space. pyCERR provides efficient routines to copy over segmentation between scans.

Define Paths for scans and segmentation

```
origNiiScan = r'path/to/original_scan.nii'
origNiiStr = r'path/to/original_seg.nii'
resampNiiScan = r'path/to/smore_resampled_scan.nii'
outputNiiStr = r'path/to/output_resampled_seg.nii.gz'
```

Import scans and segmentation to planC

```
from cerr import plan_container as pc
planC = pc.load_nii_scan(origNiiScan)
planC = pc.load_nii_scan(resampNiiScan, planC)
assocScanNum = 0 # index of the original scan
structName = 'tumor'
planC = pc.load_nii_structure(origNiiStr, assocScanNum, planC, labels_dict={1: structName})
```

```
print("Number of scans:" + str(len(planC.scan)))
print("Number of structures:" + str(len(planC.structure)))
```

Copy segmentation from the original scan to the resampled scan

```
from cerr.dataclasses import structure as cerrStruct
structNum = 0
scanNum = 1
planC = cerrStruct.copyToScan(structNum, scanNum, planC)
print("Number of structures:" + str(len(planC.structure)))
```

Figure 2: Notebook demonstrating copying segmentation between scans.

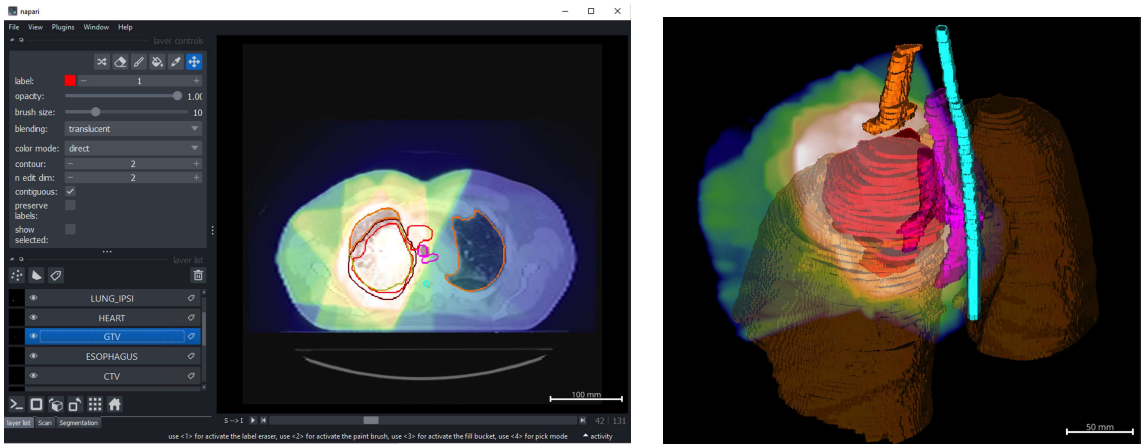

Figure 3: Radiotherapy Does distributions can be visualized along with structures in 2D and 3D. Display settings such as Window, transparency, gamma can be adjusted from GUI or command, thus making it suitable for capturing screenshots in batch mode for large number of datasets.

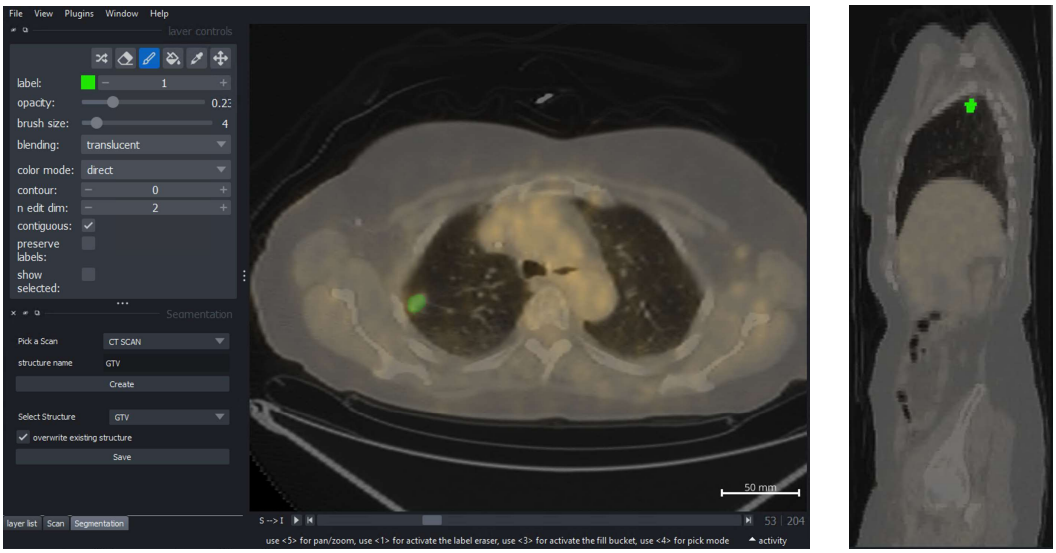

Figure 4: Contouring tools in pyCERR. Segmentation Widget provides the ability to create and edit structures. This is useful to edit contours resulting from auto-segmentation as well as to generate new structures. Napari provides Paintbrush, Eraser and Fill tools for editing segmentation / labels.

(2) Visualizing a batch of datasets

pCERR's Viewer module provides routines to overlay imaging data from the planC container such as scans, doses and structures as demonstrated in figure 3. These routines can be used locally in an interactive mode or on a remote server to capture screenshots. https://github.com/cerr/pyCERR-Notebooks/blob/main/batch_visualize_scan_seg_ex1.ipynb notebook demonstrating capturing screenshots for a batch of DICOM datasets on Google Colab platform.

(3) Image segmentation:

Manual segmentation is required to generate ground truth data for model training as well as editing the output of AI segmentation for downstream use. pyCERR provides segmentation widget which can be used on all of the orthogonal views while overlaying multiple images such as PET and CT as demonstrated in figure 4.

(4) Radiomics and DVH-based metrics calculation:

pyCERR provides "*radiomics*" and "*dvh*" modules to support feature extraction from scan and dose datasets. The *radiomics* module provides routines for IBSI-1 and IBSI-2 compatible feature extraction. The dvh module provides ability to compute commonly used metrics with user defined dose bin width.

```python
import os
from cerr import plan_container as pc
from cerr.radiomics import ibsi1

featList = []
idDict = {}
writeHeader = True
for pt_dir in all_pat_dirs[:5]:
    _, id = os.path.split(pt_dir)
    print("Data dir :" + id)
    planC = pc.load_dcm_dir(pt_dir)
    scanNum = 0
    structNum = 0
    featDict = ibsi1.computeScalarFeatures(scanNum, structNum, settingsFile, planC)
    idDict['id'] = id
    featDict = {**idDict, **featDict}
    featList.append(featDict)
    ibsi1.writeFeaturesToFile(featDict, csvFileName, writeHeader)
    writeHeader = False
```

(a)

```python
from cerr import dvh
structNum = 0
doseNum = 0
dosesV, volsV, isErr = dvh.getDVH(structNum, doseNum, planC)
binWidth = 0.025
doseBinsV,volHistV = dvh.doseHist(dosesV, volsV, binWidth)
percent = 70
dvh.MOHx(doseBinsV,volHistV,percent)
```

(b)

Figure 5: (a) Radiomics feature extraction for a batch of datasets: The ***radiomics*** module provides flexibility of selecting scan and segmentation objects from planC as well as specification of settings via JSON configuration file (b) DVH feature extraction: The ***dvh*** module provides routines to obtain RT dose within the segmentation, accumulation of dose values into histogram and calculation of scalar metrics.

4 Discussion

Napari is a relatively new project compared to more established viewers such as ITK-SNAP[16] and 3DSlicer. While the underlying Napari features are being continually updated, it is the only Python-based viewer with such as a rich feature set. Napari being a generic image viewer, supports visualization of various data types such as shapes, vectors, labels, images and allows defining custom callback events. This enables users to customize pyCERR's visualization tools as per their use cases. Additionally, pyCERR will be able to make use of incremental features on Napari's development roadmap including support for orthogonal view planes, grouping of display layers and viewing remote datasets.

5 Conclusion

pyCERR provides comprehensive tools for radiological and radiotherapy research, and leverages open-source formats and tools, including a rapid prototyping framework to train and infer from AI models. pyCERR hence facilitates reproducible research.

A system of governance for use of scripts in a commercial treatment planning system

Kenton Thompson[1], Keith Offer[2], Glen Osbourne[1], Catherine Lawford[2], Alan Turner[1], Sandro V Porceddu[3,4,5], and Tomas Kron[2,4,6]

[1]Department of Radiation Therapy, Peter MacCallum Cancer Centre, Melbourne, Australia
[2]Department of Physical Sciences, Peter MacCallum Cancer Centre, Melbourne, Australia
[3] Department of Radiation Oncology, Peter MacCallum Cancer Centre, Melbourne, Australia
[4]Sir Peter MacCallum Department of Oncology, University of Melbourne, Melbourne, Australia
[5] University of Queensland, Faculty of Medicine, Queensland, Australia
[6]Centre for Medical Radiation Physics, University of Wollongong, Wollongong, Australia

Abstract Scripting has become common practice to enhance radiotherapy treatment planning and extract additional information for decision making and research. However, scripts are not part of the commercial planning software that has been approved for clinical use by an appropriate authority. As such we have developed a process that requires scripts to be discussed by a multidisciplinary group, undergo appropriate testing and be signed off by a member of the department's executive.
Since 2019 sixteen scripts have been authorized for use in our Varian Eclipse treatment planning system. While most of them are 'plug in' and 'read only' the process has also allowed for the use of stand-alone scripts and scripts that can write to the Eclipse database. The governance process developed encourages participation of all professional disciplines and ensures all scripts that can impact the treatment plan are documented and verified.

1 Introduction

Modern radiotherapy (RT) treatment planning is a complex process involving many steps that often are institution specific. Commercial RT treatment planning systems (TPS) allow all required steps to be performed, however they often require numerous manual interactions, such as mouse clicks, keystrokes and data entries. As such, work can be streamlined using scripting, which also helps standardising planning procedures and reduces the risk of errors. It is also an integral part of full automation of treatment planning classes.[1, 2]
Additional benefits of scripting can result in data analytics which is a powerful tool to check and document practice and evaluate its effectiveness.
However, there are risks introduced by the use of scripts - in particular if they are developed in-house and there is an indication that increasing reliance on computers reduces random errors but may increase systematic ones.[3] RT planners may not know all the available scripts and their functionality and limitations. Running scripts can slow the system down or make some data temporarily inaccessible. Also the output of the script must be verified under various conditions to ensure the results are reliable. In some cases TPS offerings scripts can not only read but also write to the database, which introduces additional risks such as incorrect data being written or corrupting information in the data base. As such, it is important to develop a governance system that can ensure that scripts:

- have functionality relevant for the department
- are tested prior to implementation
- staff appropriately trained
- actions documented
- have their use monitored.

The present paper describes the governance system used in our large multi-campus RT department to develop, implement and monitor script use in a commercial TPS.

2 Materials and Methods

Our institution uses Varian Eclipse (Palo Alto, CA) for external beam radiotherapy planning for Varian linear accelerators (linacs) operating across 5 campuses. Approximately 70% of the 7000 new patients treated annually receive VMAT based treatments with a significant number of stereotactic treatments (approximately 500). The TPS is cloud based and introduced across the campuses in 2018.
All images used for planning are imported and archived in a PACS system (Vue, Philips, Amsterdam, NL)), the plans are transferred to the linacs using ELEKTA MOSAIQ (Stockholm, SE) and patient clinical details are entered into EPIC electronic medical records system. Our department has an active research program and participates in clinical trials that can benefit from data extraction.

While scripting had been conducted in an ad-hoc basis for many years, with the introduction of the cloud-based system in 2018 it was decided to put a standardised governance structure to minimise risk and ensure sufficient oversight. To achieve this goal, a scripting governance committee (SGC) was founded with representation from clinicians, physicists, therapists and planners. The committee initially met at least six times a year and now meets on demand to review requests for scripts, monitor progress of script development and organise and review testing. The committee is chaired by the clinical coordinator radiation therapist, with all scripts requiring the final validation report to be signed off by the

director of physical sciences before deployment onto the clinical system.

The workflow is illustrated in figure 1.

As part of continuous monitoring to provide feedback to the committee on usage, all scripts log their use and additional information such as the patient they were run on and the user who ran the script as well and time and date.

3 Results

The process of introducing a script in the planning environment consists of several steps:

- Request for a new script or functionality to the SGC by any member of the department.
- Review of the request by SGC, assessment of feasibility and prioritization.
- Assignment of staff for script testing and implementation
- Scoping of the script to specify exact functionality and behaviour
- Realisation of the script and installation in a non-clinical Eclipse environment for testing
- Testing and validation
- Review of the testing results and sign off by the director of Physical Sciences
- Deployment of the script to the clinical Eclipse environment

The frequency of SGC meetings is determined by the number of scripts requested and in development.

At present 16 scripts are accessible within the planning environment with the vast majority requested by radiation therapists who are also the profession performing treatment planning. Scripts are categorized by their functionality and their interaction with the TPS and its database. In Eclipse scripts are classified into two main categories of scripts:

1. Plugin scripts can access a single patient's worth of data at a time
2. Standalone scripts can access all patients in the database

Further, scripts are read-only by default, but can be marked as 'write-enabled' to allow them to change some parts of the data within the TPS for the open patient, such as changing contours, fields, plans etc. These different categorisations allow for scripts to be given the minimal permissions required for operation, limiting risk.

Fourteen of the 16 scripts are plug in and as such only affecting one patient at the time. Of these three do not just read data but also have the capability of writing data such as deleting empty contours or creating new contours based on geometric operations from existing contours or dose distribution.

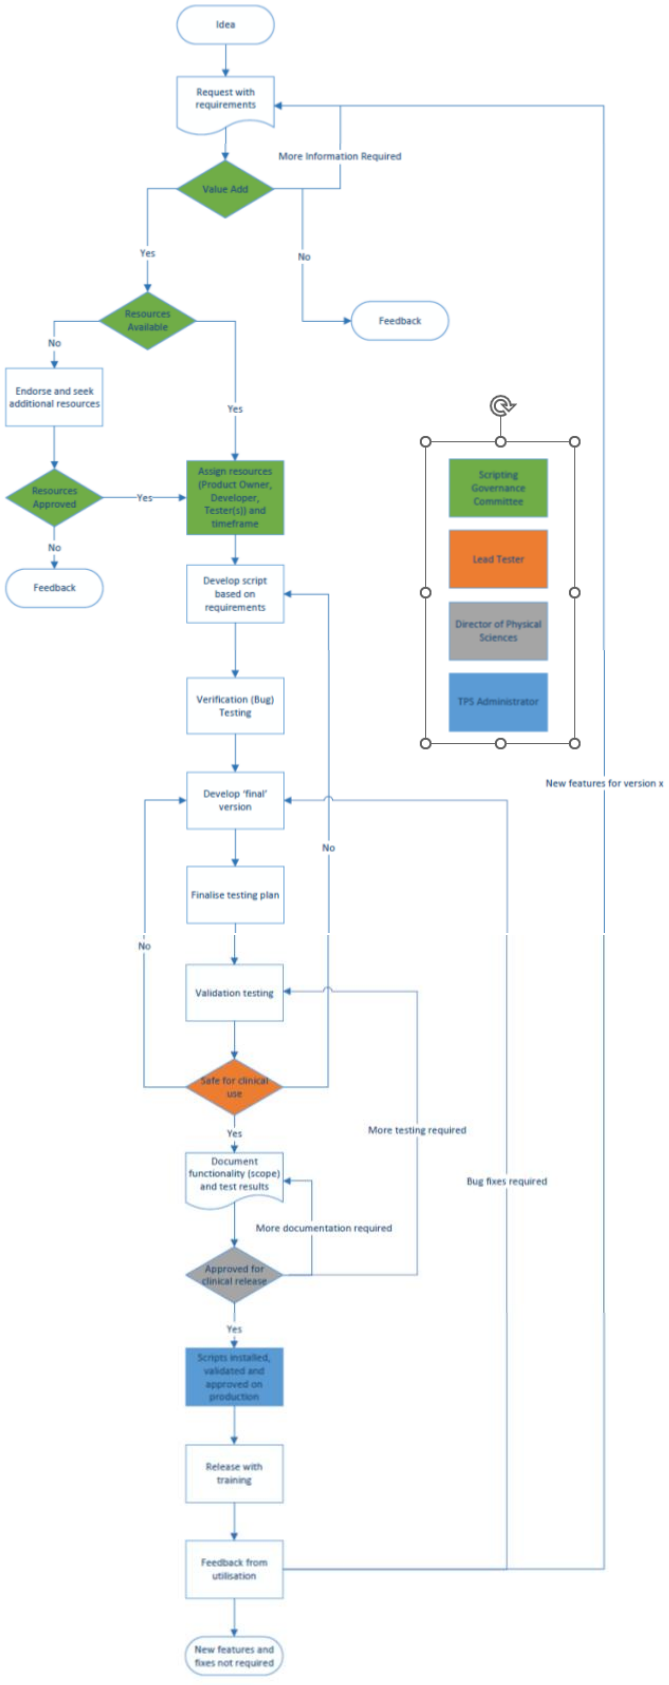

Figure 1: Workflow for script development

The two stand-alone scripts operate on multiple patients and plans based on a list of plans provided by the user. These are powerful tools for quality improvement and research. Examples are exporting dose, plan and structure metrics or planning objectives.

The use of all scripts is monitored both to provide feedback on script usage and estimation. It was found that monitoring execution time of scripts as a surrogate for system load was poor, as often scripts were left running after calculations were complete.

Monitoring use revealed that scripts have been run more than 225,000 times across over 18,000 patients by over 400 users. Scripts are most often run by radiation therapists (~76%) and physicists (~23%) and a small number of executions by radiation oncologists (<1%). The scripts executed the most often are those that aid plan checking [4] and comparing plans against internal protocols.

4 Discussion

Governance in clinical processes has always been an important part of practice. There has been awareness of this in radiotherapy for some time [5] and the recent growth of machine learning and artificial intelligence has put this questions firmly on the agenda [6]. However, there is relatively little published about governance of in-house developed software beyond the validation stage.

Shortcomings of our current processes pertain to the limited involvement of clinicians and the lack of structured monitoring of the performance of scripts in the case of software and hardware changes. In a busy clinical environment, it is also difficult to find the time for the SGC to meet and there is concern about the length of time required to bring something that is ‘obviously needed’ into the clinical environment.
We are considering a more formal risk assessment process [7] to inform the testing of scripts. However, on balance, even ‘obviously needed’ scripts need to be validated to a sufficient depth to ensure correct operation.

5 Conclusion

An important tool in the automation of processes is scripting. We have developed a process that formalises script development and employment in a clinical TPS and provides a governance structure for associated processes. There is no doubt that scripting can improve efficiency and standardization of radiotherapy treatment planning and typically also leads to a reduction of errors. However, given the potential risks a robust system of governance is required to control, validate, and monitor the development and use of scripts.

QuAAC: An interoperable routine quality assurance data format

James Kerns[1] and Randle Taylor[1]

[1]Radformation, New York, NY, United States of America

Abstract A new data format is proposed for the interoperability and exchange of routine machine quality assurance data between in-house and commercial software. The format is flexible for multiple workflows, is human-readable, and uses common standards available today.

1 Introduction

Routine machine quality assurance (QA) is a constant consideration for the clinician. Recommendations from governing bodies [1, 2] include tests that should be performed at various frequencies. Depending on the complexity of the QA, the clinician may be interacting with multiple softwares to complete it, whether a simple spreadsheet or dedicated applications for advanced tasks such as image analysis or statistical process control. This data can also be in multiple formats such as simple text files, spreadsheets, or databases.

The clinician is often faced with the task of organizing this QA data for one of several purposes such as preparing for an audit by governing authority, creating an off-site data backup, or refactoring the QA program as would be the case when introducing a new application or workflow to the QA process. This process can be daunting considering the above issues as well as the cognitive load.

This work aims to present a new data format specifically aimed at QA data called the Quality Assurance Archive & Communication (QuAAC) standard. The goal is to provide a consistent representation of QA data that can be used for the purposes of backup, communicating from one in-house QA application to another, transitioning from an in-house QA flow to a commercial one, or transitioning from one commercial system to another. Each of these tasks can be difficult given the myriad data paradigms employed. In a similar manner to how the digital imaging and communication in medicine (DICOM) standard brought a standardization for communication, this format also aims to bring those same benefits for interoperability of QA data.

2 Format Specification & Design

2.1 Rationale

The project was born out of the need to store and exchange routine QA data in a vendor-neutral format, much as DICOM did [3–5]. Clinics that move between commercial vendors of QA equipment and software are often faced with the challenge of converting their data from one paradigm to another, depending on the vendor. This can also happen when migrating from an in-house solution to a commercial solution. There currently exists no reasonable standard for the storage and exchange of this QA data. This project aims to fill this gap.

One of the gaps is that of storing "interpreted" data as well as raw data. For example, when evaluating image quality metrics for a computed tomography (CT) unit such as Houndsfield (HU) uniformity, the metrics are almost always based on digital data that was acquired (such as a scan of a phantom). The clinician then interprets, either manually or via a software application, what the metric value is. In this case, both the raw data and "interpreted" data are important and should nominally be stored and referenced together. This is not limited to DICOM data however. Some QA may require manual inputs for mechanical tests, or printouts of manual safety checks such as a photocopy of a checklist performed by service personnel. The raw data in these cases may be text, screenshots, or other binary data that is important for the proper documentation of the QA performance.

2.2 Use Cases

The use cases for such a standard are many and revolve around the concept of measurements to track the constancy and performance of a machine along with any relevant metadata and ancillary data that such data is based upon. Wheras DICOM is patient-centered, this standard is unit-centered. Some examples of data the standard is meant to represent are:

- Manual measurements of radiation output (ion chamber readings, kVp measurements)
- Imaging metrics based on a DICOM image (HU uniformity, scaling)
- Manual measurements of mechanical performance (couch flex, laser drift)
- Safety output results from simulated failures (door interlocks, emergency stops)

These examples demonstrate a wide range of measurements, both manual and digital, with and without associated data that need to be recorded as part of a routine QA workflow.

2.3 Principles

The QuAAC project has several principles that drive its design and patterns:

- It should store all data relevant to the QA workflow
- It should store both raw and interpreted data
- It is not a replacement for DICOM
- It is not a QA platform
- It does not prescribe the QA workflow
- It is not for patient data
- Data is stored in a way that is readable to humans when possible
- It should use existing standards whenever possible

2.4 Comparison to DICOM

This project can be compared to DICOM as there are many similarities. The rationale of the project is similar. There is no known standard for communicating QA data between vendors nor from in-house formats to vendor formats. An obvious question is: Why not use private tags of the existing DICOM standard? Although private tags are an option, the data and format do not cleanly align with individual tags. Further, the tags and data would have to be specified just as they are for this project. A new standard also allows for using formats and options that are commonly-accepted today. Given the desire to have the data be human readable and avoid proprietary formats, simple text formats are preferred. It's also unclear how this standard will evolve. By starting with a DICOM definition only, the standard may be limited. Finally, the DICOM standard very often centralizes the patient as the foundational starting point [6]. Routine QA data applies across patients and does not share this starting point.

DICOM has 16 different parts, most of which do not apply to the requirements of the interoperability of routine QA data. The scope of QuAAC is similar to sections 3.5 [6] and 3.6 [7] of the DICOM standard.

This project proposes specific implementations, but moreso proposes a paradigm for data serialization. With this definition, it is possible to have a DICOM-specific variant of the QuAAC standard, where private tags are defined that match the overall standard.

2.5 Comparison to an API

Usage of an application programming interface (API) would in theory allow clinics to communicate with other applications. This is commonly used for server-to-server communication. This standard is orthogonal to APIs because even if both parties expose an API, there is no standard for what that API should return and how. An API could be implemented that conforms to this standard, but until both parties agree on what could and should be exchanged, the original problem remains.

3 Format

The QuAAC format proposal is to allow users to write QA data to one or more files in an easy and readable way. We propose the use of the YAML markup language as it is commonly used in many contexts, although the standard is not limited to this file type. Datetimes use the ISO 8601 definition, and data integrity uses the cyclic redundancy check (CRC) algorithm to verify the integrity of all components within the format.

As the format is explained, we will use a scan of a phantom on a CT scanner as an example.

It contains 4 top-level keys which are shown in listing 1: `version`, `data points`, `equipment`, and `files`. The `version` corresponds to the version of the QuAAC standard used, `data points` store individual datum, `equipment` references the equipment the data was measuring on, or ancillary equipment that assisted in the measurement, and `files` reference raw data that the data points were based upon, if any. The `version`, `data points`, and `equipment` keys are mandatory while the `files` section is not required if there was no separate raw data information.

Listing 1: Root format specification

```
version: 1.0
data points:
  - ...  # array of data points
equipment:
  - ...  # array of equipment
files:
  - ...  # array of files
```

The definition of the data points section is the main and longest component and is shown in Listing 2. The `hash` key is a CRC32 hash of the content of all keys in the same data point. It is worth noting that these hashes are not meant to be cryptographically secure and only function as data integrity and uniqueness checks. The remaining keys all contain information relevant to the data point. It is important to note not all keys are required. E.g. the `reviewer name` would not be required if the `review status` is unreviewed.

The `primary equipment` references the machine or unit the QA is being performed on and the `ancillary equipment` is an array of equipment that is used to assist in capturing the data point, such as an ion chamber or water tank. Both of these keys reference entries in the `equipment` top-level key.

The `files` section is an array of references to entries in the `files` top-level key.

Listing 2: Data points section

```
data points:
  - hash: 374284055
    name: CatPhan Uniformity (Top)
    performer name: Kerns, James
    performer id: jkerns
    perform datetime: 2024-01-22T13:36:47.2620
    measurement value: 43.113
    measurement type: number
    measurement unit: HU
    reference value: 40
    description: Top HU ROI of CTP486 module
    procedure: Use CatPhan 604
    performer comments: normal scan
    primary equipment: 2349277898
    ancillary equipment:
      - 90452529
    review status: reviewed
    review datetime: 2024-01-22T13:36:47.2620
    reviewer name: Kerns, James
    reviewer id: jkerns
    reviewer comments: Looks good
    files:

    content: 4sIAKxAsGUC/+y7dVBc0d...
  - ... # further entries
```

4 Discussion

4.1 Advantages

The advantages of this standard include using human-readable storage medium (text), usage of common standards where applicable (ISO 8601 [8], YAML, etc), and the ability to communicate between vendors or programs. The scope of the standard is also limited to routine QA data and thus does not aim to replace any existing standard (e.g. DICOM) and is compatible with existing forms of storage and communication. QuAAC is not trying to re-invent the wheel.

Another advantage comes from references to equipment and files. It is not uncommon to have multiple QA data points be interpreted from a single raw data source. In our ongoing example many data points can be interpreted from a single CT scan of the CatPhan including geometry, HU linearity, HU uniformity, and more. These are individual data points that all reference one data set. By using reference keys, the data storage format does not duplicate this DICOM information yet retains all the individualized information. This logic is similar for equipment, where multiple data points may be taken on one piece of equipment.

Creating a format that is easy to store and read is critical to both adoption and transparency. With the viewpoint that the QA data is ultimately the clinician's data and not that of the vendor, such a standard encourages vendors and other clinics to embrace the ease of transferring data to and from their applications, much the same way DICOM does.

4.2 Limitations

In the current state, the standard has not been tested across multiple vendors. A consortium of clinics and/or vendors would likely be needed to gain widespread adoption. There is also often a lack of initiative on the part of some vendors who might perceive the standard as encroaching on their proprietary data format, or reducing the level of vendor lock-in. Dispelling such perceptions requires the viewpoint that the QA data belongs to the clinician.

There is also no software library available yet to load from and save to this standard. However, it is currently in progress and will be released as an open-source project alongside this standard. The standard will also be incorporated into the Pylinac library so users of that software can export their data into the QuAAC format easily [9].

The QuAAC standard is meant to encompass all routine QA data generated by clinicians working with radiation-generating equipment. However, there may be missing use cases as radiotherapy is the first domain addressed currently. More research will be necessary to ensure these are accounted for, such as in the diagnostic and nuclear medicine domains.

Finally, conformance with such a standard adds a burden to all involved. This is not unlike DICOM, but given the overwhelming advantages and appreciation by all for it, the burden is well worth the effort to give more flexibility and power to the clinician to manage and maintain their own data, wherever they choose to put it.

MCMimic: a machine learning approach for fast prediction of Monte Carlo proton dose and LET

Samuel Ingram[1,2], Karen Kirkby[2,1], Ranald Mackay[1,2], and Matthew Clarke[1,2]

[1]Christie Medical Physics and Engineering, The Christie NHS Foundation Trust, Manchester, United Kingdom
[2]Division of Cancer Sciences, University of Manchester, Manchester, United Kingdom

Abstract Monte Carlo is an important technique to achieve accurate dose and LET distributions but comes with the cost of long simulation times. In this study, machine learning is utilised to build a generator able to predict both dose and LET distributions simultaneously for proton beam therapy. An adapted pix2pix generative adversarial network is trained using Monte Carlo distributions in a fully supervised learning approach. This results in the ability to predict both dose and LET at increased speeds that are similar to analytical approaches. At 1%/1mm γ, the model can predict dose at 98.36% and LET at 67.29% pass rates. When using combinations of dose and LET, typically done for radiobiological review, γ pass rates are over 90%. Integration of the model into clinical networks will allow for it's use directly from the treatment planning system. Machine learning is well suited to learning to predict Monte Carlo results.

1 Introduction

A patient's radiotherapy treatment is carefully designed to deliver optimal dose distributions that maximise tumour control whilst minimising the probability of normal tissue toxicity. This is typically achieved using commercial treatment planning systems (TPS) that often utilise proprietary analytical dose calculation systems that are very fast. This is a necessary characteristic as treatment planning is a highly iterative process which can take many iterations to achieve a clinically viable plan. However, it is widely accepted that Monte Carlo, a simulation approach, is the gold standard for accuracy. Monte Carlo can be problematic for treatment planning as it is prohibitively computationally intensive, with traditional, central processing units (CPUs) bound options taking many hours to days to calculate a single iteration and is, therefore, either entirely omitted or reserved purely for final dose checks after the planning process has been completed. There are a growing number of accelerated Monte Carlo options which utilise graphics processing units (GPUs) to speed up the simulation process, but these can often require prohibitively expensive hardware to achieve the necessary speeds required for treatment planning optimisation and patient throughput.

The issue with not being able to utilise Monte Carlo during the planning process is that the inaccuracies of the analytical calculation approaches must be acknowledged by clinicians when reviewing a plan. In proton beam therapy two groups of patients are of specific concern where quantitatively accounting for these inaccuracies would be especially impactful. Firstly, patients with high-density surgical implants experience increased proximal dose to the implant. However, commercial TPSs do not correctly model sharp changes in density, thus under-representing this phenomenon. Monte Carlo would allow for a more accurate depiction of these effects and provide confidence to the reviewing clinician of the dose delivered to neighbouring sensitive organs (e.g., spinal cord). Secondly, Monte Carlo can also provide other physical metrics which describe how the radiation is dosing the tissue. One such metric is the linear energy transfer known to alter the radiobiological effectiveness of the administered dose. Both dose inaccuracies and lack of linear energy transfer calculation result in clinicians having to make a clinical judgement without tangible quantitative values. This can result in requiring treatment plans to be re-made or if there are safety concerns it may result in the decision to decrease the dose to avoid potential normal tissue toxicity. If Monte Carlo dose distribution and linear energy transfer can be modelled at the time of planning these decisions will be better informed.

Creating Monte Carlo distributions using machine learning is a growing area of study. There has been success shown using long short-term memory (LSTM) networks [1], U-Net [2], generative adversarial networks (GANs) [3] and transformers [4]. However, these approaches have not been extended to also creating Monte Carlo LET distributions. In this study, an adapted pix2pix GAN [5] has been used to generate both Monte Carlo dose and LET simultaneously from a model called MCMimic. This method differs from the previous approach of using a GAN [3] which used a discovery cross-domain generative adversarial network (DiscoGAN) which relies on unsupervised learning, for the pix2pix framework which supports fully supervised learning. The rationale is that utilising a fully supervised learning approach simplifies the training process which is beneficial given the model needs to predict both dose and LET distributions rather than just dose. This alteration in approach and the simultaneous generation of dose and LET distributions would provide potential value in clinical decision making as it could be generated at speeds required in planning. Furthermore, the model was developed to generate a single proton spot which allows for the fast creation of influence matrices at Monte Carlo dose accuracy. This is useful for evaluating alternative optimisation approaches and can't be readily obtained from some of the commercial TPSs.

2 Materials and Methods

2.1 Training Data

The training dataset consisted of 6,400 single spots simulated using the Monte Carlo algorithm MCsquared - Fast Monte Carlo dose calculation algorithm [6]. These single spots were generated within one of ten patient CT scans at random locations and energies to obtain a patient-representative spread of density heterogeneities for the simulation. All scans were interpolated to 1 mm voxel size and all data is kept at this resolution for training. The patient cohort was chosen to cover all areas of the body to ensure the model remains robust to the various density changes seen across different sites. The number of primaries for the MCsquared simulations was adjusted to achieve a maximum of 0.5% statistical uncertainty. For LET the MCSquared 'deposited energy' scorer was used which scores a dose-weighted average of the energy loss divided by the length travelled of particles through each voxel and accounts for LET_D from secondary particles [7]. A region of interest (ROI) was created around the single-spot of size 256x64x64 to minimise the data size required for training and inference to only what is pertinent for both dose and LET. This resulted in a targeted 2x256x64x64 output array for the model, where two indexes for the 1st dimension are dose and LET respectively.

2.2 Network

To train a generative model a modified pix2pix GAN was used. Like the targeted output array, the input is also a 2x256x64x64 array. The first index for the input array is a 256x64x64 analytical Stopping Power (SP) calculation which is based on an approximation of the Bethe equation [8]. The second index for the input array is a 256x64x64 relative stopping power (RSP) representation of the CT scan. The GAN comprises a generator and a discriminator model trained in parallel. To moderate observed instability between the generator and discriminator models, the discriminator model had a minimum threshold applied to the loss for the optimisation step to be applied. This biased the training to allow the generator model to create "challenging" outputs before the discriminator would be able to improve and helped stabilise the training.

2.3 γ-Analysis

To evaluate the predicted dose against the MCSqaured Monte Carlo dose a local 3D gamma analysis was performed using the PyMedPhys (version 0.39.3) Python module at 1%/1mm with a 10% lower threshold cutoff. Gamma analysis was carried out for dose, LET, Dose*LET and the McMahon Relative Biological Effectiveness (RBE) calculation [9]. Where the former is just the element-wise multiplication of the dose and LET distributions and the latter is given by $Dose \times (1 + 0.055 \times LET)$.

2.4 Comparison Calculation Systems

AUTOMC is an in-house developed CPU Monte Carlo solution [10] built upon GATE v8.1/Geant4 v10.3.3 and simulates plans on a 2x2x2mm dose grid to an uncertainty of 0.8% within the 90% isodose contour. AcurosPT is a commercial Monte Carlo produced by Varian and is running on CPU for this study. AcurosPT was run using a default 2% uncertainty and 0.01 density threshold. Proton Convolution Superposition (PCS) is a commercial analytical dose calculation system produced by Varian and is running on the CPU.

2.5 Compute Specifications

All MCMimic work was conducted on a Ubuntu 22.04 (LTS) workstation with an Intel Core i9 10980XE CPU, 128 GB RAM and 2x NVIDIA A6000 (48 GB VRAM). MCSquared Monte Carlo simulations were done on the CPU. Input data generation, model training and inference were done using the GPU. Model training utilised both GPUs to speed up the process.

3 Results

3.1 Model Accuracy

To examine the accuracy of MCMimic a per-spot γ-analysis was carried out for a range of spots with differing energies and density paths. The MCSquared Monte Carlo was used as the reference dose and LET. The results (Figure 1) show that the model produced accurate representations of dose across all test cases with an average 1%/1mm γ pass rate of 98.36%. The produced LET distributions were less accurate with a lower γ pass rate of 67.29% with a larger variance in the prediction. However, when coupled with dose, a typical approach to giving biological significance to LET, the γ pass rates increase to 91.94% and 98.04% for Dose*LET and McMahon RBE approaches respectively. This is due to radiobiological approximations placing higher weighting on the dose than LET resulting in good predictions from the model.

3.2 Prediction Efficiency

The time required to produce the outputted dose and LET distributions were compared to a range of other solutions (details in Section 2.4). The times recorded from the other solution was to generate dose distributions only, although AUTOMC can generate LET distributions this was not scored during the comparison tests. As MCMimic always gives you both dose and LET distributions there are no timing differences for creating both distributions. Table 1 and Table 2 show that MCMimic predictions are able to produce the distributions at a significantly faster rate than the other Monte Carlo systems included in the comparison and have similar timings to the commercial analytical solution (PCS). The two

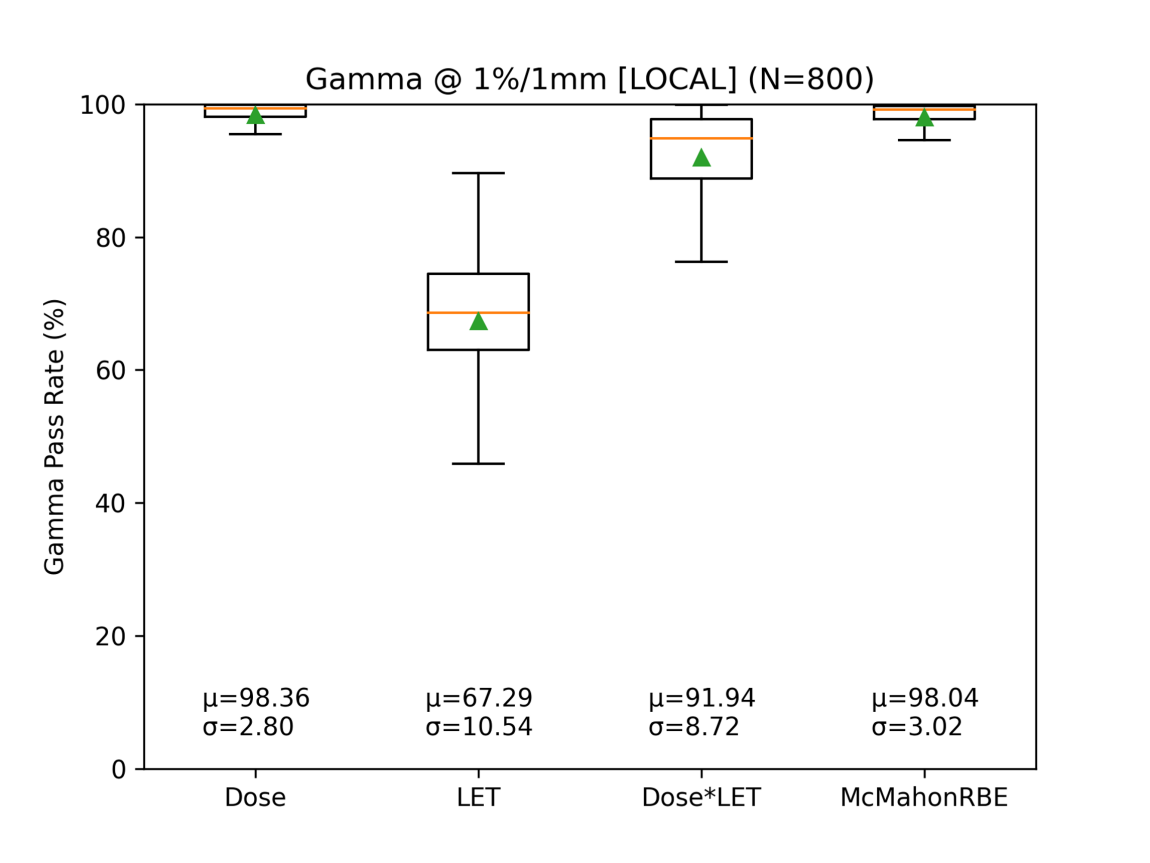

Figure 1: Box plots for the γ pass rates across a range of output distributions from the model based on 800 test spots. Dose and LET are explicitly outputted and Dose*LET and MCMahonRBE are simple combinations of the two distributions. The mean values are shown by the green triangles.

Method	Total Time (s)
AutoMC	5,330.7
AcurosPT (CPU)	126.0
PCS (CPU)	28.0
MCMimic	24.6

Table 1: Nominal 2-field Craniopharyngioma example consisting of 2,104 spots.

Method	Total Time (s)
AutoMC	59,348.7
AcurosPT (CPU)	3,600.0
PCS (CPU)	122.2
MCMimic	245.6

Table 2: Nominal 4-field Cranio-Spinal Irradiation example consisting of 26,809 spots.

nominal examples show that MCMimic plan generation time scales fairly linearly based the number of spots that need predicting, which indicates it would be a good candidate for distributed compute (multiple processors) if predictions were required at faster speeds and would scale well. Furthermore, as each spot is generated independently with its own distributions you can record the results as an influence matrix with no additional compute time required.

3.3 System Integration

For integration into the clinical workflow, careful consideration was taken on ensuring the necessary connectivity and resources were implemented within the clinical network so that MCMimic could be evaluated within a realistic setting. The integration workflow consists of using the Eclipse Scripting API (ESAPI) to trigger a DICOM daemon to push the CT and plan files to a job manager on our Scientific Compute Platform. The job manager will launch and run MCMimic with the sent CT and plan files and record the activity for monitoring purposes. The resultant dose and LET distributions will be sent back to the ESAPI which will inject the results back into Eclipse as new dose maps (LET will be shown as a dose due to not being supported in the Eclipse TPS). From the user perspective, no operations outside of Eclipse will be required by them and the resultant distributions can be viewed with the tools and views that are familiar to the end user.

4 Discussion

Modern proton beam therapy is now typically delivered using a beam scanning system where a set of magnets move the beamlet to the desired x and y position defined withing the proton treatment plan. This x and y position is true at the isocentre but includes a slight angulation to achieve this from as the beam is central before the scanning magnets. This results in beams not being perfectly perpendicular and requiring a correction method to address this. Whilst the angulation is small, given the large number of proton spots in a typical plan (1,000 - 30,000), the effect can result in an observable dosimetric difference, most notably at the patient surface. A possible correction for this, which is being evaluated, is a modification to the SP calculation using a 2D Gaussian that could be offset from the centre and, when convolved along the depth axis of the beamlet, can produce a representation of the beam steering which encodes the necessary information for the model. Whilst the alteration is small, the additional steering information being encoded results in the machine learning problem becoming substantially harder for the model to learn and requires significantly more training data. Further to this, a range of mathematical approximations for ray tracing are being evaluated along with augmenting the RSP maps to allow for perpendicular doses to be mapped back to their angled counterparts.

An alternative approach to machine learning that is growing in availability is to run the Monte Carlo simulations directly on GPUs rather than CPUs. This significantly speeds up the simulation process and can achieve similar speeds to the machine learning approaches. However, these solutions can require more GPU compute than predicting on a pre-trained machine learning model. A benefit of machine learning is that after training the model running it, also called inference, is much quicker and doesn't require the same resources. Whilst the current work has been done showing inference on GPUs it can also be done, at a slower rate, on CPUs. Furthermore, models can the quantised which can reduce the required memory to run the model and expand the places it can be run from (e.g. edge computing). Finally, with Monte Carlo, there is a trade-off between simulation quality and speed, whereas in machine learning the predictions are based on the quality of the training data, which can be simulated to very high quality given the training is only required once per version of the model.

A counterpoint to using machine learning is that the models can only be as good as the data it has been trained upon. If the model encounters anatomy that has not been seen before it could respond incorrectly. Whereas Monte Carlo remains the gold standard as it looks to simulate the underlying Physics. This means care should be taken in the way we utilise machine learning models, especially in the context of informing clinical decision-making. There is also less familiarity with machine learning within the medical physics community and the complexity of the required models used in 3D generation can make it challenging to understand and reinforce trust.

5 Conclusion

Machine learning is a viable method for predicting Monte Carlo distribution. The pix2pix framework is a good option for the presented learning problem. Understanding the limitations of the MCMimic model will be an important step to implementing it safely within a clinical context. In the meantime, it remains a valuable research tool that can quickly calculate dose and LET distributions along with influence matrices that can be used in optimisation studies.

Abstract Independent dose calculation (IDC) is an effective method to verify the planned dose in the treatment planning system before the treatment field is delivered to the patient. The open-source IDC IDEAL v1.1, using GATE-RTion v1.0/Geant4.10.3 as dose engine, is designed for the verification of dose calculation in treatment planning system for patients treated with proton and carbon ion pencil beam scanning. This study focuses on carbon ion only and investigates the GATE-RTion/Geant4 parameter settings, e.g. Geant4 reference physics lists, electron production cut, in search of the optimal simulation setting balancing speed and accuracy. Over the clinical energy range of 120-400 MeV/u, key pencil beam parameters were simulated, and compared with reference dosimetric commissioning data set of two clinical carbon ion beamlines at MedAustron Ion Therapy Center. Twenty spread out Bragg peaks of cubic targets of field size of 3-17 cm, modulation length of 3-10 cm and center at depths of 4-24 cm in water were simulated as verification. With the setting of QGSP_BIC_EMZ and high electron production cut, the simulation speed was improved by a factor of 10 compared with Shielding_EMZ, while achieving good dose calculation accuracy: range in water difference better than 0.2 mm at isocenter and better than 0.3 mm at 50 cm reduced air gap with range shifter; spot size in air difference better than 5%; point dose difference in spread out Bragg peak better than 7%. Considering the simulation speed and accuracy of the investigated GATE-RTion/Geant4 setting, IDEAL was commissioned from a dosimetric standpoint for carbon ion IDC.

1 Introduction

The state-of-the-art pencil beam scanning radiotherapy delivers intricate treatment fields meticulously devised by the treatment planning system (TPS) through the beam delivery system. The optimized field covers the planned target volume (PTV) of tumor longitudinally and laterally with pencil beams of various energies and lateral shifts. In MedAustron Ion Therapy Center, the routine quality assurance (QA) guarantees that key beam characteristics fall within tolerance level, e.g. the range and Bragg peak width, the spot size, and the beam intensity of the pristine monoenergetic pencil beam[1, 2]. The uncertainty of beam range and lateral position contributes to the 3D positioning accuracy of every spot in patient. Spot position uncertainty, along with the spot size uncertainty, the intensity uncertainty and the patient positioning uncertainty, affects the accuracy of the delivered dose in patient. Experimental patient specific QA (PSQA) verifies the dose of the planned field at various positions in water. Compared with the experimental PSQA, *in silico* independent dose calculation (IDC) within the actual patient geometry is expected to improve the specificity of the verification process, not to mention the reduction of beam time.

The first part of this manuscript would give an overview of the GATE-RTion/Geant4 settings under investigation. Next, the simulation speed of the settings was assessed. The dosimetric accuracy of the optimal setting was evaluated against measurements over the clinical energy range, with regard to range in water, spot size in air and absolute dose at reference depth in water for monoenergetic pencil beams with and without range shifter. Finally the accuracy of dose simulated at multiple positions in water was verified using 20 spread out Bragg peaks (SOBPs) of uniform physical or RBE_{LEMI} weighted dose to cubic targets of field size of 3-17 cm, modulation length of 3-10 cm and center at depths of 4-24 cm.

2 Materials and Methods

2.1 MedAustron Ion Therapy Center

Synchrotron-based Beam Delivery System at MedAustron Ion Therapy Center can provide clinical carbon ion beams between 120 and 400 MeV/u (range in water from 3 to 27 cm).

2.2 GATE-RTion v1.0

GATE-RTion v1.0, a validated and long-term stable branch of GATE v8.1 intended for clinical purposes[3], is the dose engine of IDEAL v1.0 [4] and v1.1.

2.3 Beam model and configurations of IDEAL v1.1

The beam models of the fixed horizontal beam line (HBL) and the fixed vertical beam line (VBL) of carbon ion were constructed using the method described in [5, 6]. The source-axis-distances (SADs) were defined according to baseline commissioning measurements for HBL and VBL, respectively, corresponding to the distance from the central position

of scanning magnets to the isocenter or the equivalent virtual distance[1, 6].

Several combinations of Geant4 reference physics lists and electron production cuts were tested in order to find an optimal configuration for IDEAL. The test simulation setup was defined as a cubic target of 6 cm side centered at 6 cm depth in water. IDEAL recorded the simulation speed, defined as the number of simulated primaries per second. The simulation speed of three configurations were compared: (A) with or without secondary electrons, (B) using physics builder of Shielding or QGSP_BIC, (C) using physics builder of QGSP_BIC_HP or QGSP_INCLXX_HP. Simulations with secondary electrons used electron production cut of 0.5 mm; simulations without secondary electrons set electron production cut of 100 m.

2.4 1D/2D/3D dosimetric verification of IDEAL v1.1

Integrated Radial Profiles as function of Depth (IRPDs) were measured in water for 16 energies between 120 and 400 MeV/u using the PeakFinder (PTW, Freiburg), positioned at isocenter (i.e. isocenter to detector or phantom surface equals 0 (ISD0)). Additional IRPDs were measured for 4 energies with and without Range Shifter (RaShi) at the Non-Isocentric Reference Point (NIRP)[1] with 50 cm (HBL) or 40 cm (VBL) reduced air gap. Pencil beams of the aforementioned energies were simulated in water. The scoring diameter of the measuring chamber was considered for scoring the IRPDs. Except otherwise specified, simulations were run with 1 mm dose grid and 5E+4 primaries. The absolute difference of the range at 80% of Bragg peak dose (R_{80}) of the measured and simulated IRPD was calculated.

Lynx (IBA-dosimetry, Schwarzenbruck) 2D scintillation detector was used to acquire the spot maps of major energies at several positions: isocenter (ISD0) and with 20, 30, 40 and 50 cm reduced airgaps (ISD20, ISD30, ISD40, ISD50). Aforementioned measurement was repeated with RaShi. Monoenergetic layer of 25 (HBL) or 9 (VBL) spots were simulated in air. At each measured position, the spot full width half maximum (FWHM) was extracted from the Gaussian fit of the dose distribution. The relative difference of the spot size at all ISDs were calculated for the measured and simulated spot maps.

Absolute dose was measured with plane-parallel ionisation chamber (ROOS chamber type TM34001, PTW) placed at 14 mm depth in water. The relative difference of the measured and simulated absolute dose at reference depth in water was calculated.

In 3D dosimetry, the 3D-block (PTW, Freiburg) equipped with 24 PinPoint ionisation chamber (IC) type 31015 (PTW, Freiburg) measured the point-like absolute dose at multiple positions in water. Twenty SOBP plans were optimized in the TPS to deliver a uniform physical or RBE_{LEMI} weighted dose [7] to cubic targets with field size of 3-17 cm, modulation length of 3-10 cm, centered at depths of 4-24 cm in water. Four reference plans highlighted in Table 1 were used to derive an energy-dependent MeterSet Weight Scaling Factor (w_{msw}). The w_{msw} was subsequently applied to the carbon ion beam models and verified with all the plans listed in Table 1. Dose grid of 2 mm and statistical uncertainty goal of 1% were used in simulation and the absolute dose at the positions of the 2352 PinPoint ICs was interpolated linearly. The global dose difference were calculated for 2143 valid PinPoint ICs whose dose gradient was lower than 0.04 Gy/mm and planned dose was higher than 0.05 Gy according to the experimental PSQA procedure. The statistics (signed and unsigned mean) of the global differences per plan were computed by Equation 1 and 2, respectively.

$$\overline{\Delta} = \overline{\frac{(D_i - D_i^{\text{meas}})}{max\,(D_i^{\text{meas}})}}, i \in \text{valid} \tag{1}$$

$$\overline{|\Delta|} = \overline{\frac{|D_i - D_i^{\text{meas}}|}{max\,(D_i^{\text{meas}})}}, i \in \text{valid} \tag{2}$$

Table 1: The 20 SOBPs with field size of 3-17 cm, modulation length of 3-10 cm and center at depths of 4-24 cm are presented. The four highlighted reference plans were used to derive the MeterSetWeight Scaling Factor w_{msw}.

Field size [cm]	Modulation length [cm]	Center depth [cm]	Measurement position	RaShi	Prescribed dose
3	3	4	NIRP	Yes	RBE_{LEMI}
4	4	5	ISD0	No	RBE_{LEMI}
4	4	5	NIRP	No	RBE_{LEMI}
4	4	19	NIRP	No	RBE_{LEMI}
4	4	25	ISD0	No	RBE_{LEMI}
6	6	6	ISD0	No	Physical
		6	ISD0	No	RBE_{LEMI}
		10	ISD0	No	RBE_{LEMI}
		5	NIRP	Yes	RBE_{LEMI}
		6	NIRP	No	RBE_{LEMI}
6	10	7	NIRP	Yes	RBE_{LEMI}
8	8	13	ISD0	No	Physical
			ISD0	No	RBE_{LEMI}
			NIRP	No	RBE_{LEMI}
8	8	15	NIRP	Yes	RBE_{LEMI}
10	10	21	ISD0	No	Physical
			ISD0	No	RBE_{LEMI}
			NIRP	No	RBE_{LEMI}
16	5	6	ISD0	No	RBE_{LEMI}
16	5	6	NIRP	No	RBE_{LEMI}

3 Results

3.1 Simulation speed of tested configurations

The five simulation configurations are summarized in Table 2 and the simulation speed of each tested simulation is listed. Omitting secondary electrons by using high electron production cut improved the simulation speed by approximately a factor of 4 (configuration A1 and A2). Using physics builder of QGSP_BIC instead of Shielding further improved the simulation speed by approximately a factor of 2 (configuration A2 and B1). The physics builder QGSP_BIC and

QGSP_INCLXX had comparable simulation speed, however the option HP (for high precision neutrons) reduced the simulation speed (configuration B1, C1 and C2).

3.2 Dosimetric accuracy of monoenergetic pencil beam

The R_{80} of simulated IRPDs agreed with measurement with an absolute difference of 0.2 mm at ISD0. The differnce of R_{80} of pencil beam with RaShi measured at ISD50 fell within the tolerance of 0.3 mm [1]. The absolute dose at reference depth in water agreed with measurement better than 2%.
The relative difference of simulated spot FWHM agreed with measurement better than 5% at all the non-isocentric measurement positions. This met the tolerance requirement of 10% [1].

3.3 Dosimetric accuracy of SOBP

The empirical w_{msw} derived from the dose difference of reference plans in HBL can be expressed as a third order polynomial equation of the nominal energy, with coefficients in descending order (1.82E-9, 1.70E-6, 3.62E-3, 0.983). The application scaled up the meterset weight of low-energy energy layers by around 0.5%, and scaled down the weight of high-energy energy layers by up to 2.5%. The w_{msw} of VBL was derived similarly.
Figure 1 and 2 demonstrated the global dose difference of valid PinPoint ICs in target region for SOBP plans of HBL and VBL, respectively. For the SOBP plans of HBL, signed and unsigned mean global dose difference had maximum values of 1.4% and 1.9%, respectively. For the SOBP plans of VBL, signed and unsigned mean global dose difference had maximum values of -1.4% and 1.5%, respectively. The global dose difference of all positions in target region was better than -5.1% for HBL and -7.0% for VBL, reaching agreement within the uncertainty of the measurement data.

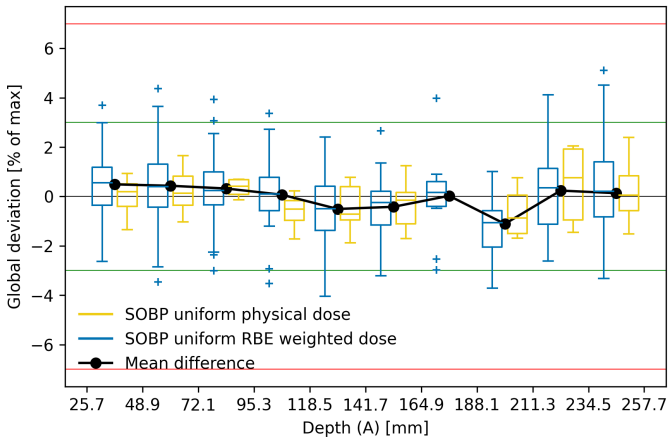

Figure 1: The histogram of the global dose difference of all the valid PinPoint ICs in the target region of all the SOBP plans of HBL.

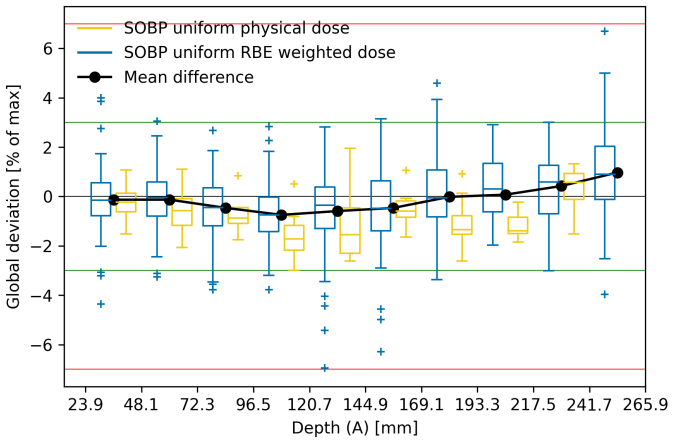

Figure 2: The histogram of the global dose difference of all the valid PinPoint ICs in the target region of all the SOBP plans of VBL.

4 Discussion

It was recommended by [3] to use the physics builder of Shiedling_EMZ, which for nuclear processes uses Quantum Molecular Dynamics (QMD) model, when simulating carbon ion with GATE-RTion v1.0/Geant4.10.3. In this work, the recommended configurations were tested against other nuclear model and electromagnetic (EM) model choices. Shielding physics builder including QMD model was slower than BIC and INCLXX by a factor of 2∼3, same finding was also reported in [8]. BIC and QMD models reported comparable agreement to experimental data with regard to the fragmentation of 400 MeV/u C-12 ion beam in water [9]. Therefore, the QGSP_BIC_EMZ physic builder was chosen in place of Shielding physics builder for the IDC application.
Configurations A2, B1, C1, C2 without secondary electrons reduced simulation time significantly by a factor of 4∼5.
Supplementary simulation of IRPD in water was conducted in order to investigate the dosimetric accuracy with high electron production cut. It was found that R_{80} of simulated pristine pencil beam had excellent agreement with measurement reference when simulated without secondary electrons. The mean range difference against commissioning measurements of 16 energies was 0.0 mm when simulated without secondary electrons, and -0.2 mm when simulated with secondary electrons. It was observed in [10] that the IRPD of the same pristine pencil beam simulated with 0.001 mm production cut and 0.01 mm step limit had shorter R_{80} than IRPD simulated with 1 mm production cut and no step limit, with the R_{80} difference of 2 mm. The finding that simulation with smaller electron production cut had shorter R_{80} was consistent between this work and [10].
The good accuracy of R_{80} with/without RaShi and absolute dose in water verified the modeling of pencil beam energy and RaShi. The agreement of FWHM in air at positions from isocenter to NIRP 50 cm off isocenter validated the optics parameters of the pencil beam and the relative position of

Table 2: The simulation speed of five configurations using different physics builders and secondary electron settings.

Configuration	Physics builder	EM option	Simulation of secondary electrons	Simulation speed [primaries/second]
A1	Shielding	EMZ	Yes	16.1
A2	Shielding	EMZ	No	72.5
B1	QGSP_BIC	EMZ	No	171.2
C1	QGSP_BIC_HP	EMZ	No	122.9
C2	QGSP_INCLXX_HP	EMZ	No	122.0

the source and the scanning magnets to isocenter. With the correction of the w_{msw}, the absolute dose in SOBP showed good agreement with measurement in spite of the positioning uncertainty of the PinPoint ICs, with no dependency on depth or optimization method (uniform physical or RBE_{LEMI} weighted dose). Similarly for proton, scaling factors of the order of 2% were required between the reference doses of monoenergetic pencil beams and the 3D doses of SOBP for TPS and IDC systems used at MedAustron[4].

5 Conclusion

IDEAL v1.1 (GATE-RTion v1.0/Geant4.10.3) settings have been evaluated with regard to simulation speed and accuracy. The physics builder of QGSP_BIC_EMZ with high electron production cut significantly improved the simulation speed, while maintaining good dosimetric accuracy compared with measurements over the clinical energy range of carbon ion radiotherapy. IDEAL in its current optimized configuration was commissioned from a dosimetric standpoint for carbon ion IDC. Further clinical commissioning comparing TPS against IDEAL in patient geometry will follow as a next step.

New global reconstruction for charged particles with the FOOT experiment

Ch. Finck on behalf of the FOOT collaboration[1]

[1]Université de Strasbourg, CNRS, IPHC UMR 7871, F-67000 Strasbourg, France

Abstract In the framework of measuring double differential cross-section for hadrontherapy purposes, a new algorithm for global track reconstruction (Tracking Of Ejectile) was implemented in the analysis package for the FOOT experiment data set. The algorithm is based on a unscented Kalman filter approach. The cluster recognition efficiency was found to be around 99% with purity above 94%. The momentum resolution of the reconstructed track for particle with a momentum $\geq$ 2 GeV/c was found to be lower than 5 % what corresponds to the desired resolution for the FOOT experiment in order to separate the different isotopes.

1 Introduction

Hadrontherapy treats deep-seated tumours with beams of charged particles (protons and heavier ions) to treat. These particles have a favourable depth-dose distribution in tissue characterized by a maximum energy deposition (Bragg peak) near the end range where the tumour is located. Moreover, Carbon and Oxygen ions have an enhanced biological effect allowing to successfully treat radio-resistant tumours. However, the nuclear interactions of the beam nuclei with the patient tissues can induce fragmentation of projectiles and/or target nuclei and needs to be carefully taken into account when planning the treatment.

At present, there is a lack of experimental data about nuclear fragmentation for light fragments (Z<10) in the energy range between 100 MeV/A and 800 MeV/A, typical energies used in hadrontherapy and relevant for space radio-protection. They would be fundamental in order to further optimize treatment planning system in hadrontherapy [1] and risk models for space missions [2]. To fill this gap, the FOOT (FragmentatiOn Of Target) experiment has been conceived with the aim of measuring differential nuclear cross sections of both target and projectile fragments with an uncertainty lower than 5%, taking advantage of an inverse kinematic approach for the measurement of target fragments.

The FOOT experiment was designed to detect, track and identify nuclear fragments and aims to measure double differential cross sections both in angle and kinetic energy. To identify fragment tracks two methods are used, one based on the GenFit [3] package and another based on a Kalman filter approach named TOE (Tracking Of Ejectile)

The performance of the TOE algorithm will be studied through different simulated data sets.

2 Materials and Methods

2.1 Experimental setup

The FOOT magnetic spectrometer setup, is optimized for the identification of fragments heavier than or equal to α particles at low angle $< 10^o$, while the emulsion chamber setup is an apparatus covering large angle up to 70° and it is optimized for the detection of fragments within Z $\leq$ 3 [4]. The FOOT electronic setup [5], depicted in Figure 1, consists of an upstream region composed of the pre-target detectors, composed by a start counter (SC) and a beam monitor (BM) to characterize the incoming beam, including the target. After the target a tracking region, including a vertex detector (VTX), the magnet, a inner tracker (ITR) and a micro-strip detector (MSD), is located. The downstream region, as for it, consists of a time of flight wall (TW) and a calorimeter (CAL).

2.1.1 Start counter

The SC is made of a thin squared foil (5 cm side, 250 μm thickness) of EJ-228 plastic scintillator. It provides the trigger signal to the whole experiment and the measurement of incoming ion flux to be used for the cross section measurement. It provides the reference time for all the other detectors and allows the time of flight measurement in combination with the TW.

2.1.2 Beam monitor

The BM is a drift chamber composed of twelve wire layers, with three drift cells per layer. The cell shape is rectangular (1.6$\times$1.0 cm^2) with the long side orthogonal to the beam. The BM was operated at atmospheric pressure, at the working voltage of 1.8 kV while using an Ar/CO2, 80/20% gas mixture. The BM detector is placed between the SC and the target and is used to measure the direction and incident of the ion beam track. The BM efficiency was measured to be $\sim$ 90% and the mean track spatial resolution was measured to be of the order of $\leq$ 100 μm [6].

2.1.3 Vertex detector and Inner tracker

The VTX is a 2$\times$2 cm^2 pixelised silicon detector based on the CMOS technology made of 4 consecutive planes of MIMOSA- 28 (M28) chip [7]. The VTX is placed downstream the target. The M28 chip is composed of 928 rows $\times$

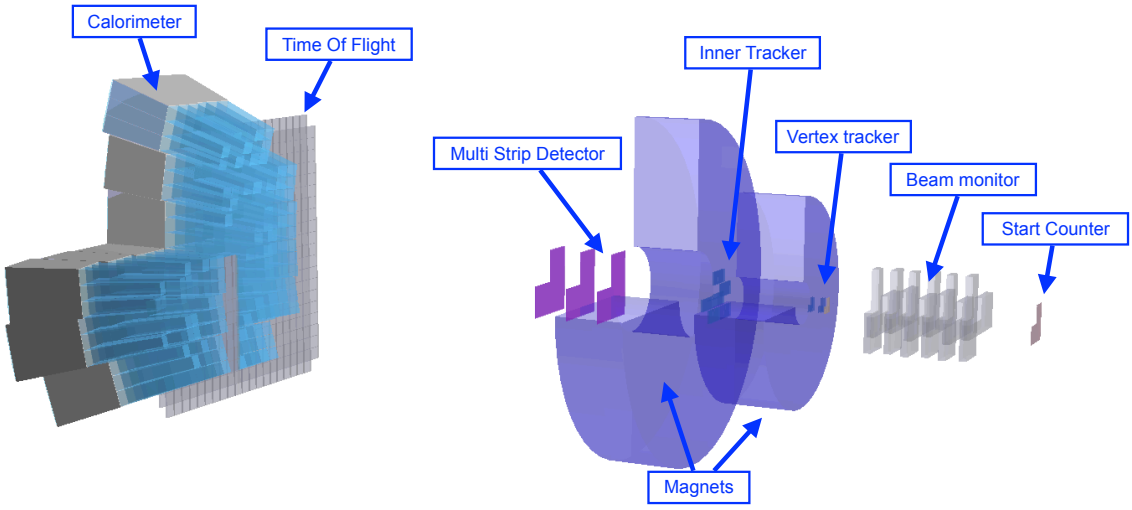

Figure 1: Schematic view of the FOOT experimental setup

960 columns with a pixels size of of 20.7 μm. The sensor has a total thickness of 50 μm with an epitaxial layer of 14 μm.
The ITR is made of two planes of 16 M28 chip each, covering a area of 4×4 cm^2. The ITR is placed in between two asymmetrical permanent magnets in a Halbach configuration with a maximum intensity of 1.4 T and 0.9 T respectively.

2.1.4 Time of flight wall

The Time of flight (TOF) wall detector (TW) is composed of two orthogonal layers of 20 plastic scintillator bars (EJ-200). Each bar is 0.3 cm thick, 2 cm wide and 44 cm long. The two x-y layers form a 40×40 cm^2 active area detector that provides the deposited energy (ΔE) measurements. The time of flight is computing by the average tine of the two planes using as reference the time given by the SC. An energy loss resolution $\sigma(\Delta E) \sim 5\%$ was obtained for different beam/energy combinations. The resolution of the time of flight was measured to be $\sim$ 75 ps [8].

2.1.5 Calorimeter

The CAL is composed of 320 $Bi_4Ge_3O_{12}$ (BGO) crystals, with a truncated pyramid shape: a front side of 2×2 cm^2, a rear side varying from 2.7×2.7 cm^2 to 2.9×2.9 cm^2 and a length of 24 cm, which are positioned with an approximately circular arrangement of about 22 cm radius. The energy resolution is expected to be less than $\sigma \leq 3\%$.

2.2 Local reconstruction

The track of a charged particle passing through the BM is reconstructed from the hits in each cell thanks to an algorithm based on the Legendre polynomials. The hit efficiency was found to be 0.929 $\pm$ 0.008 [6].

The cluster position is computed from the fired pixels of the VTX and ITR or fired strips of the MSD or fired crystal in the calorimeter, by a next neighboring algorithm [9]. The local track reconstruction of the trackers is based on a cluster position combinatorial algorithm. The tracking efficiency is higher than 98 % The vertices are computed using a less tack distance algorithm for the VTX. The efficiency was found to be higher than 98 % [9]. The alignment of the VTX detector is performed using a global χ^2 cost function [10]. The sensors are aligned better than 5 μm in x-y position and better than 0.1 ^{o} in rotation angle around the z-axis.
The space position of the track intercepted by the TW detector, the front and rear TW hits that provide respectively the (x,z) and (y,z) separate information, have to be matched. A clustering algorithm is used to pair the hits detected in the two layers and to find the proper match. The Z identification (ZID) algorithm of the TW was developed to exploits the correlation between ΔE and TOF, for a particle of charge Z, that could be expressed by means of the Bethe-Bloch formula.

2.3 Global reconstruction

The momentum (p) of the fragment can be deduced thanks to the ZID and the curvature of the track in the magnetic field. The used algorithm (TOE) is based on a unscented Kalman filter approach. The mass (m) of the fragment can be computed from the total kinetic energy (E_k) measured with the CAL using the following formula:

$$p = m\beta\gamma\, E_k = mc^2(\gamma - 1) \qquad (1)$$

where $\beta = \frac{l}{TOF}$ and $\gamma = \frac{1}{\sqrt{1-\beta^2}}$, l is the distance of the particle between the SC and the TW.
The role of the global reconstruction is dual: first, the selection of the clusters belonging to a same track, representative of a fragment trajectory inside the experimental setup; second, the extraction of the parameters of interest from the

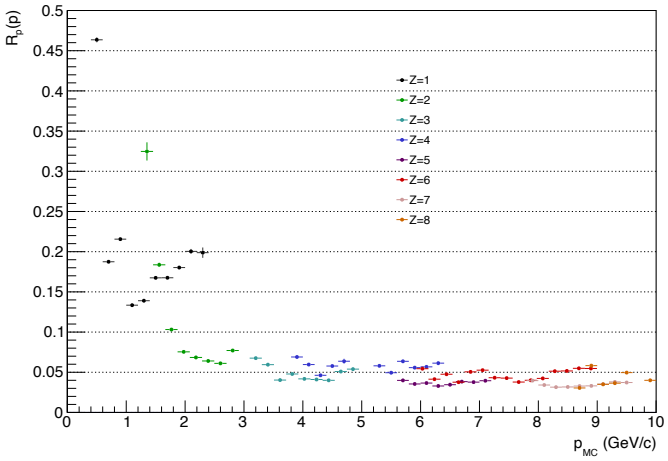

Figure 2: Resolution on momentum as a function of simulated momentum, for the data set labelled A. Each fragment charge distribution was computed individually.

corresponding reconstructed track. Those two distinct roles are respectively called track recognition and track fitting.

2.3.1 Track recognition

The goal of track recognition is to find the reconstructed clusters, formed by local reconstruction of the detectors, that belong to a same given trajectory. The method used to perform this selection must be developed and designed in accordance with the needs and characteristics of the experiment. The track recognition procedure in the TOE algorithm was designed around three intertwined components that form the basis of the algorithm: the propagator, which is dedicated to the track state propagation from one detection layer to the next; the filter, which is used to compare the extrapolation of the track parameters to the available measurements and correct the track state accordingly; and finally the arborescence, or the memory of the procedure, which holds the possible trajectories for the track under reconstruction.

2.3.2 Track fitting

Once a track has been reconstructed, i.e. the clusters belonging to it have been identified and grouped together, the extraction of the parameter of interests for the experiment can be performed; in our case, both the length of the path and the momentum of the particle.

3 Results

The results are based on simulations including the geometry and response function of the FOOT setup. Four different combinations of beam, target and energy were simulated: ^{16}O beam on C_2H_4 target at 200 MeV/u (labelled A), ^{16}O beam on carbon target at 200 MeV/u (labelled B), ^{16}O beam on carbon target at 400 MeV/u (labelled C) and ^{12}C beam on carbon target at 200 MeV/u (labelled D).

	A	B	C	D
Eff.	98.7 ± 0.4	98.7 ± 0.4	99.8 ± 0.5	99.0 ± 0.7
Purity	95.1 ± 0.1	94.5 ± 0.1	99.6 ± 0.1	94.2 ± 0.2

Table 1: Efficiency and purity for four different campaign data sets

3.1 Track recognition

The efficiency is defined as the ratio of the number of reconstructed tracks over the simulated tracks in the acceptance of the FOOT setup. The purity is defined as the number of cluster belong to the same particle over the number of clusters belonging to the same track.
The efficiency and purity results are reported in the table 1 for the given setup.

3.2 Track fitting

The resolution of the momentum $R_p(p)$ is given as the standard deviation of the difference between the simulated momentum (p_{MC}) and the reconstructed one (p_{rec}) normalized by the simulated one (p_{MC}).
Figure 2 shows the momentum resolution versus the simulation momentum for the campaign ^{16}O beam on C_2H_4 target at 200 MeV/u for each fragment in Z charge.

4 Discussion

There is no real distinction in term of efficiency separates the data sets: regardless the configuration, the overall recognition efficiency value is close to 99% for all charged particles. Efficiency for Z=1 and Z=2 (results not shown here) is not far from this value: taking into account the associated error, it fluctuates around 98% for all data sets. However, the association of clusters to the track is wrong in a non-negligible proportion of reconstructions: the purity for charge Z=1 and

Z=2 (not shown here) is respectively around 90% and 94% across data sets.

5 Conclusion

A new global tracking (TOE) algorithm was studied with four different sets of simulated data. Four data sets studied, the overall recognition efficiency of the algorithm was found to be around 99%, for a cluster purity above 94%. In order to achieve its goals, the FOOT experiment need to achieve a momentum resolution of the reconstructed track lower than 5%. For the heavier incident particles ($Z > 2$), this objective is achieved by the TOE algorithm. For lighter fragments, the performances are more nuanced: the resolution on the momentum ranges between 5% to 40%.

Abstract This work demonstrates the development and application of fast deep-learning models designed for the mitigation of noise in Monte Carlo dose distributions (MC-DDs) with high statistical uncertainty (SU) of radiotherapy treatment plans. Five 3D U-net models were developed, varying in input, input size and batch normalization. The models were trained on pairs of high/low SU MC-DD pairs of randomly generated clinically motivated treatment plans calculated on open source available computed tomography (CT) scans. Depending on the model, the CT was included as input. The accuracy of the models is evaluated on the test set using gamma passing rate (2% global, 2 mm, 10% threshold) comparing denoised and low SU MC-DD. The best performing model included the CT input and no batch normalization. It was retrained for detailed evaluation on inhouse data, consisting of high/low-SU MC-DD pairs generated from 106 clinically-motivated volumetric modulated arc therapy (VMAT) arcs for 29 CT scans. The dataset was augmented to encompass a total of 3074 pairs. On the test set, the denoised MC-DDs agree with low-SU MC-DDs, by an average (standard deviation) gamma passing rate of 82.9% (4.7%). Applied to 12 previously unobserved clinically-motivated cases originating from different treatment sites yields an average gamma passing rate of 91.0%. Denoised DDs are computed, on average, in 35.1 seconds, a 340-fold efficiency gain compared to the calculation of low-SU MC-DDs.

1 Introduction

Monte Carlo (MC) dose calculation is widely acknowledged as the gold-standard for radiation therapy dose calculation, mostly due to its ability to accurately simulate the particle transport in heterogeneous media [1]. However, the necessity for a substantial number of particle histories in MC simulations to achieve reasonable statistical uncertainty (SU) leads to prolonged calculation times [2] and poses challenges for clinical implementation. Current clinical practice often resorts to analytical or simplified MC dose calculation algorithms, balancing accuracy with calculation times typically in the range of several minutes [3].

Deep learning (DL) presents a promising avenue to circumvent long calculation times while maintaining promising accuracy. There exists several approaches, incorporating U-nets [4, 5] and general adversarial networks [6–8] to perform dose predictions, relying only on CT and/or structure set as input, for specific treatment techniques. However, these dose predictions approaches have inherent drawbacks. They may produce results substantially deviating from the ground truth, introducing errors such as predicting doses far away from the tumor [9]. Additionally, their employment is often constrained by training dataset specificity, rendering them dependent on particular cancer types, treatment sites, or techniques [5].

To address these limitations, a promising approach is to give an "informed" input: This involves first the computationally cheap and fast calculation of MC dose distributions (MC-DDs) with high SU using only a limited number of particle histories. This informed input potentially reduces the risk of introducing errors such as mentioned before. In a second step, these DDs are denoised using DL to infer DDs similar to MC-DD with low SU [10, 11]. This approach is expected of being applicable to different treatment sites and techniques, as the primary task is denoising instead of full dose prediction. Moreover, using this approach, the problem of limited training data can be adressed, as random MC-DDs with low/high SU can be generated if needed. In our research group, the Swiss Monte Carlo Plan (SMCP) [12] has been developed and presents a flexible framework to calculate MC-DDs of various treatment techniques and is able to generate the necessary MC-DDs for training such DL models.

The objective of this study is therefore to develop and test different flavors of these denoising models and to apply the best performing model to 12 unseen clinically motivated cases.

2 Materials and Methods

In this work five different DL-powered denoising models are developed and tested (table 1). The main architecture consists of a standard 3D U-net [13] with four layers, integrating skip connections between encoding and decoding layers. Convolutional kernel sizes are 3*3*3 voxels, and max-pooling dimensions are 3*3*1 for the first and 2*2*2 voxels for the subsequent layers. The input dimension is 192*192 voxels in x*y direction and varying size in z direction. Geometries exceeding 192 voxels in x- and y-direction are cropped centrally and geometries exceeding 64 voxels in z-direction are handled using a patched-based approach [14]. Resulting overlapping voxels are averaged using TorchIO [15]. Geometries with less voxels are padded with zero voxels to fit the model input size. The model has 1-2 input channels, depending whether the CT is given as an additional input to the MC-DD with high SU or not.

Model	z-size	CT	Batch normalization
1	32	yes	no
2	64	yes	no
3	96	yes	no
4	64	no	no
5	64	yes	yes

Table 1: 3D U-net model flavours 1-5. The models differ by with varying input, input size and batch normalization.

During training, random patches with size 192*192*z are selected from DDs (and CTs, if specified), with additional data augmentation involving random mirroring and/or rotations in multiples of 90° in the xy-plane. The training employs a summed-squared-error loss function and a batch size of two. The ADAM optimizer [16] is used, starting with an initial learning rate of 10^{-4}. The learning rate decreases by a factor of 5, if the validation loss remains unchanged for four consecutive epochs. Training concludes when there is no improvement in the loss function over the last 30 epochs. The model is trained on a GeForce RTX 3090 GPU.

The dataset for training, validation and testing consisted of 5364 randomly generated volumetric modulated arc treatment (VMAT) plans: random multi-leaf collimator shapes are generated for a full gantry rotation, the collimator angle is randomly assigned and the monitor unit weights for each control point are assigned by randomly sampling numbers between 0 and 1 and sorting them in ascending order. Additionally, a random isocenter (within +- 5 cm in x, y and z of the center of the CT) is assigned. The beam energy is set to 6 MV. Always 12 plans were applied to 447 open source clinically motivated CTs to obtain a total of 5364 high/low SU MC-DD pairs. The high/low SU MC-DDs were calculated using SMCP [11], with $1.5*10^6$ particle histories (high SU >60%) and $3*10^8$ particle histories (low SU <2%), respectively. The dataset is divided into training, validation, and test set with 80%/10%/10% split.

The model accuracy is evaluated by comparing the low-SU MC-DD (reference) with the denoised DD by means of root-mean-squared error (RMSE) over all voxels and Gamma passing rate on the test set. Gamma evaluation with 2%/2 mm [17] and 3%/3 mm [18], 10% threshold is denoted as gamma-2 and gamma-3, respectively.

The best performing model out of those considered was re-trained on 106 clinically motivated VMAT applied to 29 CTs from our own data base. The plans were augmented by randomly changing the beam energy (6, 10, 15 MV), the isocenter (within +-5 cm in x, y, z direction), and the collimator angle, to a total of 3074 high/low SU MC-DD pairs. Training was completed within 28 h 19 min (149 epochs).

The re-trained model is applied to 12 previously unseen clinically motivated cases, including 4 head and neck, 4 non-small-cell lung, and 4 prostate cases. RMSE, gamma-2, and gamma-3 are evaluated. The noise reduction from high SU MC-DD to denoised DD, is quantified using the Improved Signal-to-Noise Ratio (ISNR) [11].

The computation time to calculate a high-SU MC-DD, the subsequent preprocessing, denoising and storing is recorded and compared to the calculation time of the low-SU MC-DD.

3 Results

The accuracy of the five models is shown in table 2. Including the CT information improved the model accuracy. Moreover, batch normalization had a negative impact on the model accuracy.

Model	Average gamma-2 [%]	Average gamma-3 [%]	RMSE [10^{-4} Gy/MU]
1	89.16±3.99	97.30±1.69	1.21±0.22
2	**89.74±4.00**	**97.50±1.66**	**1.16±0.20**
3	89.72±3.92	97.48±1.61	1.15±0.20
4	89.23±4.16	97.30±1.78	1.16±0.20
5	83.54±4.77	94.50±2.55	1.26±0.27

Table 2: Model accuracy including standard variation. The best performing model is marked in bold.

The model 2 had a mean (standard deviation) calculation time of 32.7 s (7.5 s) to obtain a high-SU MC-DD on a single CPU. Subsequent data preprocessing, denoising, and storage were completed on average (standard deviation) within 2.6 s (0.3 s). This contrasts an average (standard deviation) calculation time of 3 hours and 19 minutes (42 minutes) for low-SU MC dose calculation, including storage, on one CPU: an efficiency gain of factor 340. The application of the retrained model to 12 unseen cases is demonstrated for one head and neck and one lung case in figure 1.

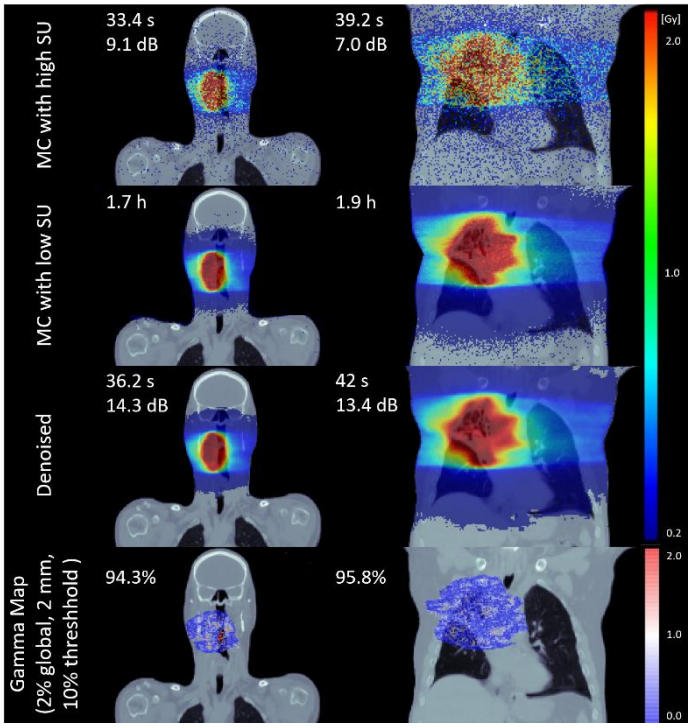

Figure 1: High SU, low SU and denoised DDs are visualized with 10% dose threshold for a head and neck (left) and a lung (right) case. Their computation times and signal to noise ratio as compared to the MC-DD with low SU are shown on the respective upper left corner. The gamma evaluation (low SU DD as reference and denoised DD as evaluation) is shown on the bottom. In the gamma map, voxels failing the gamma criteria (> 1.0) are shown in red tones with the gamma passing rate shown in the top-left corner of the gamma map.

For the 12 cases, the average [range] RMSE is $1.1*10^{-4}$ Gy/MU [$0.5*10^{-4}$, $1.7*10^{-4}$]. The average [range] gamma-3 and gamma-2 is 97.5% [93.4, 98.7] and 91.0% [79.6, 95.9], respectively. The average [range] ISNR is 9.9 dB [4.2, 15.2].

4 Discussion

In this work, we have developed and tested DL-powered models to denoise MC-DDs.

Generally, the differences in accuracy between the models are small: the different z input sizes had little impact on the gamma-2, gamma-3 and RMSE. However, the patched borders could be identified visually due to "steps" in the dose distribution. Keeping in mind, that the GPU has a limited memory [19], the results suggest choosing a z-size conforming to the availability and specifications of the available GPU model. Similarly, no substantial improvement in accuracy due to the additional CT input was observed. However, in the context of explainable results and minimizing the risk of false dose predictions, the CT input is potentially beneficial. Including batch normalization substantially degraded the accuracy of the denoising. Although batch normalization is used in many segmentation tasks and similar U-nets [20], it was not beneficial for the denoising task. This might be due to the fact that batch normalization tends to lose the information of the absolute dose values, which is critical for predicting accurate dose distributions. This effect can be magnified when using patching, as the information of the previous patch is not available for the next one.

Denoised DDs generated with the best performing model considered exhibit an average RMSE of $1.1*10^{-4}$ Gy/MU when compared to low-SU MC-DDs, aligning with findings in literature using similar methodologies [10, 19]. For a representative VMAT arc with 300 MU and a prescription of 50 Gy, delivered in 2 Gy fractions, this leads to an average RMSE of 0.9 Gy for the whole treatment. Although these results are quite promising, they do not conform to the dose calculation accuracy levels recommended by AAPM [21].

For the 12 unseen clinically motivated cases slightly lower gamma passing rates are observed when compared to previous works using DL-powered denoising or dose prediction methods [10, 18]. This can be partly explained by the slightly different task of denoising the DD of entire VMAT arcs rather than beams from single directions, resulting in a 9.9 dB average improvement in SNR, a factor 2 smaller than in other studies [11]. Moreover, the other studies used less/more particle histories for the high/low SU MC-DDs.

The denoising computation time is comparable to the findings in literature [10]. The entire workflow, encompassing the generation and denoising of high-SU MC-DDs, is completed within less than a minute, surpassing the speed of the majority of clinically applied dose calculation algorithms [3, 22].

5 Conclusion

We developed and tested DL-powered denoising model for MC-DD. The most accurate model showed an impressive efficiency gain (factor 340), substantial noise reduction and promising accuracy.

Development of a Range Probe to Improve Dose Delivery Accuracy in Proton Beam Therapy

Josephine Jones[1,2], Adam Aitkenhead[1,2], Samuel Manger[1,2], and Michael Taylor[1,2]

[1]University of Manchester, Division of Cancer Sciences, Manchester, UK
[2]The Christie NHS Foundation Trust, Manchester, UK

Abstract Proton therapy requires accurate calculation of proton range in the patient. Several factors are potential sources of range error, and in-vivo range verification could be used to improve range accuracy. However, no methods for in-vivo range verification are currently in routine clinical use. A proton range probe is a possible solution, which we define as a small number of pencil beams that traverse the patient to measure water equivalent thickness (WET) and verify calculations from X-ray CT. The proposed range probe is based on time-of-flight (TOF) measurements. A pair of sensors upstream of the patient measure initial proton energy and a pair of sensors downstream measure final proton energy. The mean energy change can be used to calculate the WET along the proton path using a calibration curve. Monte Carlo modelling of the TOF range probe was done using Geant4 to investigate how sensor parameters affect the accuracy and precision of WET measurement and quantify sensor requirements. Simulations with homogeneous materials demonstrated WET uncertainty below 1% with sensor timing resolutions ≤60ps. WET projections of an inhomogeneous phantom were also simulated and used to assess the performance of the probe near boundaries of different media.

1 Introduction

Range error is a significant challenge in proton beam therapy treatment planning. It arises due to several factors, including dose calculation error and patient set-up uncertainty. Most significantly, the treatment is planned using an X-ray CT and CT Hounsfield units must be converted into proton stopping power. The stoichiometric method is the most common approach to generating a CT-proton calibration curve but was found to generate up to 3.4% error for some treatment sites[1].

There is currently no method of in-vivo proton range verification in clinical use. Several methods have been proposed including PET, prompt gamma imaging and proton-CT. These require complicated and expensive technology, and it could be several years before they are implemented in the clinic.

Proton range probes have been suggested as an alternative method of range verification. In this study, a range probe is defined by a small number of proton pencil beams that fully traverse the patient to measure the water equivalent thickness (WET) along their path. The purpose of the range probe is to make measurements that complement data from X-ray CT.

The use of multi-layer ionization chambers for range probing has previously been investigated [2][3]. These devices are limited by their large size, low sensitivity and poor spatial resolution. This study will explore an alternative range probe design, based on time-of-flight (TOF) measurements.

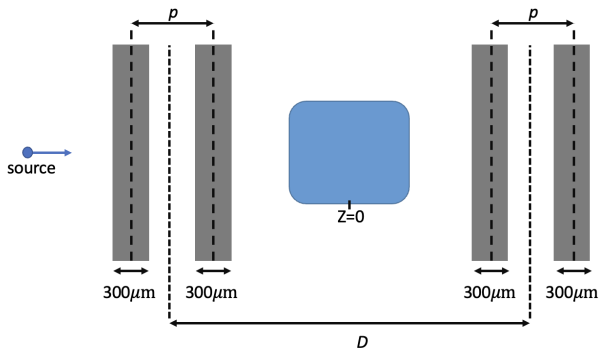

Figure 1: Schematic of range probe detector set-up (not to scale). Four identical 300μm silicon sensors, with two upstream and two downstream of the object to be measured, which is at the beam isocentre.

2 Materials and Methods

2.1 Geant4 Simulation Toolkit

Geant4 is a Monte Carlo toolkit for the simulation of particle transport through matter (https://geant4.web.cern.ch/). Version 11.0.3 was used to simulate a TOF detector for use as a proton range probe. These simulations used the '*QGSP_BIC*' physics list with EM option 3, as recommended for medical applications.

2.2 TOF Detector Design

The TOF range probe consists of two sensors upstream and two sensors downstream of the object to be imaged. In simulations, the sensors were modelled by 300μm of silicon. Each pair of sensors had a plane separation p, and the two pairs were separated by a flight distance, D. This setup can be seen in Figure 1. The object was placed at the beam isocenter.

2.3 Kinetic Energy Calculation

Analysis was performed on a proton-by-proton basis. The proton's hit time, t_i, and position, (x_i,y_i) on each sensor ($i = 1,2,3,4$) were recorded. The hit data were filtered to include only those protons that recorded exactly one hit on each sensor. The distance a single proton travelled between the

planes is described by Equation 1 and its TOF by Equation 2.

$$\Delta d_{initial} = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + p^2} \quad (1)$$

$$\text{TOF}_{initial} = \Delta t_{initial} = t_2 - t_1 \quad (2)$$

The initial proton energy was then calculated using the relativistic energy equation:

$$E_{initial} = m_p c^2 \left(\frac{1}{\sqrt{1 - \frac{v_{initial}^2}{c^2}}} - 1 \right) \quad (3)$$

Where c is the speed of light, m_p is proton mass and $v_{initial} = \frac{\Delta d_{initial}}{TOF_{initial}}$. The final proton energy, E_{final}, was calculated in the same way, using the hit data for sensors 3 and 4. A Gaussian distribution was then fitted to find the mean energy change ΔE.

2.4 Calibration Curves

Calibration curves were generated that related the average change in proton energy, ΔE, to the WET of the path along which it travelled. Simulations were performed with water blocks of thicknesses between 5mm and 340mm. For each thickness, 10^7 protons were simulated and ΔE was found, as described in section 2.3. Calibration curves with varying sensor timing resolution are shown in Figure 2.

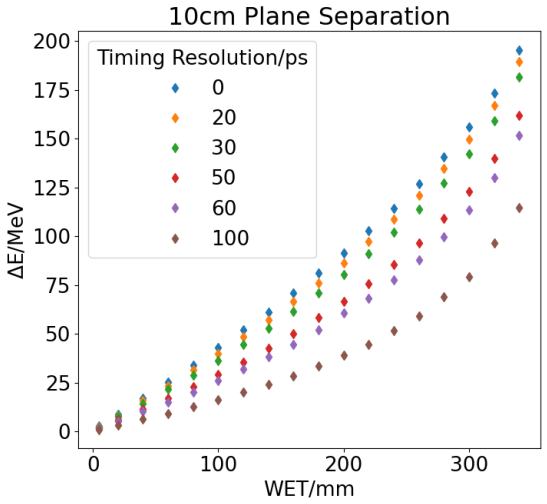

Figure 2: Calibration curves with 1m flight distance for 10cm plane separation and varying timing resolution.

2.5 Investigation of Detector Parameters

The aim of this investigation was to quantify the detector requirements for achieving accurate and precise WET measurements. Intrinsic sensor specifications (timing resolution, σ_t, and spatial resolution, σ_{xy}), as well as set-up geometry (plane separation, p, and flight distance, D), were investigated. The number of protons simulated, n, was also varied. The values used for each parameter are shown in Table 1.

Timing and spatial resolution were modelled by Gaussian blurring of hit times and positions with distributions of width σ_t and σ_{xy}. Measurements were simulated in blocks of water, PMP and Teflon with WET values between 10mm and 300mm. The simulation was run 100 times for every measurement. For each run, n protons were simulated and ΔE fitted. An estimate of the WET was then obtained from the calibration curve and the mean and standard deviation of the estimates were calculated across 100 runs.

Parameter	Values
σ_t/ps	0,20,30,50,60,100
σ_{xy}/mm	0.1,0.5,1,5
p/cm	5,10,15,20
D/m	0.5,1,1.5
n	10^5,10^6,10^7

Table 1: Detector parameters and the values that were used in an investigation of WET accuracy and precision.

2.5.1 True WET Calculation

The WET of a block with physical thickness T can be calculated using Equation 4. The values R_{water} and $R_{material}$ are the CSDA (constant slowing down approximation) ranges for protons in the specified material. The function '*GetCSDARange*' in the Geant4 '*G4EMCalculator*' module was used to obtain the CSDA ranges for water, PMP and Teflon. For each WET value investigated, the required physical thicknesses of PMP and Teflon were then calculated.

$$\text{WET} = T \frac{\text{R}_{water}}{\text{R}_{material}} \quad (4)$$

2.6 Measurements in an Inhomogeneous Phantom

Measurements were also simulated in an inhomogeneous object. The phantom consists of an ethylene cylinder with two cylindrical inserts of tissue-equivalent materials; dense bone and lung. Pencil beams were simulated through a CT of the phantom on a two-dimensional grid, at 2mm increments along x and y. The phantom was oriented with its axis along the z-direction, such that the beam was perpendicular to the circular face. These simulations were run with 10^6 protons, p=10cm and D =1m. For each probe position, ΔE was fitted and the WET value was obtained from the appropriate calibration curve.

2.6.1 True WET projection

A WET projection of the phantom along the beam path was generated from the X-ray CT. For each voxel, the material was determined from the HU value, and the corresponding CSDA range was used to calculate the WET with Equation 4. The WET values were then summed along the z-axis to generate a two-dimensional map (Figure 4(a)).

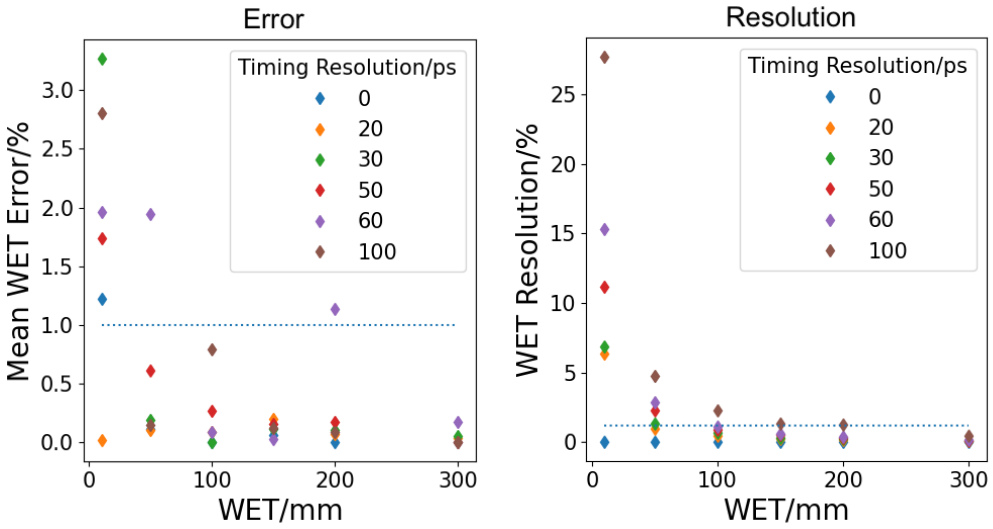

Figure 3: Results of WET measurements in water, with 10^6 protons, 10cm plane separation and 1m flight distance (a) Mean WET percentage error (b) WET resolution.

3 Results

3.1 Parameter Investigation

Results of WET measurements in water are shown in Figure 3. Generally, measurement accuracy and resolution are better at higher WET values and the resolution improves as timing resolution decreases. There is no clear relationship between accuracy and timing resolution. Greater plane separation and larger proton number improve measurement resolution. There was no difference in results between measurements in water, PMP and teflon. Spatial resolution and flight distance were not found to affect results. Overall, measurements made with a timing resolution of 60ps or better and at least 10^6 protons had accuracy and resolution better than 1%.

3.2 WET Image of Phantom

The phantom WET projection from the CT image is shown in Figure 4(a), the phantom range probe measurements in Figure 4(b) and the absolute difference between the two in Figure 4(c). Qualitatively, it can be seen that greater errors occur near boundaries of different media, for example at the edges of the phantom and the inserts. Error in the homogeneous regions is generally below 1mm for measurements with 0ps timing resolution. Near the edge of the phantom, however, the range error is as high as 50mm. This is caused by lateral proton scattering, meaning individual protons pass along paths of different WET. The introduction of an angular cut, to include only those protons that travelled along a near straight path could be used to improve the calculation[4]. It was also found that the average magnitude and spread in the WET error increase as the timing resolution increases.

4 Discussion

This detector is intended for use as a range probe with a small number of pencil beams. A method must be developed for choosing the optimal positions of these beams, which should take into account both measurement accuracy and clinical application.

The method proposed relies on proton-by-proton tracking. Therapeutic proton beams deliver a particle flux of up to 10^{10} protons per second. The data acquisition system must, therefore, be able to operate at MHz frequencies to avoid pile-up effects[5]. Methods have also been proposed to reduce the beam intensity. For example, the OPTIma project has explored the use of a collimator to reduce beam currents to 10pA[6]. Further work will explore the compatibility of the TOF range probe with a clinical beam. It will consider alternatives to proton-by-proton tracking using statistical methods.

The intrinsic timing resolution of the sensors will also affect the ability to make single proton measurements. As uncertainty in the arrival time increases, it becomes harder to identify which hits correspond to the same proton. Furthermore, as timing resolution increases, the resolution of the WET measurement worsens. The results suggest a timing resolution of $\leq$60ps would be required, which has been achieved with some detectors such as low-gain avalanche diodes (LGADs)[7].

A major advantage of this TOF technique is that a large range of WET values can be measured. This is because protons exiting the patient only need enough energy to travel as far as the final sensor. The largest WET that can be measured with the probe, however, is still limited by the maximum proton energy. A further limitation of range probing is that it is a projection of the WET along the whole path, including tissue outside of the treatment area.

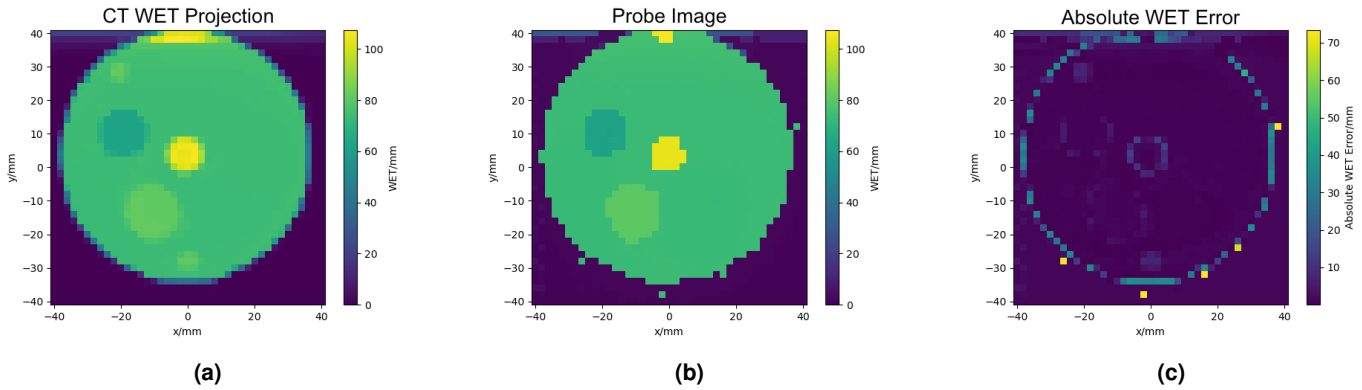

Figure 4: WET map of inhomogeneous phantom (a) WET projection from x-ray CT (b) Simulated range probe WET measurements (c) Absolute range error map

Experimental validation of these results is required. From a clinical perspective, there is an additional need to assess the best use of the probe. Among the questions to be addressed are the number of pencil beams required and at which point in the treatment process measurements will be made. The answers will depend on measurement dose, speed and accuracy.

5 Conclusion

It has been shown that a TOF range probe can be used to measure WET with an accuracy better than 1% and a resolution close to the range straggling limit. This is achievable with sensor timing resolutions better than 60ps. Experimental validation of this range probe is required, as well as an evaluation of the dose delivered during measurement.

[2]Department of Radiation Oncology, Mayo Clinic Florida, Jacksonville, FL, United States of America

Abstract In ion beam therapy a higher relative biological effectiveness (RBE) with respect to X-rays is well established. The RBE is known to be changing dynamically depending on multiple factors requiring complex biological models. A posteriori recalculation of most of these biological models using e.g. different cell-line data are challenging, requiring a complete recalculation of the whole treatment plan.

The abridged microdosimetric distribution methodology (AMDM) attempting to solve this issue, was integrated into the open-source Monte Carlo toolkit OpenGATE10. Furthermore, the calculation of RBE based on the Mayo Clinic Florida microdosimetric kinetic model (MCF MKM) was implemented and used to compare the RBE of two nozzle designs of the MedAustron and Mayo Clinic Florida. First investigations indicate that the nozzle design does not markedly affect the RBE. However, for mono energetic carbon ion beams changes in the initial energy spread due to different ripple filter designs may have a non-negligible influence.

1 Introduction

Radiation therapy uses ionizing radiation to treat malignant tissues. Due to their physical characteristics, ion beam therapy allows for improved dose conformity compared to conventional photon-based irradiation. In addition to the physical dose characteristics, ion beam therapy is general characterized by higher the relative biological effectiveness (RBE) with respect to the X-rays used in conventional radiation therapy.

For protons, the RBE is attributed to be 1.1, while for carbon ions, the second clinically most used ion, the RBE is known to be changing dynamically depending on multiple factors such as energy or penetration depth. So far two biological models to calculate the RBE are employed clinically, the local effect model (LEM1) [1] and the microdosimetric kinetic model (MKM) [2]. However, both models were found to have limitations, leading to the development of improved models. The Mayo Clinic Florida microdosimetric kinetic model (MCF MKM) [3] aims to predict the in-vitro clonogenic survival in the low as well as the high linear energy transfer (LET) range using computationally efficient single-event microdosimetric spectra.

The multitude of existing biological models indicates the need of model comparisons. Due to the implementational details of most of these models a posteriori calculations using different cell-line data or even different model formulations are challenging, requiring a complete recalculation of the whole treatment plan. Our group recently introduced a methodology potentially enabling a much faster and efficient comparison of biological modelling aspects [4].

The Mayo Clinic Florida (MCF) announced the construction of a synchrotron-based ion-therapy center being able to provide proton and carbon ion for treatment [5]. Ion therapy centers from different vendors are in operation all over the world. Although they all provide nominally comparable carbon ion beams in terms of energy or spot size, due to different design approaches especially of the beam delivery system and respective nozzles, it is not fully clear whether the different materials involved might alter the radiation quality, potentially affecting the RBE.

We have modelled the treatment nozzles of the MedAustron ion therapy center (MedAustron iontherapy center, Wr. Neustadt, Austria) and the Mayo Clinic Florida (Mayo Clinic Florida, Jacksonville, FL, USA) using the GATE Monte Carlo code. After implementing a method to calculate the RBE, we compared the biological impact of both nozzle designs.

2 Materials and Methods

Monte Carlo tool kit

The development version of OpenGATE10, based upon the Monte Carlo toolkit Geant4 was employed for this study. OpenGATE10 is designed to lower the user threshold for Monte Carlo simulations as much as possible. It uses a python wrapper, allowing user interaction directly from python scripts, without having to refer to C++ or macro commands. Installation can be performed using a simple pip install command without requiring the user to manually download and compile multiple software packages. OpenGATE10 is an open-source toolkit for Monte Carlo simulations initially developed for nuclear imaging applications, but later extended towards other modalities such as ion beam therapy [6–9].

Biological actor implementation

The abridged microdosimetric distribution methodology (AMDM) [4] was implemented as an actor into OpenGATE10. An actor allows to extract data from an OpenGATE simulation. AMDM creates spatially resolved multi-dimensional output which can then be used in post processing to calculate the RBE. This approach enables

the use different biological models or input parameters with the same simulation output, without having to redo time and resource intense Monte Carlo calculations. For our study post processing was performed using data from the HSG cell line and the MCF MKM biological model [10].

Nozzle modelling

For the MedAustron ion therapy center a pre-existing model of the treatment nozzle was employed [11,12]. The particles leaving the treatment nozzle were stored into separate phase space files for each treatment energy.

For the MCF treatment nozzle, confidential manufacturer data sheets were used to model the nozzle components in OpenGATE10 directly. It features an extensible nozzle allowing to adjust the distance between the nozzle exit and the isocenter in the range from 20 to 120 cm. For simplicity only the extended nozzle was used in this manuscript.

As at the facility is currently under construction, no existing beam data could be used. Instead, the beam parameters were modelled using design specifications. To facilitate comparison, the ranges of the MCF system was matched with the MedAustron ranges in terms of the range at 80% dose fall off (R80).

Simulations

Simulations were performed using a development version of OpenGATE10 alongside Geant4 v11.1.1. After exiting the nozzle (in case of the MCF nozzle) or the corresponding phase space (for the MedAustron nozzle) the beam impinged a water phantom with dimensions of 50x40x40 cm³. The physics list QGSP_BIC_EMZ with global cuts of 10 cm and smaller cuts of 0.1 mm in the water phantom were employed.

A total of 10^6 carbon ions were simulated for each set-up.

Mono energetic carbon ion beams with a range in water of 3 and 27 cm, corresponding to approximately 120 and 400 MeV/u were used, termed low and high energy in this manuscript, respectively.

Range shifters consisting of water were inserted for the 27 cm carbon ion beams. The thickness of the range shifters was chosen such, that the R80 of the higher energy was reduced to match the 3 cm range in R80 of the lower energetic beams. The carbon ion energy spectra at the beginning of the water phantom were evaluated.

The laterally integrated dose deposited in each voxel, using a resolution of 0.1 mm was stored. In addition, the multidimensional AMDM output, consisting of 23 additional parameters was stored in three files (restricted energy deposition, dose-mean lineal energy histogram, fraction of absorbed dose deposited by lineal energy events histogram).

Using a python script, the RBE for each voxel was calculated based on AMDM data using the MCF MKM after the simulation was finished. For RBE calculations the HSG cell line was used with RBE = $RBE_\alpha = \alpha_{AMDM}/\alpha_{ref}$.

3 Results

The R80 between MedAustron and MCF beamlines were matched for the extended MCF nozzle to be within 0.1 mm. Differences between the peak heights were observed within 5 to 14%.

In Figure 1 a comparison of laterally integrated depth-dose curves is displayed. The range at 80% dose fall-off was matched to be within 0.1 mm between beams with and without range shifter, respectively. As expected, the Bragg-peak width is increased for the initially higher energetic particle beams.

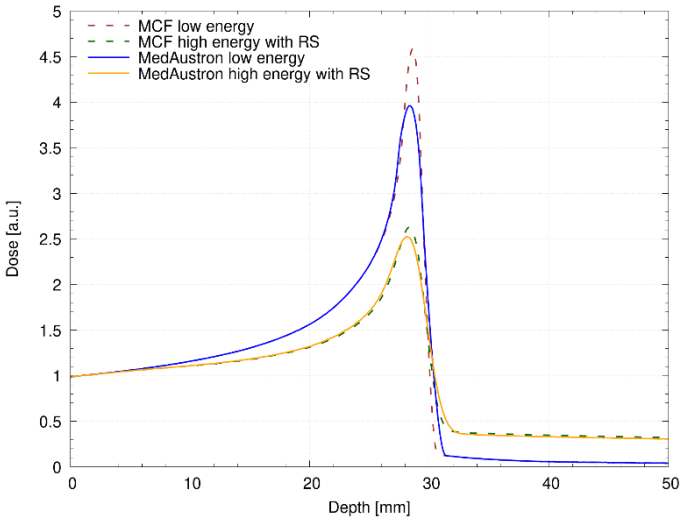

Figure 1 Laterally integrated depth-dose curves of carbon ions for the MCF and MedAustron nozzles. Range shifters were introduced to match the ranges to 3 cm for all initial energies and beam lines. Profiles were normalized at a depth of 1 mm.

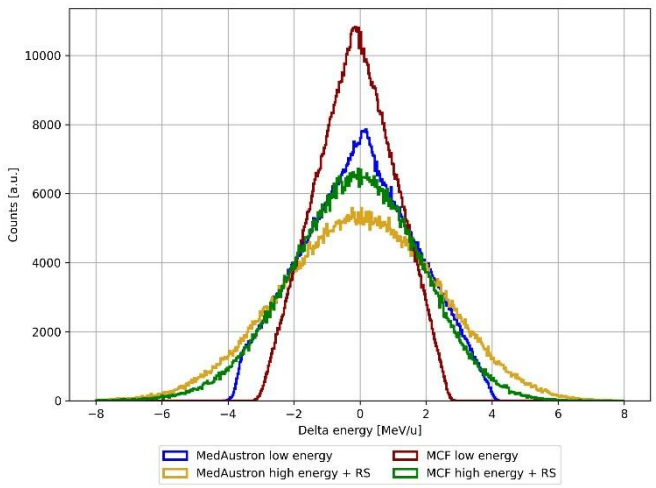

Figure 2: Energy spectra at the water phantom start for all investigated configurations. Data was normalized to the mean energy of the MedAustron low energy beam.

A comparison of the energy spectra (see Figure 2) showed that the overall energies were similar, with only minor deviations of the mean due to the range matching accuracy.
As expected, the width of the energy spread increased for the initially higher energetic particle beams, compared to the low energetic beams. The energy spread of the MCF nozzle was found to be narrower compared to the MedAustron nozzle.

In Figure 2Figure 3 the corresponding RBE of the mono energetic particle beams in water is shown. As expected, the maximum RBE of the broader Bragg peaks of the high energy carbon ions including a range shifter was up to 14% lower compared to the low energy beams. The average RBE of both nozzles agreed within 0.1%.

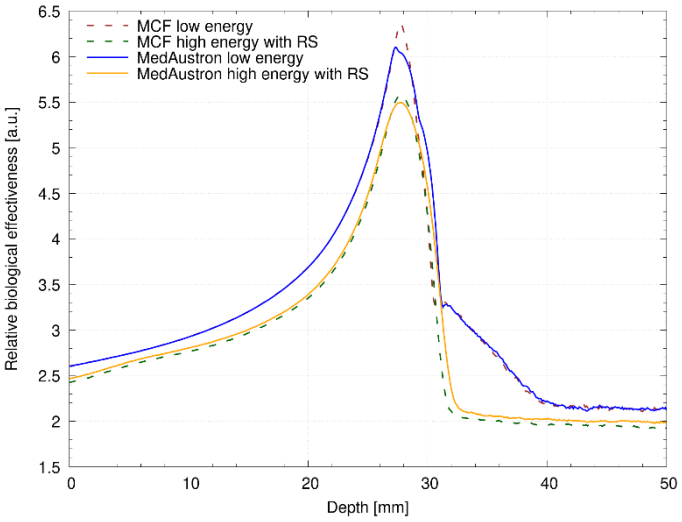

Figure 3. Relative biological effectiveness (RBE) of carbon ion beams for the MCF and MedAustron nozzle. Range shifters were introduced to match the ranges to 3 cm for all initial energies and beam lines.

4 Discussion

The overall shapes of the Bragg peaks for the MCF and MedAustron nozzle were found to be very similar. Differences between the peak heights are most likely related to the different specifications of the ripple filters. This was substantiated by the energy spectra. For the dose contribution a sensitivity study indicated that a variation in the initial energy spread from 0.01% to 0.1% did not have a considerable effect.

Multiple coulomb scattering resulted in larger Bragg peak width for the carbon ion beams transversing the water range shifters compared to the lower energetic carbon ions. This was also apparent in the energy spectra.

The RBE curves were similar with some notable changes. A change in RBE after the Bragg peak was apparent for all particles traversing the range shifter, indicating a small change in beam quality.

Changes in RBE between the MCF and MedAustron nozzle were most likely related to the slightly different employed ripple filters and correspondingly different energy spread. Mono energetic carbon ion beams might be the most sensitive to changes in this regard. A more realistically comparison would be to using spread out Bragg peaks instead of mono energetic ones. Such a comparison is currently ongoing.

5 Conclusion

The abridged microdosimetric distribution methodology (AMDM) was integrated into the open-source Monte Carlo toolkit OpenGATE10. Furthermore, the calculation of RBE based on the Mayo Clinic Florida microdosimetric kinetic model (MCF MKM) was successfully tested.
First investigations indicate that the nozzle itself does not markedly affect the radiation quality and the RBE. The average RBE of both nozzles agreed within 0.1%. However, for mono energetic carbon ion beams changes in the initial energy spread due to different ripple filter designs may have non-negligible influences.

Abstract In recent advancements in proton therapy, MR-based treatment planning is gaining momentum to minimize additional radiation exposure compared to traditional CT-based methods. This transition highlights the critical need for accurate MR-to-CT image synthesis, which is essential for precise proton dose calculations. Our research introduces the Diffusion Schrödinger Bridge Models (DSBM), an innovative approach for high-quality MR-to-CT synthesis. DSBM learns the nonlinear diffusion processes between MR and CT data distributions. This method improves upon traditional diffusion models by initiating synthesis from the prior distribution rather than the Gaussian distribution, enhancing both generation quality and efficiency. We validated the effectiveness of DSBM on a head and neck cancer dataset, demonstrating its superiority over traditional image synthesis methods through both image-level and dosimetric-level evaluations. The effectiveness of DSBM in MR-based proton treatment planning highlights its potential as a valuable tool in various clinical scenarios.

1 Introduction

In radiation therapy, proton therapy stands out for its exceptional precision and ability to minimize radiation exposure to non-target tissues. In traditional proton therapy treatment planning, reliance on Computed Tomography (CT) scans is standard practice. However, CT imaging for pre-treatment planning, as well as daily verification, often results in extra radiation doses to the patient. Recognizing this challenge, there's a growing interest in exploring Magnetic Resonance (MR) imaging as a potential alternative, given its ability to provide detailed anatomical information without the associated radiation exposure [1]. This paradigm shift towards MR-based proton treatment planning underscores the need for high-quality MR-to-CT image synthesis, where attaining both anatomical precision and accurate density information within synthetic CTs is essential for proton dose calculations.

Recent advancements in AI-based generative imaging techniques, particularly the Diffusion Models (DMs) [2], have shown promising results for natural image generation tasks [3]. DMs have also been proven for their capacity to produce detailed and realistic synthetic medical images [4]. However, traditional DMs often involve lengthy sampling chains, which can significantly reduce sampling efficiency. Furthermore, given the higher image generation variability compared to conventional approaches, DMs may have limitations in clinical MR-to-CT synthesis, where both image generation precision and stability are crucial.

To tackle these challenges, we propose the Diffusion Schrödinger Bridge Model (DSBM) for MR-to-CT synthesis. Unlike conventional diffusion methods that sample from a Gaussian distribution, this approach directly learns the nonlinear diffusion processes between MR and CT data distributions. This method can establish a more direct transition model between MR and CT data, enhancing image generation quality and stability while increasing efficiency through fewer sampling steps, thereby boosting its potential application in proton therapy clinical practices.

2 Materials and Methods

2.1 Diffusion Schrödinger Bridge Models (DSBM)

Schrödinger Bridge (SB), as introduced by Schrödinger in 1932 [5], represents an entropy-regularized optimal transport model that incorporates the following forward-backward Stochastic Differential Equations (SDEs):

$$\mathrm{d}X_t = \left[f_t + g_t^2 \nabla \log \Psi_t\left(X_t\right)\right]\mathrm{d}t + g_t\, \mathrm{d}W_t, \tag{1a}$$

$$\mathrm{d}X_t = \left[f_t - g_t^2 \nabla \log \widehat{\Psi}_t\left(X_t\right)\right]\mathrm{d}t + g_t\, \mathrm{d}\bar{W}_t, \tag{1b}$$

where $X_t \in \mathbb{R}^d$ is a d-dimensional stochastic process, indexed by discrete time steps $t \in [0, T]$. The Wiener process is represented as W_t, while its reverse-time process is denoted as $\bar{W}_t$. Here, X_0 is sampled from the boundary distribution p_{CT}, representing CT image data, while X_T is drawn from p_{MR}, representing the paired MR image data. The functions $\Psi_t, \widehat{\Psi}_t$ represent time-dependent energy potentials that satisfy the following coupled Partial Differential Equations (PDEs):

$$\begin{cases} \frac{\partial \Psi_t(x)}{\partial t} = -\nabla \Psi^\top f - \frac{1}{2} g^2 \nabla^2 \Psi \\ \frac{\partial \widehat{\Psi}_t(x)}{\partial t} = -\nabla \cdot (\widehat{\Psi} f) + \frac{1}{2} g^2 \nabla^2 \widehat{\Psi} \end{cases} \tag{2}$$
$$\text{s.t. } \Psi_0(x)\widehat{\Psi}_0(x) = p_{\mathrm{CT}}(x), \Psi_T(x)\widehat{\Psi}_T(x) = p_{\mathrm{MR}}(x)$$

However, addressing the SB models involves simulating stochastic processes and requires resource-intensive iterative procedures [6, 7]. Consequently, this approach faces challenges in terms of tractability and practical applicability.

To tackle this problem, we implement the concepts from [8], transforming the SB model into the following SDEs:

$$\mathrm{d}X_t = f_t(X_t)\,\mathrm{d}t + g_t\,\mathrm{d}W_t, X_0 \sim \widehat{\Psi}_0, \tag{3a}$$

$$\mathrm{d}X_t = f_t(X_t)\,\mathrm{d}t + g_t\,\mathrm{d}\bar{W}_t, X_T \sim \Psi_T. \tag{3b}$$

This form adheres to the fundamental structure of the score-based generative models (SGM) [9], where $\nabla \log \widehat{\Psi}_t(X_t)$ and $\nabla \log \Psi_t(X_t)$ are the *score functions* of the above SDEs. Then, we delve into practical strategies for applying the above model to MR-to-CT synthesis. Given the fact that the availability of paired information during training, where $p(X_0, X_T) = p_{\mathrm{CT}}(X_0)\, p_{\mathrm{MR}}(X_T \mid X_0)$, with p_{CT} and p_{MR} corresponding to the CT and MR data distributions respectively. This framework allows us to construct tractable Schrödinger Bridges between X_0 and $p_{\mathrm{MR}}(X_T \mid X_0)$. According to [8], we can adopt an analytic posterior given the boundary pair MR-CT data (X_0, X_T):

$$\begin{gathered} q(X_t \mid X_0, X_T) = \mathcal{N}(X_t; \mu_t(X_0, X_T), \Sigma_t), \\ \mu_t = \frac{\bar{\sigma}_t^2}{\bar{\sigma}_t^2 + \sigma_t^2} X_0 + \frac{\sigma_t^2}{\bar{\sigma}_t^2 + \sigma_t^2} X_T, \quad \Sigma_t = \frac{\sigma_t^2 \bar{\sigma}_t^2}{\bar{\sigma}_t^2 + \sigma_t^2} \cdot I. \end{gathered} \tag{4}$$

Here, we define $\sigma_t^2 = \int_0^t g_\tau^2 \mathrm{d}\tau$, $\bar{\sigma}_t^2 = \int_t^1 g_\tau^2 \mathrm{d}\tau$. Then, based on the network parameterization settings in [3] with a 3D U-Net [10], the training and sampling procedures can be done under the same framework as [8].

2.2 Dataset and Model Implementations

This study used a dataset of head-and-neck images from 58 patients treated at PSI between 2017 and 2022, divided into training (46 patients) and testing (12 patients) sets. CT scans were performed using a Siemens Sensation Open CT scanner (resolution: 1 × 1 × 2 mm), and MR scans with a 1.5T Siemens Aera MR scanner (voxel size: 1 × 1 × 1 mm), primarily using the T1 vibe Dixon sequence. Data pre-processing, including a neural network-based data registration step, followed protocols outlined in [11]. We strictly adhered to ethical standards in human data research, obtaining informed consent for using anonymized patient data and ensuring confidentiality and ethical compliance. DSBM was comprehensively compared with two other established medical image synthesis approaches, namely the pix2pix model [12] and the nnU-Net model [13]. While the nnU-Net model utilized the same 3D data inputs as DSBM, the pix2pix model was trained on 2D image slices.

2.3 Image-level Evaluation

We evaluated the accuracy and anatomical fidelity of synthetic CT (sCT) and planning CT (pCT) using various image-related metrics, including: Mean Absolute Error (MAE) on Hounsfield Units (HU), Peak Signal-to-Noise Ratio (PSNR), and Structural Similarity Index (SSIM) for intensity value mapping, focusing on different regions of interest (RoIs). For anatomical conformity, Dice Coefficients (Dice) were calculated to assess structural overlaps, especially in bone regions (HU greater than 250).

2.4 Dosimetric-level Evaluation

Dosimetric evaluations were performed to validate the clinical utility of the generated sCT images in proton therapy. Treatment plans were optimized on pCT using in-house developed Juliana software [14], and doses were recalculated for sCTs as direct comparison. We assessed Mean Dose Error at various dose thresholds (10%, 50%, and 90%), and used gamma pass rates (1%/1mm and 2%/1mm) for gamma analysis between planned and recalculated dose distributions. Dose-Volume Histograms (DVHs) and Differential Dose-Volume Histograms (DDVHs) were analyzed, providing insights into the dosimetric impact of using sCTs. We further investigated the variations in several typical dose indices, specifically V95, D95, D2, Dmean, and Vdosediff>3% (the percentage of voxels in the same structure with an absolute point dose difference larger than 3% of the prescribed dose), for both PTVs and OARs, to comprehensively understand the accuracy of the new MR-to-CT synthesis approach for calculating proton therapy treatment plans.

3 Results

At the image level, DSBM outperformed conventional nnU-Net and pix2pix models in the testing set. It achieved a lower Mean Absolute Error (MAE) of 72.30 ± 8.31 HU and a higher Dice score of 83.10 ± 3.90%, indicating enhanced anatomical accuracy, especially in bone structures (Table 1). Visual comparisons in Figure 1 further corroborate this, with error histograms showing DSBM's reduced errors and improved fidelity in synthetic CT images (sCTs).

At the dosimetric level, DSBM also demonstrated improved agreement for calculating doses when compared to those calculated on the corresponding pCT. It showed mean voxel-wise differences in the body region of less than 0.01% of the prescribed dose (Table 2), and the 1%/1mm gamma pass rate of 95.53 ± 2.89% in the RoI (Table 3). Figure 2 offers a visual comparison between synthetic (sDoses) and planned doses (pDose) in terms of voxel-wise dose differences, DVHs and DDVHs of a single case. Figure 3 compares the differences of dosimetric indices for PTVs and OARs across all 12 cases in the testing set. These results underscore DSBM's dosimetric accuracy, confirming its efficacy and potential utility in clinical proton therapy settings.

4 Discussion

The evaluations in our study, both at the image and dosimetric levels, have demonstrated the superiority of the Diffusion Schrödinger Bridge Model (DSBM) approach over

DSBM (50-step)	0.01±0.06	0.09±0.11	0.32±0.29	0.36±0.28

conventional classic MR-CT synthesis methods. The DSBM-generated CT images not only exhibit remarkable accuracy and anatomical fidelity but also demonstrate dosimetric accuracy, vital for applications like adaptive or even MR-only proton treatment planning. A notable aspect of the DSBM method is its efficiency in generating high-quality results even with a limited number of neural function evaluation steps (NFEs). Our findings reveal that the DSBM can still outperform conventional methods when operating in very few sampling steps, even in a single step. In practical terms, generating a volume batch of size $128 \times 128 \times 4$ pixels takes only about 0.2 seconds per sampling step with DSBM. It should be noticed that conventional diffusion models require over 100 sampling steps for comparable results, which can lead to a generation time of more than 20 seconds per volume batch. Consequently, the DSBM method offers a speed enhancement of 10 to 50 times, marking a substantial leap in efficiency. Moreover, increasing the number of sampling steps does not necessarily correlate with further outcome improvement. We postulate that this phenomenon could be attributed to the introduction of noise at each step due to the inherent randomness in the sampling process.

5 Conclusion

In this study, we propose the Diffusion Schrödinger Bridge Models (DSBM) which enhances the performance of MR-to-CT image synthesis, both in quality and efficiency. By learning the nonlinear diffusion processes between MR and CT data distributions and initiating synthesis from a prior distribution, DSBM outperforms traditional methods, as validated in our head and neck cancer case studies. This approach has demonstrated its value through comprehensive evaluations at both the image and dosimetric levels. DSBM can improve the accuracy and efficiency of MR-based treatment planning in proton therapy, which could potentially reduce imaging-related dose and improve patient outcomes in radiotherapy.

Abstract Due to involuntary organ motion, prostate magnetic resonance images are often acquired in 2D with thick through plane spacings and reconstructed into anisotropic voxelized volumes. In prostate cancer (PCa) radiotherapy, annotations such as zonal or lesion segmentation are then performed on the few axial slices in which the prostate appears, leading to coarse and often inconsistent delineations across slices, which are nevertheless used as ground truth for deep segmentation model training and performance reports.
Recently, deep self-supervised super resolution (SSR) was proposed in brain MRI to remove the need for calibrated training data, by learning the low-resolution to high-resolution mapping from the anisotropic image itself. In this work, we propose a new training objective (loss function) for SSR based on the alignment of normalized image gradient vectors, a technique normally used for image registration. Preliminary experiments on the public Prostate158 dataset suggest that automatic PCa detection could be improved using SSR with the proposed training objective. However, the low quality of lesion annotations obtained on a few slices is a major bottleneck to confirm these findings quantitatively.

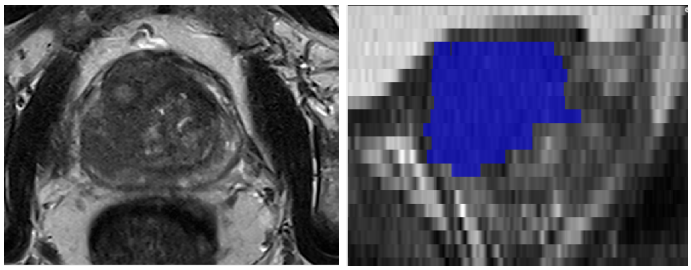
1 Introduction

1.1 Context

Prostate cancer (PCa) is a major form of cancer that affects about one man in six during his lifetime [1]. Approximately 75% of PCa originate in the peripheral zone of the gland (PZ), as opposed to the more central transition zone (TZ) [2]. Radiotherapy treatment planning of PCa relies on multiparametric magnetic resonance imaging (mpMRI) comprising T2-weighted and diffusion-weighted sequences for lesion detection and characterization [3].

1.2 Image anisotropy

Due to involontary movements, recommendations are to perform fast 2D T2-weighted pulse sequences, preferably along the three anatomical planes but sometimes along the axial direction only [3]. However, such acquisitions lead to high resolution (HR) in-plane images (e.g. from 0.5×0.5 mm^2 down to 0.25×0.25 mm^2, Fig. 1a) but to low resolution (LR) through-plane images due to large spacings (typically of around 3 mm, Fig. 1b). Such anisotropy in the data representation may hamper image analysis downstream. In particular, the detection and characterization of the PCa lesions from such degraded acquisitions is difficult and subjected to high inter reader variability. In this context, the automatization of these tasks of high clinical relevance.



(a) Axial view **(b)** Sagittal + lesion "ground truth"

Figure 1: Example 2D axial prostate MRI acquisition with high in-plane resolution (0.27 mm^2) and thick through-plane spacing (3 mm). The lesion mask is also imprecise with strong "staircasing" effect.

1.3 Objective

In this work, we study whether enhancing image resolution through Single Image Super-Resolution (SISR) techniques can improve PCa lesion deep learning-based segmentation. More specifically, we leverage a self-supervised super resolution (SSR) method, SMORE, recently proposed for brain MR SISR [4]. SMORE alleviates the need for any training data outside the anisotropic image itself. In this context, we propose a new reconstruction objective (loss function) to improve SMORE results based on the alignment of normalized gradient fields (NGF) between the LR and HR planes, a technique normally used for image registration [5]. Preliminary results on the Prostate158 public dataset suggest that SSR is indeed beneficial to PCa detection, and that the addition of the proposed NGF loss term may further improve the quality of the detection.

2 Related works

The majority of modern computerized medical image analysis approaches rely on (deep) machine learning techniques. A canonical example is the U-Net convolutional neural network (CNN) model [6] for segmentation [7] and detection [8]. When dealing with highly anisotropic data, little to no gain is achieved using 3D models, and 2D models are generally preferred [7]. However, 2D models inherently discards the consistency of the signal along the (degraded) third dimension, which is suboptimal.

Among major research directions, careful curation and preprocessing of input data is generally considered a critical aspect for the improvement of learning-based model performances [7]. In this work, we hypothesize that improving the resolution of highly anisotropic images through self-supervised SISR techniques can be beneficial to a variety of downstream image analysis tasks.

2.1 Single image super resolution

Current state of the art SISR methods generally require curated external supervised training data with predetermined downsampling factors to learn a mapping between the LR and HR spaces using e.g. deep residual networks [9]. However, such training data may be difficult to obtain in practice, as data collections are typically gathered from multiple centers with heterogeneous practices. Moreover, these methods are subject to the domain shift between training and deployment conditions.

2.2 Self-supervised super-resolution with SMORE

Recently, Zhao et al. proposed Synthetic Multi-Orientation Resolution Enhancement (SMORE), a self-supervised super resolution (SSR) approach for anisotropic volumes [4]. SMORE removes the need for external training data as the LR to HR mapping is learned directly on the 3D volume itself (i.e. between the two LR planes and the HR plane). First, SMORE proposes a forward degradation model on the HR 2D slices to mimick the degradation in the LR planes due to the 2D acquisition protocol, taking into consideration both aliasing due to sampling in the slice direction and blur. In practice, the degradation is achieved through downsampling followed by upsampling and blurring. A supervised deep-learning super-resolution model, such as EDSR [10] is then used to learn the mapping between synthetically degraded LR patches and HR patches.
SMORE operates under a dual objective that combines a pixel-level reconstruction loss (using the ℓ_1 norm) with an edge loss ensuring similarity between image gradients using a Sobel filter.
Once trained, the model is applied to LR orientations (here sagittal and coronal, without loss of generality). Finally, a unique HR isotropic volume is reconstructed by merging volumes upsampled by SSR in the frequency domain through Fourier burst accumulation [11].

3 Method

3.1 Problem statement

Let $\boldsymbol{x}_{\mathrm{LR}}$ be a LR T2 image having thick through-plane spacing along the last dimension, i.e. a resolution of $r_x \times r_y \times r_z$ mm^3, with voxel spacing $r_z > r_x$ and where $r_y = r_x$ for simplicity. We hypothesize that $\boldsymbol{x}_{\mathrm{LR}}$ is a downsampled version of an unobserved HR image $\boldsymbol{x}_{\mathrm{HR}}$ of superior resolution $r_x \times r_x \times r_x$ mm^3. Our objective is to recover an estimate $\hat{\boldsymbol{x}}_{\mathrm{HR}} = \mathscr{G}(\boldsymbol{x}_{\mathrm{LR}})$ from $\boldsymbol{x}_{\mathrm{LR}}$ using a neural network $\mathscr{G}$, which is a typical single image super resolution (SiSR) problem [12].

3.2 Normalized Gradient Field loss

The original SMORE is trained under a joint ℓ_1 reconstruction and Sobel gradient objective, the latter promoting edge similarity. However, gradient similarity prioritizes high-contrast edges over low-contrast ones (i.e. of weaker gradient magnitude). As a result, some of the finer aspects of the image might be lost or blurred in the enhancement process. To counter this effect, we propose to give equal weight to weak and strong edges through gradient normalization. The idea of normalizing gradients is popular in image registration to obtain contrast-independent similarity metrics and known as the normalized gradient field (NGF) [5].
The NGF loss if defined as :

$$\mathscr{L}_{NGF} := 1 - \frac{1}{2}\langle \boldsymbol{n}_\varepsilon(\boldsymbol{x}_{\mathrm{HR}}), \boldsymbol{n}_\varepsilon(\mathscr{G}(\boldsymbol{x}_{\mathrm{LR}}))\rangle^2, \tag{1}$$

where $\langle\cdot,\cdot\rangle$ is the dot product and $n_\varepsilon(\boldsymbol{x})$ is the NGF :

$$\boldsymbol{n}_\varepsilon(\boldsymbol{x}) = \frac{\nabla \boldsymbol{x}}{\|\nabla \boldsymbol{x}\| + \varepsilon}, \tag{2}$$

with ε a noise threshold scalar parameter controlling the influence of noise, with higher values corresponding to higher suppression. The reason for normalization is to encourage gradient vector alignment between generated and target images while being agnostic to contrast.
In this work, we thus propose to use the NGF in the context of image super resolution by training the SSR model under a joint ℓ_1 and a NGF objective (instead of the Sobel loss).

4 Experiments and Results

4.1 Experiments

The evaluation of super resolution can be done either using reconstruction metrics when ground truth HR images are available, or task-based considering a downstream objective (e.g. segmentation, detection, prediction, ...). In this work, we studied to what extent the proposed SSR approach can be beneficial to the training of deep learning-based PCa lesion detection models. In our experiments, we used the public Prostate158 dataset [13] constituted of 158 patient image data, of which we selected 63 images with annotated PCa lesions on axial T2-weighted MR images, showing voxel anisotropy ranging from $0.27 \times 0.27 \times 3$ mm^3 to $0.47 \times 0.47 \times 3$ mm^3. Images were clipped to the 1%-99% percentile and rescaled in the range [0-1] following common practice. The noise parameter ε was set to 0.1. Note that the annotations were performed on the LR axial images and are thus imperfect ground truth.
The SSR method was implemented using PyTorch and Kornia and applied individually to each image of the training and

testing set. The SSR model required approximately one hour per image on a NVIDIA RTX A6000 GPU. Once processed by the various upsampling methods, images were fed to a 3D full resolution nn-UNet model [7] for 1000 epochs using 5-fold cross validation and ensembling. Our baseline comparisons comprised results achieved the original SMORE model (using a joint ℓ_1 and Sobel loss), or by letting the nnU-Net chose the resampling space dynamically using its inner heuristics (resampling to the median resolution of the training set). We used the first 47 images in lexicographic order patients for training and the remaining 16 for testing. Detection evaluation was performed using volumetric overlap between predicted and real lesion masks. A detection was considered positive if the Dice score exceeded 0.2.

4.2 Results

Fig. 2 shows representative upsampling results obtained in one patient of the Prostate158 set, with much better recovery of high frequency details using SSR, and especially when considering the NGF loss with a clearly sharper output. Out of the 16 images tested, 8 were deemed unsuccessful as they recorded a Dice score of less than 0.2 across all methodologies. This can be attributed to the inherent challenges associated with prostate cancer (PCa) segmentation on complex images. Achieving accurate segmentation in these cases often requires the support of additional modalities, typically Apparent Diffusion Coefficient (ADC) MRI, which were not utilized in our study. However, using SMORE allowed for a better detection on average, which translated into better quantitative scores (Table 1). Note one failure case for nnU-Net interpolation and one failure case for baseline SMORE. Our proposed NGF training objective for SMORE allowed better results on average, with a Dice score of around 50. However, these quantitative results are to be taken with caution due to the very limited quality of the lesion segmentation in such anisotropic images. For instance, patient 118 has only two annotated axial slices.

Patient ID	nnU-Net interp.	SMORE	SMORE+NGF
112	18.1	**29.0**	13.7
118	59.2	**71.2**	62.2
125	**64.5**	62.8	34.1
131	**72.7**	69.2	70.6

(c) SMORE ($\ell_1 + \text{NGF}$)

Figure 2: Upsampling result in the Prostate158 dataset. Self Super-Resolution with the proposed NGF objective lead to better detail recovery and sharper outputs.

5 Conclusion

In this preliminary work, we have investigated whether self supervised resolution could be used to improve the detection of PCa images from T2-weighted MR images. Leveraging the SMORE model, we have proposed a new loss function that aims at promoting the alignment of normalized gradient vectors between high resolution and low-resolution patches during training. Preliminary results tend to suggest a positive impact of such an approach, both visually and quantitatively. However, further experiments need to be conducted in a more controlled environment to ensure the interest of the approach, for instance using better annotations or synthetically degraded pseudo low resolution images. Other downstream tasks will also be investigated, such as e.g. segmentation of vascular structure in liver CT images for surgical planning.

Patient-specific simultaneous CT and MR reconstruction from sparse projection measurements using implicit neural representation

Oscar Pastor-Serrano, Liang Qiu, Siqi Ye, and Lei Xing

Department of Radiation Oncology, Stanford University, Stanford CA, United States

Abstract Radiotherapy workflows can significantly benefit from the simultaneous acquisition of paired computed tomography (CT) and magnetic resonance (MR) images, particularly in MR-guided treatments. In this study, we introduce a patient-specific algorithm designed to precisely reconstruct CT scans and their corresponding MR intensities using sparse measurements (i.e., as few as 10 projections). We propose a novel framework based on a generalizable implicit neural representation (GINR) with two channels, a method that incorporates prior patient information into the weights of a neural network mapping spatial coordinates to CT or MR values. With only a few projections, GINR can reconstruct the new CT anatomy and the corresponding MR within a few minutes. GINR achieves a peak signal-to-noise ratio (PSNR) of 40.13±1.05 dB when reconstructing brain CTs from 10 projections, and 26.64±0.57 dB for their corresponding MR counterparts, establishing itself as a fast and accurate alternative to traditional algorithms.

1 Introduction

Imaging plays a pivotal role in radiation therapy (RT) treatments, from patient diagnosis to treatment simulation and patient positioning and monitoring during treatment delivery. Computed tomography (CT) stands as the reference image modality in radiotherapy, providing both the patient's geometry and the electron densities needed for the calculation of the physical radiation dose [1]. Alternatively, the utilization of magnetic resonance (MR) images, such as for tumor localization or treatment delivery guidance, is swiftly gaining prominence. This surge is attributed to the heightened soft tissue contrast and diminished radiation exposure that MR provides [2].

The success of an RT treatment depends, among other factors, on the speed and quality of critical steps, such as image acquisition and the subsequent organ delineation and dose calculation based on the acquired images. These speed requirements become notably stringent in adaptive or MR-guided treatments. In these approaches, aimed at minimizing treatment uncertainties and tumor margins, the entire workflow, possibly involving re-planning, is compressed into just a few seconds before or during the delivery of each treatment fraction. Hence, fast and accurate imaging emerges as a pivotal factor for the success of such treatments.

Currently, CT and MR image acquisition is formulated as an inverse problem aimed at reconstructing the final image from measured sensor data. Generally, obtaining low-noise images necessitates dense sampling in measurement space, posing challenges for both image modalities, e.g., increasing the dose delivered by CT projections and the MR reconstruction times. Furthermore, while ideally employed in tandem to leverage their respective strengths and weaknesses, pairing CT and MR images presents its own set of challenges. Firstly, both image modalities must be independently acquired within the shortest time possible to minimize anatomical changes, thereby increasing the total treatment time. Secondly, the registration of both images to the same coordinate system introduces additional uncertainties. Only after both steps have been completed can one, in principle, calculate the outcome of the treatment, such as the dose distribution, which is also impacted by the quality of the images used as input.

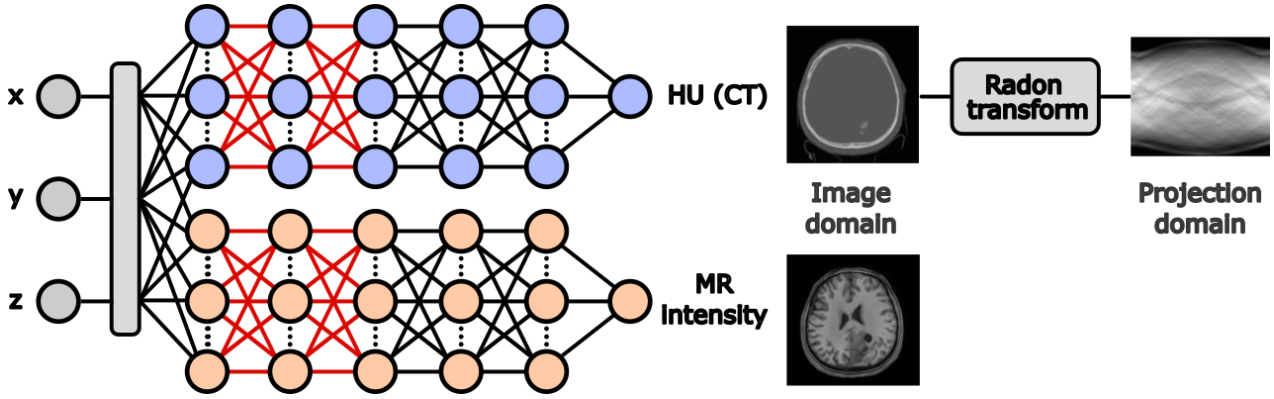

Figure 1: ***Overall generalizable implicit representation workflow.*** *A two-branch multi-layer perceptron maps spatial coordinates to CT, and MR or dose values. First, any prior information (few available scans from a single patient) can be directly embedded into the weights of each branch by minimizing the square difference between the network outputs and the prior images. The weights of the first layers (in red), containing transformations specific to each geometry, are shared between branches. Once obtaining new projections, these shared weights can be adjusted via backpropagation through the Radon transform operation.*

To minimize treatment time, image reconstruction must leverage sparse measurement data. Likewise, simultaneous CT/MR image acquisition is highly preferable. Recent deep learning approaches that learn a mapping function between synthetic CT/MR [3] face the challenge of choosing between speed and accuracy. This dilemma arises either by opting to wait until the source image is obtained from dense measurements or by compromising performance when using a sub-optimal sparsely reconstructed source image.

Recent advancements in implicit neural representation methods such as NeRP [4] represent the culmination of a series of works leveraging prior knowledge to address the challenges of sparse sampling image reconstruction [4]. In this study, we introduce an INR-based algorithm capable of reconstructing CT images from sparse projection data while simultaneously providing the corresponding MR image. As a patient-specific approach, the resulting INR model embeds prior patient information (e.g., the planning CT or MR scan) into the weights of a multi-layer perceptron (MLP) neural network. This design eliminates the need for extensive training or large-scale datasets. With only a few newly acquired projections, the MLP weights can be adjusted to accurately represent the new CT anatomy and its corresponding MR counterpart.

2 Materials and Methods

Figure 1 illustrates the proposed framework. We employ a generalizable implicit neural representation (GINR) using two parallel multi-layer perceptron (MLP) branches that map input spatial coordinates to their respective CT/MR values. The first MLP, represented in blue, embeds CT images by mapping spatial coordinates to Hounsfield Unit (HU) values. The second MLP (in orange) learns the paired MR image by mapping spatial coordinates to MR intensities. The initial layers' weights (in red) are shared between both networks, capturing instance-specific variations, while the remaining weights are consistent across patient samples and encapsulate modality-specific characteristics. When new projection measurements are recorded, we exclusively adjust the shared weights using the CT branch. Subsequently, these adjusted weights are utilized to obtain the corresponding MR image from the secondary branch.

Problem formulation. We frame the reconstruction problem as starting from a forward process $y = Ax + e$, where $x \in \mathbb{R}^M$ is the CT image of the unknown subject with M voxels, $y \in \mathbb{R}^{N_p \times D}$ are a finite number N_p of sampled projections, A represents the forward model (i.e., the Radon transform), and e is acquisition noise. The corresponding inverse process aims at recovering x from sparse y measurements, and is generally formulated as an optimization problem with regularization as

$$\min_{x} E(Ax, y) + \rho(x), \quad (1)$$

with an error term $E(Ax, y)$ such as the L2 norm, and a regularization term $\rho(x)$ characterizing generic image prior information, which can be defined in multiple ways.

Implicit neural representation. Following previous work [4], we use a MLP $M_{\theta,\phi}$ with parameters θ and ϕ to represent images CT images, mapping spatial coordinates $c \in [0,1)^3$ to the corresponding HU values. Likewise, we define a secondary MLP $M_{\theta,\eta}$ mapping coordinates to a secondary modality such as MR intensity. The parameters θ from the first layers are shared across both MLPs and capture sample specific variations, while the parameters ϕ and η embed modality-specific information.

Prior embedding. For a given subject, we can embed a small set of prior CT images x_p and a paired prior MR images or dose distributions z_p of the same patient within the weights of the MLPs. Examples of these datasets can be the images recorded during the first few days of treatment delivery, or even a single planning image with simulated deformations. Embedding this prior data into a GINR consists of obtaining a set of optimum weights $\{\phi^*, \eta^*, \ \{\theta_n\}_{n=1}^N\}$ via an iterative optimization problem:

a) For each $\{x_p^n, z_p^n\}_{n=1}^N$, keeping ϕ^* and η^* fixed:

$$\min_{\theta_n} \frac{1}{M} \sum_{i=1}^{M} \left\| M_{\theta_n,\phi^*}(c_i) - x_{p,i}^n \right\|_2^2 + \left\| M_{\theta_n,\eta^*}(c_i) - z_{p,i}^n \right\|_2^2. \quad (2)$$

b) For all $\{x_p^n, z_p^n, \theta_n\}_{n=1}^N$, freezing θ_n:

$$\phi^*, \eta^* = \underset{\phi,\eta}{\operatorname{argmin}} \frac{1}{M} \sum_{i=1}^{M} \left(\left\| M_{\theta_n,\phi}(c_i) - x_{p,i}^n \right\|_2^2 + \left\| M_{\theta_n,\eta}(c_i) - z_{p,i}^n \right\|_2^2 \right). \quad (3)$$

where Equation 2 (inner loop) finds the optimum geometry-specific weights θ_n for each image pair, and Equation 3 (outer loop) finds the best ϕ and η weights over all available prior images. This process is repeated over T iterations.

Image reconstruction. Starting from the trained weights (ϕ^* and one of the θ_n), and once new projections are obtained, we can effectively formulate the search in image space as an optimization over the θ weight space as

$$\min_{\theta_r} \left\| A M_{\theta_r,\phi^*} - y \right\|_2^2, \quad (4)$$

aiming at obtaining the shared weights θ_r of the new geometry. Since the Radon transform A is differentiable, the gradients can be backpropagated to obtain the new INR minimizing Equation 4. Note that we disregard the explicit regularization term $\rho(x)$ in Equation 1, since all prior information is contained in the starting network's weights.

Technical details. In our implementation, we construct 2 MLPs with 9 layers, 256 neurons per layer, and a periodic activation function, where the weights of the first layer are shared for both image modalities. Based on previous works [5], we use a Fourier feature mapping of size 256 that encodes the input coordinates before the first layer and helps the network learn high-frequency functions. The MLPs are implemented in Pytorch [6] and trained for $T = 1000$ iterations using the Adam optimizer [7], with a starting learning rate of $1e^{-4}$ that is halved each time the loss plateaus for 20 epochs.

3 Experiments and Results

To demonstrate the capabilities of the proposed GINR method, we conducted experiments to reconstruct brain CTs and their corresponding MR images. We compare the performance of reconstructing CTs (Equation 4) from 10, 20 or 30 projections, using the peak signal-to-noise ratio (PSNR) as a metric representing reconstruction quality for MR and CT images. As a baseline, we report the results of performing CT image reconstruction using the filtered back-projection (FBP) algorithm.

Table 1: CT/MR reconstruction accuracy. *Peak signal-to-noise ratio (PSNR) between model outputs and the original image pairs, for both the proposed GINR model and the filtered back-projection (FBP) baseline. All values are in decibels (dB).*

Image	Methods	Pat 1	Pat 2	Pat 3
10 projections				
CT	FBP	14.78	13.71	14.77
	GINR	39.57	39.22	41.60
MR	GINR	26.27	26.20	27.45
20 projections				
CT	FBP	15.52	14.63	15.47
	GINR	39.81	41.24	42.87
MR	GINR	26.28	26.59	27.68
30 projections				
CT	FBP	15.73	14.75	15.77
	GINR	40.93	41.66	43.19
MR	GINR	26.48	26.70	27.73

Dataset. We obtained CT/MR pairs from brain patients undergoing radiation therapy from the publicly available dataset of the SynthRad challenge [8]. All pairs were rigidly aligned and anonymized via de-facing both images. We pre-process CT scans, cropping them and rescaling all HU values to the interval [0,1], using the maximum and minimum of each image. Likewise, after performing a bias field correction, all MR images are standardized by subtracting the mean and dividing by the standard deviation. All volumes are cropped to a cube of size $200 \times 200 \times 32$ and a voxel resolution of 1 mm.

Reconstruction accuracy. For each patient, we train the GINR using 10 artificial image pairs, obtained from applying random elastic deformations to the original images, with random displacements large enough to cause significant differences. The average PSNR for the embedded CT and MR images is 44.2 dB and 33.5 dB, respectively. After embedding these 10 prior pairs, and starting from a random prior representation (i.e., a random θ_n weight matrix), we reconstruct the original CT/MR from sparse measurements pair via Equation 4. Table 1 shows the PSNR values obtained by each method when reconstructing images with 10, 20 and 30 projections. With a higher PSNR for CT scan reconstruction, GINR significantly outperforms the FBP baseline. Although also being able to reconstruct MR images from the shared weights as seen in Figure 2, GINR cannot match the CT reconstruction accuracy for its MR reconstruction task, producing images that are in between the ground truth and the prior.

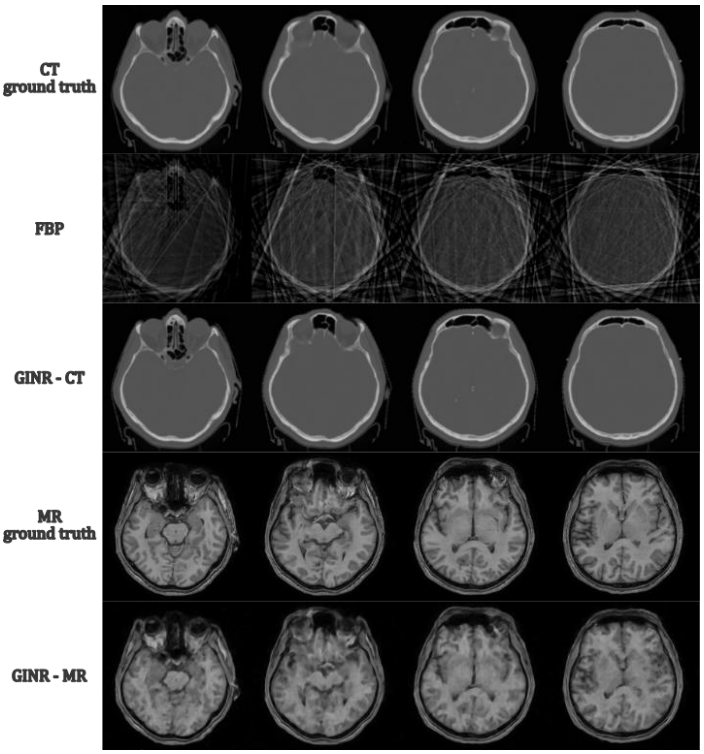

Figure 2: Qualitative results, using 10 projections. *From top to bottom: the CT ground truth image for patient 1, the CT reconstructed via filtered back-projection (FBP), the CT reconstructed by the proposed GINR, the MR ground truth image, and the MR reconstruction from GINR. All rows show 4 2D slices obtained from the 3D volumes.*

4 Discussion

The challenge of acquiring paired CT/MR images has remained a focal point within the realm of radiation therapy. Recent advancements in deep learning have predominantly focused on training models to establish mappings between various image modalities, relying on extensive datasets and substantial computational resources. In contrast, the proposed approach is patient-specific and obviates both problems. GINR maps input coordinates to image intensities and can be trained with minimal data samples in just a few hours with a single graphics processing unit.

The patient-specific nature of our methodology also confers distinct advantages in terms of reconstruction performance. Population-based deep learning methods, which must contend with the challenge of generalizing to unseen samples beyond the training distribution, especially when confronted with variations in machinery settings across diverse clinical environments. Instead, our proposed GINR method deliberately over-fits to prior information derived solely from a single subject, effectively capturing patient-specific intricacies often eluded by other models.

The expeditious image reconstruction capabilities of GINR render it well-suited for real-world clinical applications within the domain of radiotherapy, especially those demanding swift processing times. Notably, it proves instrumental in online adaptive workflows that necessitate the rapid acquisition of CT/MR pairs, concurrently facilitating contour delineation and physical dose distribution reconstruction.

While GINR demonstrates notable capabilities, there exists room for improvement. This is particularly evident in its MR outputs, which exhibit lower quality compared to its CT counterparts, and retain discernible traits from the prior images. This discrepancy is attributed to the exclusive reliance on CT projection data for the reconstruction of both images, leading to a dominance of shared weights that play a more significant role in CT output calculations. The resulting limitation in accurately capturing MR image characteristics underscores the need for refinements in GINR's methodology, with considerations for a more balanced incorporation of MR-specific information to enhance the fidelity of MR image reconstructions.

Looking ahead, future research endeavors could be directed towards extending the applicability of GINR to reconstruct paired images directly from MR sensor data. This extension holds significant promise, as it would enable the utilization of GINR in calculating doses within MR-guided treatments. By addressing the reconstruction challenge inherent in MR sensor data, GINR could play a pivotal role in advancing the capabilities of radiotherapy systems, offering enhanced precision and efficiency in treatment planning and delivery within the MR-guided paradigm.

5 Conclusion

In this work, we propose a framework for concurrent reconstruction of CT and MR images, based on a generalizable implicit neural representation (GINR) algorithm that embeds few prior CT/MR pairs within the weights of a neural network. By comparing the reconstructed images with the recorded data from a few brain cancer patients, we demonstrate that GINR can correctly reconstruct CT/MR scans even with sparsely sampled measurements, providing high-quality CT images. Compared to other deep learning approaches, the proposed GINR is patient-specific and does not require large datasets extensive training, or broad generalization capabilities across treatment sites and machines.

FDDM: Unsupervised MR-to-CT Translation with a Frequency-Decoupled Diffusion Model

Yunxiang Li[1], Hua-Chieh Shao[1], Xiaoxue Qian[1], and You Zhang[1]

[1]Department of Radiation Oncology, University of Texas Southwestern Medical Center, Dallas, TX, USA

Abstract Diffusion models have shown great promise in unsupervised medical image translation applications. However, diffusion models are often challenged by inaccurate anatomical structure translations especially for unpaired training data, while anatomical structures are crucial for reliable disease diagnosis and treatment planning. We introduced a Frequency-Decoupled Diffusion Model (FDDM) to achieve unsupervised, accurate MR-to-CT translations for unpaired data. FDDM separates the frequency components of medical images in the Fourier domain to enable structure-preserving image conversion. Specifically, it combines an unsupervised frequency conversion module with a diffusion model that is initialized and conditioned on the converted frequency information. We evaluated FDDM on a brain MR-to-CT dataset, comparing it with GAN-, VAE-, and diffusion-based models. FDDM excelled in all metrics including Fréchet inception distance (FID), peak signal-to-noise ratio (PSNR), and structural similarity index measure (SSIM). The substantial improvement offered by FDDM demonstrated its ability to generate realistic CT images without compromising the underlying anatomical accuracy.

1 Introduction

Magnetic Resonance (MR) and Computed Tomography (CT) imaging, pivotal in medical diagnosis and treatment planning, offer complementary information: MR provides superior soft-tissue contrast while CT shows detailed bony anatomy. Specifically for radiation therapy, MR is often used for tumor localization, while CT is used for treatment dose calculations with its accurate electron density information. In current clinical settings, MR and CT are acquired separately in different machines, resulting in increased imaging time, radiation dose (from CT), and healthcare costs. Moreover, this sequential process leads to potential mis-registrations which impact anatomical alignment and localization. To address these challenges, researchers are exploring deep learning-based Generative Adversarial Networks (GANs) or Variational Autoencoders (VAEs) to convert MR images to synthetic CT scans. Notable developments in GAN-based methods include CycleGAN, which is based on cyclic consistency; and GcGAN, which is built on geometrically consistent mappings. Despite some success, GANs often suffer from low-quality MR-to-CT translations (low realism), due to the stark differences in anatomical presentations between MR and CT. In addition to GANs, VAE-based approaches such as UNIT [1] and MUNIT [2] share similar problems of low-quality translations.

Recently, diffusion models have emerged as powerful tools for generating high-quality and realistic images, surpassing GANs and VAEs. An example of the diffusion model is SDEdit [3] , which translates images through iterative denoising via stochastic differential equations. Another diffusion model, EGSDE [4], guides unpaired image translations with pre-trained energy features. In medical image translation, SynDiff [5] represents a significant advancement with its adversarial diffusion design, although its dependence on a separate CycleGAN model for paired data synthesis has limited its performance. In general, diffusion models work by a forward diffusion process and a reverse diffusion process. Forward diffusion adds Gaussian noise via a predefined scheme to gradually corrupt an image, while the diffusion model applies a reverse diffusion process to de-noise and recover the high-quality image by learning the underlying data distribution. In medical image translation, the forward diffusion process tends to eliminate critical structural details that are difficult to recover in the reverse diffusion. This issue is further compounded in unpaired medical datasets, where a one-to-one anatomical correspondence does not exist between source and target domains. However, unpaired datasets are far more prevalent and accessible than paired datasets. Thus, it is of practical importance to develop an unsupervised diffusion model on unpaired training datasets to both achieve high-quality image translations (as compared to GANs and VAEs) and preserve the anatomical details (maintaining the faithfulness of the translated anatomical structures).

To address this unmet need, we proposed a novel diffusion model-based approach for unsupervised MR-to-CT conversion, named Frequency-Decoupled Diffusion Model (FDDM). FDDM utilizes the decoupled frequency information to guide the anatomical structure-preserving image conversion. Specifically, FDDM is composed of an unsupervised frequency conversion module and a diffusion model initialized and conditioned on the converted frequency information. The unsupervised frequency conversion module, which can be GAN- or VAE-based, performs an initial MR-to-CT conversion. Based on the pros/cons of the GAN- or VAE-based methods, such conversion can produce CT images with high anatomical translation accuracy (faithfulness), but suffers from low image quality (realism). By FDDM, the frequency conversion module was designed to output two channels, one with high-frequency CT information to extract the faithfully-translated anatomical structure boundaries, and the other with full-frequency CT information for further diffusion model-based fine-tuning. In detail, the high-frequency CT output, containing the anatomical information, can be used to condition the subsequent diffusion model for structure-preserving MR-to-CT translation. The full-frequency CT, on the other

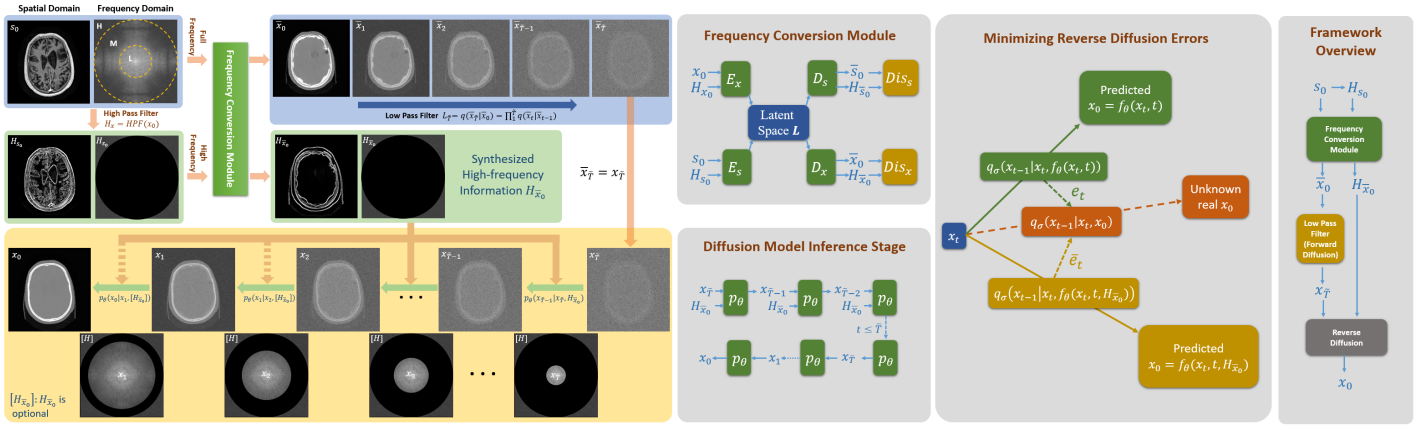

Figure 1: FDDM first uses an unsupervised frequency conversion module to generate two outputs: a high-frequency CT image and a full-frequency CT image. The full-frequency CT image undergoes a forward diffusion process that acts as a low-pass filter to extract the low-frequency information, which initiates a reverse diffusion process conditioned by the high-frequency CT information from the frequency conversion module, to produce the final synthetic CT image.

hand, is fed into a forward diffusion process (acting as a low-pass filter) to capture the overall CT intensities and semantic contents. The output is then used by the diffusion model as a starting step for the reverse diffusion process to gradually recover the missing frequency information of the CT image (especially that at the middle-frequency ranges), conditioned by the aforementioned high-frequency CT information. Compared with the original full-frequency CT generated by the unsupervised frequency conversion module, the new CT generated by the conditioned diffusion model sees boosted realism and image quality, while retaining accurate anatomical structures. In summary, our key contributions are:

1. We constructed a frequency-decoupled framework that utilizes high-frequency information to achieve anatomy-preserved image translations.

2. We proposed a flexible high-frequency conditioning and low-frequency initialization scheme in the diffusion model (based on a reverse diffusion error minimization scheme) to reduce/minimize the errors from the frequency conversion module to achieve more accurate MR-to-CT conversion.

3. FDDM demonstrated superior performance in MR-to-CT translations compared to existing state-of-the-art methods, including those based on GANs, VAEs, and other diffusion models.

2 Methods

Given a source MR image s_0 and a target CT image x_0, we used a VAE-based unsupervised frequency conversion module to convert the high-frequency and full-frequency information of the MR image into its counterpart in the CT image. The synthesized full-frequency CT images are then fed into a forward diffusion process (as a low-pass filter), and the output low-frequency information is used to initialize the reverse diffusion process for further fine-tuning. During reverse diffusion, the synthesized high-frequency CT information serves as a condition/guide to generate the final translated CT image. In the following sections, we first introduced the diffusion model, frequency filters, and the frequency conversion module. Following those, we introduced an unique and flexible high-frequency conditioning and low-frequency initialization scheme employed in FDDM to minimize reverse diffusion process errors, shown in Figure 1.

2.1 Diffusion Model

Diffusion models, as discussed in [6], use a forward diffusion procedure $q(\cdot)$, which progressively introduces white Gaussian noise with a constant variance I to the initial image x_0 through T steps:

$$q(x_{1:T}|x_0) = \prod_{t=1}^{T} q(x_t|x_{t-1}) \tag{1}$$

$$q(x_t|x_{t-1}) = N\left(x_t; \sqrt{\frac{\alpha_t}{\alpha_{t-1}}}x_{t-1}, (1-\frac{\alpha_t}{\alpha_{t-1}})I\right) \tag{2}$$

x_t denotes the noise-corrupted image at step t, and N is a normal distribution. The sequence $\alpha_{1:t}$ decreases monotonically and stays within $(0,1]^T$. With θ denoting model parameters, the reverse diffusion process, $p_\theta(\cdot)$, is then described as:

$$p_\theta(x_{0:T}) = p(x_T)\prod_{t=1}^{T} p_\theta(x_{t-1}|x_t) \tag{3}$$

Based on the study of Ho et al. [7], the forward diffusion process can be viewed as a Markov chain with Gaussian transitions, regulated by the descending sequence $\alpha_{1:t}$. Derived from Eq. 2, a specific attribute of the forward process can be expressed as:

$$q(x_t|x_0) = N(x_t; \sqrt{\alpha_t}x_0, (1-\alpha_t)I) \tag{4}$$

2.2 Frequency Decoupling and Conversion

On the basis of our previous work [8], it is known that when noise is introduced to an image, the power spectral density of the noise gets combined with that of the image. Since α_t decreases monotonically with diffusion steps, when the diffusion step t increases, the signal-to-noise ratio (SNR) decreases. Given an SNR threshold ϕ (below which the signal is viewed as totally corrupted), beyond a specific step t, only low-frequency information remains:

$$SNR_t = \frac{\sqrt{\alpha_t}k}{\sqrt{1-\alpha_t}\|(u,v)\|^a I}, \quad \begin{cases} < \phi, & \|(u,v)\| > \psi \\ \geq \phi, & \|(u,v)\| \leq \psi \end{cases} \quad (5)$$

where u and v represent the horizontal and vertical components of spatial frequencies. For detailed derivation of Eq. 5, please see our previous work [8]. If we denote this step as $\tilde{T}$, then the forward diffusion mirrors the effect of a low-pass filter:

$$x_{\tilde{T}} = LPF_{\tilde{T}}(x_0) = q(x_{\tilde{T}}|x_0) \quad (6)$$

In addition to the low-pass filtering naturally offered by the forward diffusion, FDDM employs a high-pass filter, the Sobel operator, to extract high-frequency information, which is based on the calculation of the image intensity gradient.

$$H_{x_0} = HPF(x_0) = Sobel(x_0) \quad (7)$$

In our previous work on CBCT-to-CT translation [8], we can directly extract the high-frequency information from CBCT via the Sobel filter to condition the diffusion model; and can directly use the forward-diffused (low-pass filtered) CBCT to initiate the reverse diffusion process for CT generation, since CBCT and CT share similar high-frequency and low-frequency information, and the diffusion model mainly works to correct the middle frequency differences. However, since MR and CT differ substantially in all frequency ranges, aligning MR's frequency traits with those of CT's requires an additional frequency conversion before applying our diffusion model. For FDDM, the frequency conversion module, based on a VAE framework with cycle consistency and a shared latent space L, is illustrated in Figure 1.

2.3 Minimizing Reverse Diffusion Errors by Flexible High-Frequency Conditioning and Low-Frequency Initialization

After obtaining the full-frequency information $\bar{x}_0$ and high-frequency information $H_{\bar{x}_0}$ of the synthesized CT through the frequency conversion module, the low-frequency CT image $\bar{x}_{\tilde{T}}$ is further derived through the forward diffusion (as a low-pass filter) of $\bar{x}_0$. In reverse diffusion, x_{t-1} is obtained through a specific reverse conditional distribution $q_\sigma(x_{t-1}|x_t, x_0)$, defined in [6]. To derive x_{t-1}, we first need to predict x_0 by our model $f_\theta(x_t, t, [H_{\bar{x}_0}])$, where $[H_{\bar{x}_0}]$ indicates that the high-frequency condition $H_{\bar{x}_0}$ is optional. We define e_t as the error of $q_\sigma(x_{t-1}|x_t, f_\theta(x_t, t))$, where x_0 is predicted without the high-frequency condition; and we define $\bar{e}_t$ the error of $q_\sigma(x_{t-1}|x_t, f_\theta(x_t, t, H_{\bar{x}_0}))$, where x_0 is predicted with the high-frequency condition . If there is an optimal step $\overline{T}$ in the reverse process, beyond which $\bar{e}_t > e_t$, dropping the high-frequency condition can further minimize the error in the generated CT image. The condition-dropping process is shown in Figure 1.

In addition to the high-frequency condition dropping mechanism, the low-frequency CT information, which was low-pass filtered by the forward diffusion process from the converted full-frequency CT, can also be customized by using an optimized number of forward diffusion steps during testing.

The optimized step number determines the threshold of the low-pass filter, and the optimization of which will allow us to remove unnecessary/incorrect information from the converted full-frequency CT image while maintaining sufficient information to initialize the conditioned reverse diffusion process.

3 Results

Dataset: In our study, we employed the SynthRAD2023 dataset[1], which includes 31,142 MR and 31,142 CT slices for training and 3,417 MR and 3,417 CT slices for testing. To simulate unpaired (unsupervised) training, we re-arranged the slices and removed the pairing information from the training dataset. All slices were uniformly resized to a resolution of 256×256 pixels.

Comparison with other methods: We compared FDDM with eight other image translation methods, based on metrics including FID, SSIM, and PSNR scores. GcGAN, CycleGAN, and RegGAN (GAN-based), UNIT and MUNIT (VAE-based), and SynDiff, SDEdit, EGSDE (diffusion-based) are included in the comparison. From Table 1, GAN and VAE methods generated images with consistently worse FID scores, indicating challenges in creating realistic images. These methods however performed comparably to FDDM in SSIM, showing good anatomical preservation ability in image translations. SynDiff excelled in SSIM by using CycleGAN for paired MR-CT data synthesis, but training on CycleGAN-generated data limited its FID score. Both SDEdit and EGSDE used low-frequency MR information to synthesize the CT images, while the low-frequency information of MR and CT varies greatly, which in turn affects the translation accuracy and results in overall poor results. FDDM outperformed all other methods with the lowest FID and the highest SSIM and PSNR, demonstrating its strength in balancing image realism and structural fidelity.

Parameter Study: For FDDM, the total steps of the low-pass forward diffusion process can be adjusted. As shown in Figure 2, using too many forward diffusion steps can lead to significant information loss which cannot be fully recovered by the high-frequency condition, and result in worse FID, SSIM, and PSNR scores. In contrast, using too few diffusion steps may fail to remove incorrect information from the preceding frequency conversion module and result in low realism (FID). Based on the tests in Table 1, we chose 500 steps to enhance FID while preserving relatively high SSIM/PSNR.

Regarding high-frequency conditioning, Table 1 showed that by applying the condition up until step 200 in the reverse diffusion process yields a good FID and SSIM/PSNR balance. Beyond this point (by using a smaller $\overline{T}$), continuing applying the condition can increase the structural errors due to the inaccuracy inherent in the converted high-frequency information and lead to worse SSIM, PSNR, and FID. In contrast, dropping the high-frequency condition too early ($\overline{T}$ = 500) will diminish its guidance to the diffusion model and result in lower SSIM and PSNR scores.

Ablation Study: After acquiring the synthesized high- and low-frequency information, the final CT image is generated by reverse diffusion. An ablation study in Table 1 assessed the importance of using the diffusion model and adding the frequency guidance. The SSIM and PSNR scores for FDDM without high-frequency information conditioning were lower than those of the conditioned FDDM, demonstrating the benefit of introducing high-frequency information to preserve anatomical details. On the other hand, the removal of the diffusion model resulted in scores consistently worse than FDDM, suggesting that the diffusion model not only improves the image quality (better FID), but also corrects the erroneous information generated in the frequency conversion module, which in turn improves the SSIM and PSNR.

4 Conclusion

In this study, we introduced FDDM, a novel frequency-decoupled diffusion model for MR-to-CT image translations. FDDM uniquely combines the structure preservation ability of VAE-based models with the realistic image generation capability of diffusion models, achieving high faithfulness and realism in unsupervised MR-to-CT translations. Its frequency decoupling mechanism allows different frequency information to be flexibly applied to initiate and condition the diffusion models and maintain the integrity of translated anatomies. Extensive evaluations showed FDDM's superiority over current GAN-, VAE-, and diffusion-based models, making it a valuable tool for accurate MR-to-CT translations and downstream clinical applications.

Abstract This study presents an innovative method for correcting shading artefacts in cone-beam computed tomography (CBCT) by employing an Artificial Intelligence (AI) generated synthetic CT (sCT) as a reference template. Our approach enhances CBCT image quality, improving both visual clarity and achieving a notable reduction in spatial non-uniformity (SNU) and mean Hounsfield Unit (HU) error between the CBCT and its paired planning CT (pCT). For fat tissue, SNU decreased from an average of 360.76 HU to 129.09 HU, and for muscle tissue it decreased from 277.69 HU to 109.44 HU. Similarly, the mean HU error between the CBCT and its pCT for fat tissue was reduced on average from 122.76 HU to 42.28 HU, and for muscle tissue from 113.56 HU to 62.59 HU. This approach represents an advancement over previous techniques by eliminating the need for a previously available pCT and increasing the correction's speed from an average of 45 seconds of previous methods to 23 seconds. Most importantly, our method demonstrates its robustness by effectively enhancing CBCT image quality even when the sCT is of very low quality, characterized by significant hallucinations and artefacts. This feature is crucial as it allows for the effective use of sCT to correct shading artefacts in CBCT while ensuring that any existing artefacts in the sCT are not transferred to the corrected image, possibly introducing a more reliable pathway for integrating sCTs into clinical practice.

1 Introduction

Cone-beam computed tomography (CBCT) is crucial for accurate patient positioning in radiation therapy and image guided surgery [1, 2]. However, the quality of CBCT images often falls short compared to fan-beam CTs, primarily due to significant scatter artefacts [3]. Additionally, other artefacts such as beam hardening and motion artefacts further challenge its image quality [4]. Among the numerous methods to address scatter radiation in CBCT, analytical modelling remains the dominant approach in commercial CBCT systems. Yet, even with the latest analytical scatter correction techniques, CBCT images occasionally still exhibit substantial shading artefacts, adversely impacting diagnostic and therapeutic accuracy. Recent advancements in deep learning have shown promise in effectively addressing CBCT artefacts via the generation of synthetic CT (sCT), notably improving image quality and Hounsfield Unit (HU) value accuracy [5]. However, networks trained on specific datasets, may not perform predictably with input images that deviate from their training conditions, such as those with unique patient anatomy or different imaging settings. Complicating this unpredictability in AI-generated sCTs is the lack of a widely recognized and established quality control (QC) tools for the sCT verification, posing a hurdle to sCTs direct and unrestricted clinical use [6]. Recent developments in shading correction methods by L. Shi et al. have shown the potential to further improve the shading artefacts correction when applied in tandem with traditional analytical scatter correction techniques [7, 8]. This study introduces a novel approach that combines the strengths of a sCT reference images, which include eliminating the need for an available pCT and omitting the registration step, with the improved shading correction techniques developed by L. Shi et al. By doing so, we aim at increasing the speed and versatility of the traditional method and facilitate the safer integration of AI-generated images into clinical practice.

2 Materials and Methods

2.1 Network implementation and training

In order to generate the sCTs for this study, we implemented a 3D UNet in PyTorch based on the library implemented by Pérez-García F. [9] consisting of 4 encoding blocks, linear upsampling and a PReLU activation function. The data used for training the network comes mainly from the SynthRAD2023 Grand Challenge [10] consisting of 360 CBCT-CT pairs of H&N and pelvis anatomies coming from different vendors. Additional 104 image pairs, covering H&N, pelvis and spine anatomical regions, come from paired CBCT-CT images acquired using medPhoton's mobile ImagingRing [11]. The data has been divided into train, validation and test using the proportion 80/10/10. During training, data augmentation was implemented via the TorchIO [12] framework, and the images were preprocessed using the Z-normalization. Batch normalization was also used to better stabilize the training. For the loss function of the network, we used a combination of the structural similarity index (SSIM) and perceptual loss that have been highlighted as yielding better results than standard MAE or MSE loss functions [5]. The network used for the perceptual loss is implemented in the paper by S. Chen et al. [13].

2.2 Shading correction implementation

The proposed method aims to correct shading artefacts in CBCT images by employing an sCT as a template. Initially, a binary mask f is created from the CBCT data using specific HU thresholds (-600 HU and 300 HU were used in our case). This mask isolates the fat and muscle tissues while excluding air and bone, thereby focusing the correction on relevant tissue areas in this study. Within this mask, the

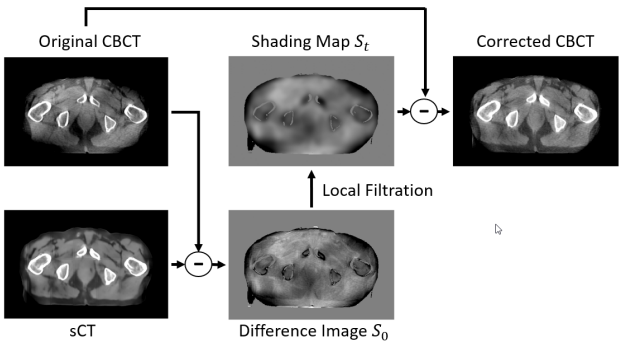

Figure 1: Shading Correction workflow using a sCT image as a template.

sCT is subtracted from the CBCT, resulting in an intermediate image that we call S_0 in continuity with [8]. S_0 is then processed yielding the final shading map S_t using a local filtration algorithm [7, 14] implemented as:

$$S_t = \frac{(S_0 \cdot f) * w}{f * w} \tag{1}$$

where w is a 3D Gaussian smoothing kernel with standard deviation σ. In our study, we selected a kernel with $\sigma = 5$ *mm*. This shading map is then subtracted from the original CBCT, yielding a corrected CBCT image free from the identified shading artefacts. A schematic diagram of the proposed workflow can be seen in Fig.1. The entire shading correction algorithm was implemented using the Python wrapping of the Insight Segmentation and Registration Toolkit (ITK)[15] on a Dell Precision laptop equipped with an Intel i7-12800H 2.40 GHz CPU and an NVIDIA RTX A2000 8GB GPU running Windows 10.

2.3 Method evaluation

In this preliminary evaluation, our method was applied to CBCTs of five different patients. Two of the CBCT images were acquired using an Elekta XVI CBCT system (Patient 1 and Patient 2) coming from the SynthRAD2023 Grand Challenge dataset [10], while the other three were acquired using medPhoton's ImagingRing (Patient 3, Patient 4 and Patient 5). Paired rigidly registered pCT images were available for two of the CBCT images from the ImagingRing system and for both CBCT images from the Elekta system. Both imaging systems incorporate an embedded proprietary analytical scatter correction algorithm to correct scatter artefacts. The two CBCT images obtained from the SynthRAD2023 Grand Challenge dataset originally had a voxel spacing of $(1 \times 1 \times 2.5)$ *mm*. To accommodate the requirements of our 3D U-Net architecture, specifically the z-dimension of the input patches, these images were resampled to a uniform spacing of $(1 \times 1 \times 1)$ *mm*. This resampling was essential because the original z-spacing of 2.5 *mm* resulted in fewer pixels in the z-direction than necessary for the U-Net input patches' specifications. For evaluating the performance of the method, as in [8], we manually selected for each image five regions of interest (ROI) with a size of 15-by-15 pixels for the two investigated tissue types (e.g. fat and muscle). For each tissue type, we then computed the Spatial Non-Uniformity (SNU) defined as:

$$SNU = \bar{\mu}_{max} - \bar{\mu}_{min} \tag{2}$$

where $\bar{\mu}_i$ represents the average CT number computed inside a single ROI, and we indicated with $\bar{\mu}_{max}$ ($\bar{\mu}_{min}$) the maximum (minimum) $\bar{\mu}_i$ among the ROIs. In the cases where the pCT was available, it was used to further evaluate the model's performance. This was done by calculating, for each tissue type, the mean CT value error $\langle\Delta\rangle$ between the CBCT and the pCT ROIs defined as:

$$\langle\Delta\rangle = \frac{1}{N}\sum_{i=1}^{N} |\Delta_i| \tag{3}$$

where $\Delta_i = \bar{\mu}_{CBCT,i} - \bar{\mu}_{pCT,i}$ represents the difference of the mean CT number between the CBCT and its paired pCT in the same ROI. Additionally, we investigated the impact of varying the σ parameter of the Gaussian filter. This parameter acts as a proxy for the level of trust in the generated sCT. A lower σ, indicating high trust in the sCT, allows the method to correct high-frequency artefacts. Conversely, when the sCT is considered less reliable or of lower quality, increasing the σ can still enhance CBCT image quality by correcting predominantly low-frequency shading artefacts.

3 Results

3.1 Paired image evaluation

Fig.3 shows the CBCTs from Patient 1 to Patient 4 with and without the applied shading correction. First of all, it is shown visually how the proposed method successfully suppresses the shading artefacts in all the CBCT images and improves the overall image uniformity. Table 1 presents the computed SNU for the five selected ROIs alongside the mean CT errors. Additionally, Fig.3 illustrates that some hallucination artefacts in the sCT are absent in the corrected CBCT, which retains the original CBCT's correct anatomical information. For our dataset, the processing times for the correction varied depending on the image size. For the largest image, with dimensions of $(500 \times 482 \times 266)$ voxels, the time required for our sCT generation was 25 seconds, and the subsequent shading correction took 6 seconds. Conversely, for the smallest image in our dataset with dimension $(396 \times 256 \times 260)$ voxels, the sCT generation and shading correction were completed in 13 and 2 seconds, respectively.

3.2 Effect of the sigma

We investigated the impact of varying the Gaussian kernel's standard deviation on the CBCT correction, particularly in challenging cases where the sCT generated by the network is

The yellow arrows highlight anatomy discrepancies between the CBCT and the sCT. Display window: [-250 250] HU.

of extremely low quality and clinically unsafe due to severe hallucinations. Our findings, illustrated in Fig.2, reveal that our correction method effectively improves CBCT uniformity across a range of σ values despite the low quality of the sCT, therefore allowing for the safe use of the sCT in scenarios where its quality would typically render it unusable.

4 Discussion

Our proposed method for correcting shading artefacts in CBCT images, utilizing an sCT as a template, has shown success in improving CBCT image quality. Specifically, we observed a significant decrease in the SNU; for fat tissue, SNU reduced on average from 360.76 HU to 129.09 HU, and for muscle tissue, from 277.69 HU to 109.44 HU. Additionally, the accuracy of HU values improved, with the average CT number error for fat tissue dropping from 122.76 HU to 42.28 HU, and for muscle tissue from 113.56 HU to 62.59 HU. Patients 1 and Patient 2 exhibited smaller SNU than Patient 3, Patient 4, and Patient 5, possibly reflecting the imbalance in our training dataset, which predominantly features images from the SynthRAD2023 Grand Challenge. The smallest improvement in terms of SNU is achieved on Patient 5, where the correction was made using a low-quality sCT. Despite this, our method still improved the CBCT visualization by correcting the shading artefacts, and correctly mitigating the severe artefacts present in the sCT, showing

how our implementation could be useful for a safer implementation of sCTs in clinical scenarios. Using the sCT as a template for shading correction in CBCT presents advantages over traditional methods in terms of speed and in terms of complete independence of the availability of a pCT that would also need to be registered to the CBCT. Indeed, our processing time, achieved without an intensive focus on performance optimization, still renders our method faster overall than the previously implemented techniques by decreasing the correction time from 45 s to 23 s on average. Despite these results, the effectiveness of our method in terms of HU accuracy depends on the fidelity of the sCT's HU values. The strategy of blurring the difference between the CBCT and the sCT adds robustness against sCT artefacts, but further refinements in sCT generation could improve the accuracy of our corrections. Currently, our method results mainly in adaptive filtration at the CBCT border due to the absence of sparse sampling of the difference between the CBCT and the sCT. Future implementations will incorporate error estimation from the sCT using Monte Carlo (MC) dropout. This will allow us to identify and exclude voxels with high prediction uncertainty and use local filtration to create a more accurate shading map for a more precise correction.

5 Conclusion

This study presents a novel sCT-based shading correction method for CBCT, offering improvements over existing techniques both in terms of speed and versatility. The main impact of our method is promoting the accuracy of segmentation and navigation for image guided radiotherapy or surgery using in room CBCT. Particularly noteworthy is the method's ability to enhance CBCT image quality safely, even when the sCT is inaccurately rendered or contains severe artefacts, paving the way for a safer integration of sCT in clinical practice. Future research directions include enhancing the accuracy of the sCT HU values to further reduce the mean CT number error of the shading correction, and integrating uncertainty prediction in the network. This advancement will allow for the exclusion of voxels with higher uncertainty in the correction process, ensuring even more precise and reliable results in term of HU values accuracy. Such improvements would allow us to assess the feasibility of the method for dose recalculation.

Abstract In cone-beam computed tomography (CBCT), the cone-beam (CB) artefact causes object-dependent image distortions away from the central plane. Non-circular trajectories such as saddles or helices can mitigate the CB artefact, but are challenging to execute with scanners not specifically designed for non-circular scanning. In this work, we made use of a recently available mobile robotic CBCT scanner (mobile ImagingRing, medPhoton, Salzburg, Austria) which allows sinusoidal motion perturbation of several degrees of freedoms during a source and detector rotation, coupled with infrared (IR) motion tracking to measure the geometry of each trajectory. We scanned a disk phantom designed to highlight CB artefacts with circular, saddle and helical trajectories executed by driving motion with wheels. We computed an incompleteness metric, $\tan(\psi)$, and correlated it with the region free from CB artefacts in the images. Using a separate cylindrical phantom, we additionally computed the modulation transfer function at 10 percent (MTF_{10}) to assess the accuracy of the calibration correction. We found regions free of CB artefacts of up to 190 mm in the superior-inferior direction for the saddle trajectory, and of 120 mm to 140 mm for the helical trajectory. MTF_{10} was 1.39 lp/mm, 0.98 lp/mm and 1.03 lp/mm for the circular, saddle and helical trajectories with IR tracking, while without IR tracking the saddle and helical trajectories had MTF_{10} less than 0.4 lp/mm.

1 Introduction

In cone-beam computed tomography (CBCT), non-circular scanning trajectories can eliminate the well known cone-beam (CB) artefact, which stems from data incompleteness when moving away from the plane containing the source trajectory. For points away from that plane, Tuy's condition is not satisfied since there will always be planes through these points which do not intersect the trajectory [1]. This issue can reduce image quality in a wide range of medical imaging applications, including dentistry, image-guided surgery and image-guided radiotherapy. The degree of incompleteness can be quantified with the $\tan(\psi)$ metric introduced by Clackdoyle et al. [2], which provides a continuous value which was shown to correlate with the severity of the CB artifact [3]. It is well known that using non-circular trajectories in CBCT scanning can mitigate the CB artifact, with publications demonstrating sinusoidal trajectories [4–6], circle-and-line or circle-and-arc trajectories [7, 8], or even freely optimized trajectories [9–11]. While several works have demonstrated improvements from such trajectories, often they have been performed at devices not specifically designed for such a purpose, entailing complex trajectory programming or long scanning times. Recently, a mobile robotic CBCT scanner (mobile ImagingRing, medPhoton GmbH, Salzburg, Austria) has become available with the option to execute sinusoidal perturbations along various axes of motion. This allows implementing time-efficient non-circular trajectories which can be executed with one rotation of the source and detector, such as saddle [12] and helical [13, 14] trajectories. The device is further equipped with infrared (IR) tracking technology which allows mitigating geometric inaccuracies in recorded trajectories, which can degrade spatial resolution. In this work we compared CB artefact reduction achievable with saddle and helical trajectories using scans of a disk phantom and $\tan(\psi)$ evaluation, in addition to modulation transfer function at 10 percent (MTF_{10}) analysis with a separate phantom.

2 Materials and Methods

2.1 Mobile robotic CBCT scanner and trajectories

All CBCT scans were acquired at the mobile robotic CBCT scanner described in Figure 1 and equipped with IR tracking based on a pair of cameras which monitor the position of a tracking object placed on the phantoms (Rigid Body Marker Base, MCP1145; NaturalPoint, Inc., Corvallis, USA). The scanner's motorized wheels allowed the execution of saddle and helical trajectories. For the saddle trajectory, a rotation with angle β around a vertical yaw rotation axis, which is displayed in Figure 1, was performed during source and detector rotation, expressed with rotation angle θ, according to

$$\beta(\theta) = A_{\text{saddle}} \sin(\omega_{\text{saddle}}\theta + \phi_{\text{saddle}}) \quad (1)$$

where A_{saddle}, ω_{saddle} and ϕ_{saddle} are the amplitude, the angular frequency and the phase shift of the yaw perturbation. For the helical trajectory a similar sinusoidal perturbation D displacing the scanner longitudinally in the superior-inferior (SI) direction followed

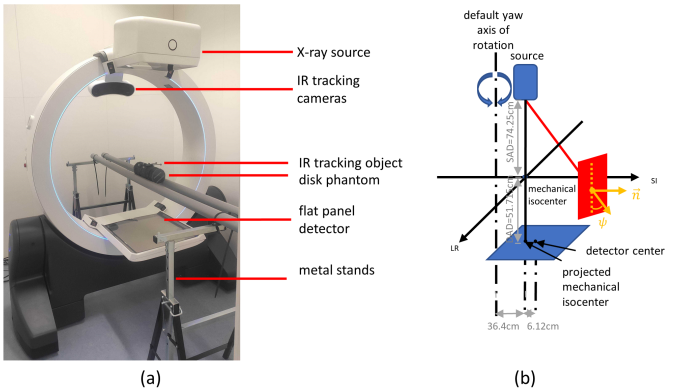

Figure 1: Setup and geometrical information of the CBCT scanner. (a) The whole setup for the experiments (note that the plastic support was replaced by a carbon fiber table). IR tracking markers are put on the phantom to be visible by both tracking cameras. (b) Basic geometrical information of the CBCT scanner and the rotation axis and source projection offset relative to the detector center. The geometry used to calculate $\tan(\psi)$ is shown in red and orange (see Ref [2] for details).

Table 1: Parameters of the saddle and helical trajectories defined by equations 1 and 2 with θ expressed in rad. A_{saddle} is expressed in degrees for clarity.

A_{saddle} [°]	ω_{saddle} [rad^{-1}]	ϕ_{saddle} [rad]	A_{helical} [cm]	ω_{helical} [rad^{-1}]	ϕ_{helical} [rad]
10	1	π	7.7	0.5	$\frac{\pi}{2}$

$$D(\theta) = A_{\text{helical}} \sin(\omega_{\text{helical}}\theta + \phi_{\text{helical}}) \quad (2)$$

where A_{helical}, ω_{helical} and ϕ_{helical} are the amplitude, the angular frequency and the phase shift of the longitudinal perturbation. The values used in this work are listed in Table 1.

The IR tracking system provided the position and direction of the rigid object for each projection, which were transformed into a rotation matrix R and translation t. The recorded source position s, detector position d and orthogonal detector direction vectors u and v (in the gantry's coordinate system) were transformed as follows to account for the perturbations executed following equations 1 and 2.

$$\begin{aligned} s' &= R_0 R^{-1}(s-t) + t_0, \\ d' &= R_0 R^{-1}(d-t) + t_0, \\ u' &= R_0 R^{-1} u, \\ v' &= R_0 R^{-1} v, \end{aligned} \quad (3)$$

where R_0 and t_0 are for the first frame and R and t for the current frame.

2.2 Phantoms, experiments and simulations

Two phantoms were used in this work. The first was a disk phantom consisting of eleven 1 mm thick acrylic disks of 100 mm diameter separated by 20 mm foam spacers, which was used to assess CB artefacts. The second was an acrylic cylinder of 152 mm diameter used to evaluate MTF_{10}. Both phantoms were scanned using circular, saddle and helical trajectories acquiring 720 projections with θ ranging from 0 to 2π, exposure of 20 ms and 5 mA and with IR tracking enabled. The detector was 432 mm $\times$ 432 mm with 1440 pixels $\times$ 1440 pixels. The geometrical information from equation 3 was additionally used to simulate a digitally reconstructed radiograph (DRR) for each projection of the disk phantom, using a digital voxelized version of the phantom with a voxel size of 0.5 mm^3. This was done using functions from the Reconstruction Toolkit (RTK) software package (version 2.3.0) [15].

2.3 Image reconstruction

All images were reconstructed using RTK. We used penalized least-squares minimization with the conjugate gradient algorithm with a regularization weight of $\gamma = 10$, a voxel size of 0.5 mm^3 and 50 iterations. We reconstructed all experimental and simulated acquisitions defined above.

2.4 Image analysis

For each experimental acquisition, the incompleteness metric $\tan(\psi)$ was calculated according to Clackdoyle et al. [2] for all positions in the reconstructed image. The value of $\tan(\psi)$ is 0 for complete data and has been shown to allow adequate reconstruction up to 0.02 [16], above which conspicuous CB artefacts can be expected. In more detail, for all the projection lines passing through a voxel, we calculated and kept those projection lines that fell on the detector, following the approach of Sun et al. [16]. Then, for one specific direction $\vec{n}$, we took the lowest $\tan(\psi)$ from all the source positions. Finally, we took the largest $\tan(\psi)$ value from all directions as the incompleteness value for this voxel. Here, ψ was the angle between the plane and the projection line. The red and orange parts of Figure 1(b) show the geometry of this calculation. For the saddle and helical trajectories, we quantified the extent of the region free from CB artefacts based on visual inspection and overlaid $\tan(\psi)$ isolines.

The MTF_{10} was calculated using an over-sampled edge obtained from the cylindrical phantom's outer diameter and was used to determine the performance of IR tracking. This was done slice-by-slice for an SI region of 100 mm and we calculated the mean and standard deviation of MTF_{10}. Comparison of simulations and experiments was used to determine whether potential image distortions stemmed from the trajectories themselves or from issues with IR tracking.

3 Results

Figure 2 shows the source trajectories performed in experiments. All the trajectories started at 0 mm in SI, the saddle

trajectory extended to −135 mm, and the helical trajectory extended to −154 mm in SI. The source executed a single rotation around the gantry for all the trajectories. Table 2 reports the MTF_{10} for the circular, saddle, and helical trajectories. The spatial resolution was the same for the circular trajectory with and without IR tracking. The spatial resolution of the saddle and helical trajectory both had important improvements when using IR tracking correction. The spatial resolution was improved from 0.37 mm to 0.98 mm for the saddle trajectory and from 0.34 mm to 1.03 mm for the helical trajectory.

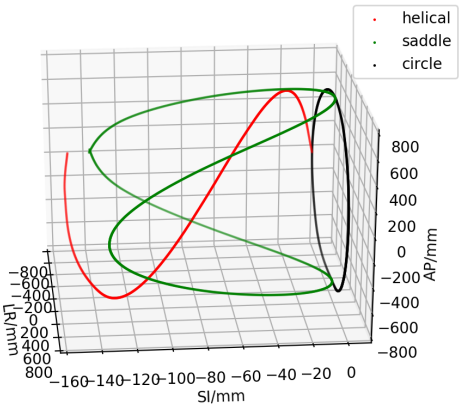

Figure 2: The three trajectories used in this work. The black line represents the circular trajectory, the green line is the yaw-based saddle trajectory, and the red line is the helical trajectory. Axes not to scale.

Table 2: MTF_{10} for different trajectories w/ and w/o IR tracking (mean ± standard deviation).

	with IR tracking	**w/o IR tracking**
	[lp/mm]	
circle	1.39 ± 0.06	1.39 ± 0.04
saddle	0.98 ± 0.07	0.37 ± 0.04
helical	1.03 ± 0.09	0.34 ± 0.01

The reconstructed images from the simulations of the three trajectories are shown in Figure 3. The disks inside the low incompleteness region ($\tan(\psi) < 0.02$) are all well reconstructed without CB artifacts and distorted into spindle shapes when lying outside of the low incompleteness region. For the saddle trajectory, the shape of the low incompleteness region was an irregular cylinder with 190 mm height in SI and a cross-section which had a short axis of 255 mm and a long axis of 270 mm. For the helical trajectory, the low incompleteness region had a round cross-section with diameter 255 mm, while the height in SI ranged from 120 mm to 140 mm as shown in Figure 3 (c).
Figure 4 shows the coronal plane of the reconstructed images from the experimental acquisitions with the three trajectories,

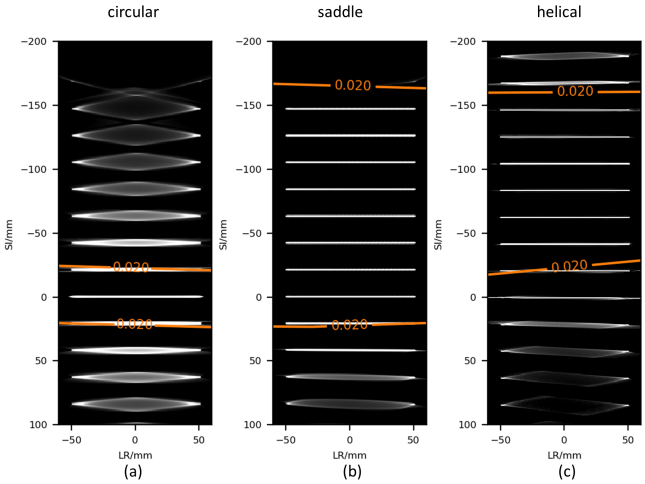

Figure 3: Reconstructed images of the digital disk phantom from the three simulated trajectories in a superior-inferior (IR) and left-right (LR) view. Orange lines indicate the edges of the low incompleteness region where $\tan(\psi) < 0.02$.

with convex hull and incompleteness overlays. The sizes and shapes of the low incompleteness regions are the same as the simulation, and whithin all disks are well reconstructed. We could confirm the observation from the simulation that the saddle trajectory provided a larger region where disks are well reconstructed. We can observe that the low incompleteness region is larger than the convex hull for all trajectories.

4 Discussion

Table 2 and Figure 4 show that the IR tracking correction is reliable and can provide accurate geometrical corrections online. The MTF_{10} of the saddle and the helical trajectories with IR tracking, although lower than for the circular scan, were comparable to that achievable at a linac-mounted CBCT scanner (XVI, Elekta, UK), for which we measured a MTF_{10} of 1.00 ± 0.01 lp/mm with a circular scan. Both the simulation (Figure 3) and the experiment (Figure 4) show that the helical trajectory provides a longer reconstructed region where more disks than for the saddle scan could be reconstructed, albeit in a distorted fashion. However, the low incompleteness region of the helical trajectory was smaller in SI than that of the saddle trajectory, despite the source having moved a larger distance along the SI direction for the helical trajectory. This was attributed to the non-closed nature of the trajectory, and helical trajectory simulations demonstrated that using $\omega_{\text{helical}} = 2\,\text{rad}^{-1}$ could provide a convex hull with an SI extent corresponding to $2A_{\text{helical}}$. We can also see in Figure 3 that at least one disk outside of the low incompleteness region is well reconstructed. These observations suggest that the SI length of the low incompleteness region is limited by a direction $\vec{n}$ other than that normal to the disks. One advantage of the helical trajectory over the saddle was that it was less likely to collide with the patient couch, which might occur when performing saddle trajectories with larger A_{saddle}.

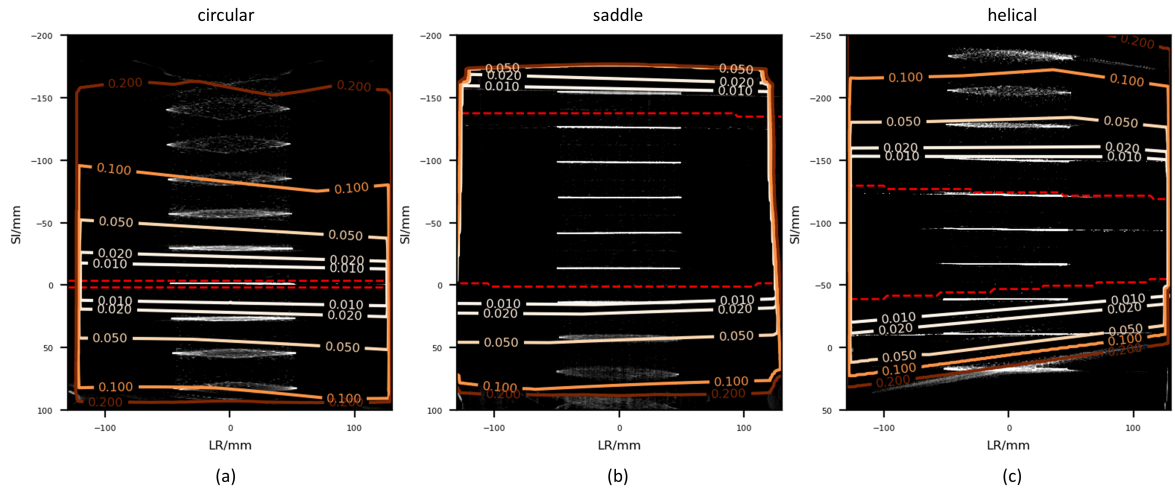

Figure 4: Reconstructed images of the disk phantom from experimental trajectories in a superior-inferior (IR) and left-right (LR) view, with convex hull and $\tan(\psi)$ isolines overlay. Red dashed lines are edges of the convex hull and the solid lines are $\tan(\psi)$ isolines.

5 Conclusion

In conclusion, both the yaw-based saddle and helical trajectories were feasible with online IR tracking geometrical corrections at the mobile robotic CBCT scanner used in this work. This allowed an important increase of the low incompleteness region ($\tan(\psi) < 0.2$) and elimination of the CB artifact.

Deep learning-based Normal Tissue Complication Models for Head and Neck Cancer patients

Lisanne V. van Dijk[1], Suzanne P.M. de Vette[1], Hendrike Neh[1], Luuk van der Hoek[1], Hung Chu[1], Johannes A. Langendijk[1], Peter M.A. van Ooijen[1], and Nanna M. Sijtsema[1]

[1]Department of Radiotherapy, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands

Abstract Accurate pre-treatment toxicity risk estimation in head and neck cancer (HNC) patients is essential to optimize radiotherapy and minimize long-term toxicities. This study utilizes the potential of deep learning (DL) to predict based on 3D data to improve the current conventional 1D Normal tissue complication probability (NTCP) models. Our results show that DL models that incorporating full 3D dose and image information improved the predictive performance for late xerostomia, dysphagia, and taste loss compared to conventional NTCP models. The attention maps showed that the DL model's focus is on the salivary gland dose for xerostomia, a broad scale of swallowing muscles for dysphagia, and parotid glands and anterior region of the tongue for taste loss. This research sets a new benchmark for toxicity prediction in current HNC radiotherapy, paving the way for more informed treatment decisions, minimizing toxicities, and enhancing patients' quality of life.

1 Introduction

Head and neck cancer (HNC) patients are often faced with severe toxicities during and after radiotherapy, the most prominent of which are xerostomia (dry mouth), swallowing, and taste dysfunction. These toxicities significantly impact the quality of life [1]. Combined with the increasing survival rates of HNC patients [2,3], this underscores the need to optimize treatment and minimize radiation-induced toxicities. The growth in recent radiotherapy advancements that aim to reduce toxicity while maintaining effective treatment (e.g., image-guided radiotherapy and proton therapy) has resulted in an increase in treatment options [4–7]. To select the most suitable treatment for individual patients, accurate pre-treatment toxicity risk estimation is required.

Normal tissue complication probability (NTCP) models predict radiation-induced toxicities based on discrete dose parameters of one or a couple organs (e.g., mean dose parotid gland) and clinical variables (e.g., baseline toxicity scores). NTCP models have been published for xerostomia [8–10], swallowing dysfunction [11–13], and recently Bosch et al. [14] developed the comprehensive toxicity risk prediction profile (CITOR) incorporating an array of swallowing, salivary, taste, speech, pain, and general toxicities[14]. These models have shown to be effectiveness for selecting HNC patients for proton therapy of in the Netherlands [15]. However, they lack the capacity to consider the 3D nature of radiation-induced damage. Incorporating complete dose distributions has the potential to significantly enhance their predictive performance.

Deep learning (DL) models, particularly convolutional neural networks (CNNs), directly extract features from 3D information, preserving spatial details in dose and image data without reducing them to 1D dose-volume or image parameters. Building upon Men et al.'s demonstration of a 3D CNN's potential in predicting late xerostomia in RTOG-0522 HNC patients[16], our research group developed DL models for more comprehensive HNC toxicities, utilizing a large-scale prospective toxicity dataset of patient treated with current radiation standards. Moreover, our models incorporate clinical variables, explore alternative DL architectures, employ attention maps to enhance interpretability, and assess them against the latest NTCP modeling standards.

The study aims to develop DL NTCP models for moderate-to-severe late xerostomia, swallowing dysfunction and taste loss in HNC radiotherapy patients, comparing them to the current state-of-the-art NTCP models.

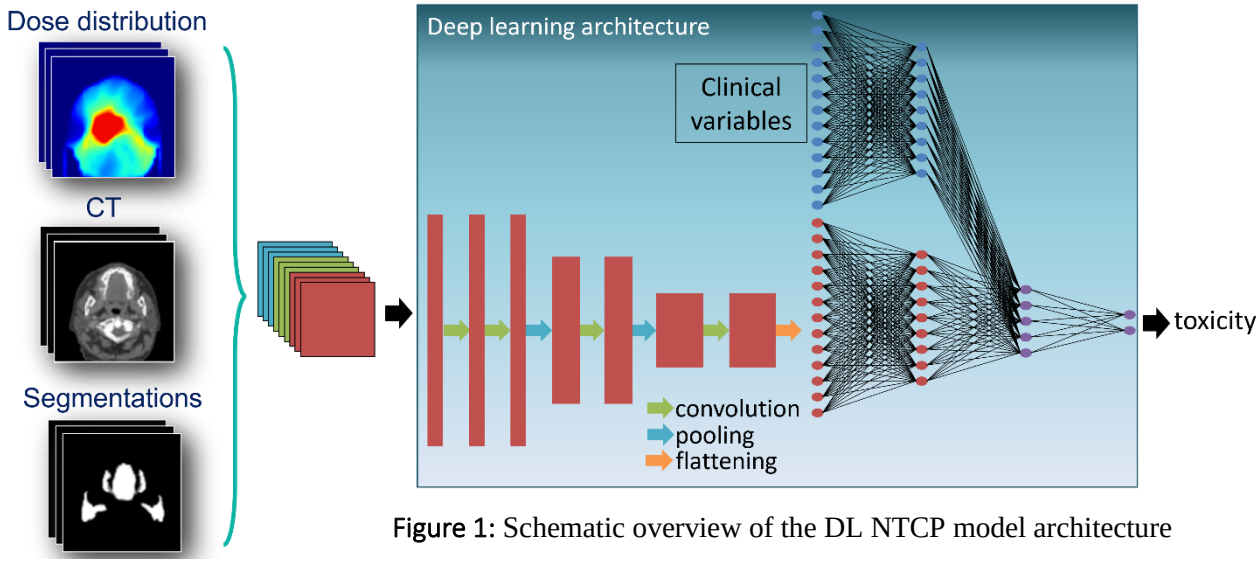

Figure 1: Schematic overview of the DL NTCP model architecture

2 Materials and Methods

2.1 Patient cohorts and treatment

The training and independent validation cohort included HNC patients treated with curative (chemo)radiotherapy for squamous cell carcinoma in the oropharynx, larynx, oral cavity, or nasopharynx at University Medical Centre Groningen from 2007-2021. Most patients received IMRT or VMAT (79.1), with a minority receiving IMPT (13.7%) or 3DCRT (7.2%). All patients had a planning CT approximately 2 weeks before treatment (> 80% contrast-enhanced).

2.2 NTCP endpoints

The NTCP model endpoints were moderate-to-severe:

1) patient-rated xerostomia 12 months after RT
2) patient-rated taste loss 6 months after RT
3) physician-rated dysphagia 6 months after RT

All toxicity scores were prospectively collected. Patient-rated endpoints were collected with the EORTC QLQ-HN35 questionnaire ('none,' 'any' vs. 'moderate,' 'severe'). Dysphagia was assessed using CTCAEv4 (grade ≥2).

2.3 Reference NTCP models

The CITOR NTCP models [14] for xerostomia, taste, and dysphagia (Table 1), developed/validated on 750/395 HNC patients, were fitted to the current datasets to serve as competitive reference for the DL NTCP models.

	Baseline Tox	oral cavity	parotid glands	Submandibular glands	PCM	sup/mid/inf	Buccal mucosa	Cricopharyng.	Smoking status	WHO score	T-stage	N-stage	Tumor location	Age	Sex	P16-status
Xerostomia	♦		♦	♦			⁕							⁕	⁕	
Taste		♦	♦	⁕										♦		
Dysphagia	♦	♦	⁕	⁕	♦			⁕	⁕	⁕	⁕	⁕	♦			⁕

Table 1: Predictors in NTCP models.
♦ = in reference and DL model, ⁕ = in DL model only

2.4 Deep learning (DL) Model development

The UMCG cohort was split into a training/cross-validation (70%/15%), and independent validation cohort (15%).

The DL model architecture consisted of convolutional layers encoding image information followed by fully connected layers to make the final prediction (Figure 1). The input into the convolutional layers was a three channel stack image – the *3D dose*, *CT*, *organ-at-risk* (*OAR) segmentations* (Table 1); while the clinical variables were fed into the fully connected layers. Model architectures were DCNN, ResNet and ResNet-DCNN. Hyperparameter tuning was performed per toxicity and was aided by the Optuna framework [17]. Cyclic learning rate was used for dysphagia and taste loss, while a cosine learning rate was used for xerostomia. The optimizer were MADGRAD for dysphagia, Adam for taste loss, and AdaBound for xerostomia. Internal validation was performed with 10-fold cross-validation.

The input data – CT, dose, segmentations – was registered to each other, normalized, resampled [2x2x2 mm^3] and cropped [96x96x96 voxels] based on anatomic landmarks. Data augmentation was applied to improve generalization: cropping, lateral flip, minor translation, zooming, rotation, and intensity shifting.

2.5 Model evaluation metrics

The performance of all NTCP models was assessed with the area under the curve (AUC) in the cross-validation sets and independent test set. Calibration was assessed in the test set.

3 Results

3.1 Patient cohort

A total of 1442 HNC patients were included (Table 2). Incidence rates for xerostomia, dysphagia, and taste loss were 35%, 25%, and 27%, respectively.

	Train set		Test set	
Total	**1226**		**216**	
Available scores				
Xerostomia	759	62%	138	64%
Taste	807	66%	142	66%
Dysphagia	941	77%	171	79%
*Clinical characteristics**				
Age (SD)	63.8	(10.1)	64.0	(10.3)

T-stage >T2	488	52%	90	53%
N-stage=N+	497	53%	95	56%
HPV= pos	158	17%	26	15%

**for the largest set (dysphagia)*

Table 2: Patient numbers and characteristics

3.2 Model performance

The performance of the *xerostomia* DL model was good in the cross-validation (AUC_{train}=0.79), and was improved when compared to the reference model (AUC_{train}=0.75). When tested in the independent validation set, the performance of the DL model was consistently good (AUC_{test}=0.79), and again better than the performance of the reference NTCP model (AUC_{test}=0.74). The calibration plot of the predicted versus the observed xerostomia rates in the validation set demonstrated that the DL model gives a clearer line, yet with a slightly larger inclination than the identity line, where the reference model follows the identity line better, but the points are more scattered.

The performance of the *dysphagia* DL model was excellent in the cross-validation (AUC_{train}=0.85). The performance of the reference NTCP model was also high (AUC_{train}=0.79), yet still substantially lower than the DL model. This improvement remained present in the independent validation set: with an AUC_{test} of 0.84 for the DL model and AUC_{test} of 0.76 for the reference model. The calibration plot

	Xerostomia		Dysphagia		Taste Loss

Cross-validation	0.75 [0.72 – 0.78]	**0.79** [0.76 – 0.82]	0.79 [0.76–0.82]	**0.85** [0.81–0.89]	0.70 [0.66–0.75]	**0.74** [0.70 - 0.77]
Independent validation	0.74 [0.66 – 0.83]	**0.79** [0.71 – 0.86]	0.76 [0.68–0.84]	**0.84** [0.77–0.90]	0.71 [0.70 - 0.72]	**0.72** [0.69 - 0.74]
Calibration plot on independent validation						

Table 3: Model performance of the reference model and deep learning (DL) NTCP models

showed a better fit to the observed dysphagia rates than the reference model (Table 3).

Both the DL model (AUC_{train}=0.74) and reference model (AUC_{train}=0.70) showed good performance for *taste loss*, yet was lower compared to the other two toxicities. While the performance of the DL model in the validation set (AUC_{test}=0.72) was still higher that of the reference (AUC_{test}=0.71), the improvement was less pronounced than for the other toxicities. Calibration was arguably marginally better for the DL than the reference model, as the calibration points show a more consistent incline.

3.3 Attention maps

The attention maps of the DL xerostomia NTCP model show that the main focus of the network was on the salivary glands (Figure 2a). Moreover, high focus was seen in the center of the parotid glands.

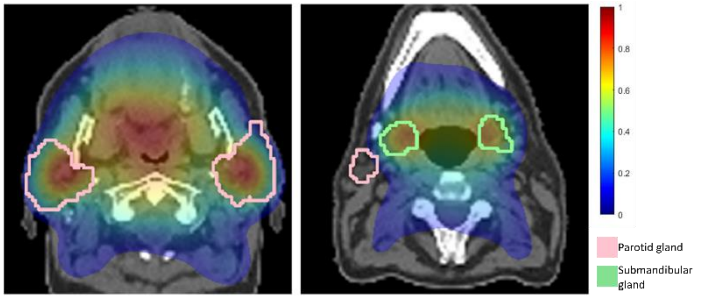

Figure 2a: Attention map for the DL xerostomia model

For the taste DL NTCP model, the attention was somewhat focused on the anterior site of the tongue and on the parotid glands (Figure 2b). The attention maps showed a more diffuse picture than for xerostomia and dysphagia.

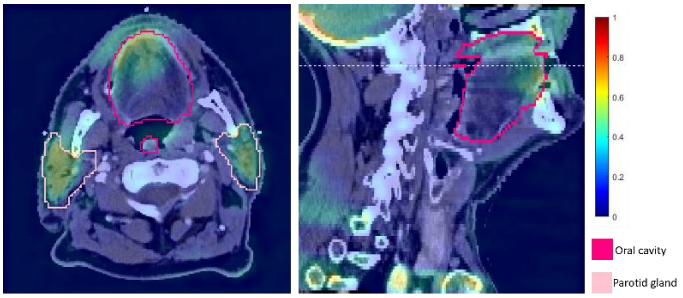

Figure 2b: Attention map for the DL taste NTCP model

The attention maps for the DL dysphagia NTCP model showed that the DL model focusses on the swallowing structures (Figure 2c). For instance, high focus was seen for the oral cavity and pharyngeal constrictor muscle (PCM).

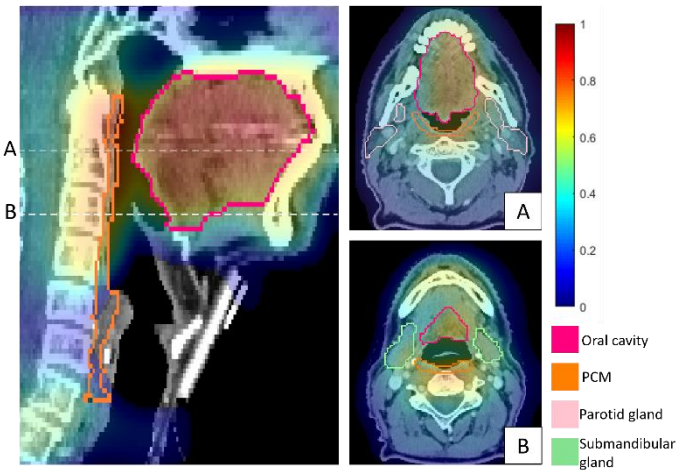

Figure 2c: Attention map for the DL dysphagia model. PCM = pharyngeal constrictor muscle.

4 Discussion

Our results suggest that using the full 3D dose and image information results in improved prediction performance over the conventional models that are based on average dose to distinct OARs. A large dataset with prospectively collected toxicity scores was used to develop and subsequently validate 3D DL models to predict late xerostomia, dysphagia and taste. The DL models performed well in both the training set and the independent test set.

The biggest improvement was seen for dysphagia, which is likely due to the many swallowing structures that are involved in maintaining swallowing functionality which makes conventional modelling approaches very complicated due to insuperable issues with multicollinearity between dose parameters of those structures. Also for xerostomia, the 3D DL model shows improved performance over the conventional NTCP model. The attention maps show that the model is still guided by the radiation dose administered to the salivary glands. Furthermore, higher

focus on the center of the parotid gland can be recognized, which corresponds to the stem cell-rich region of the gland [18]. The DL model improved the prediction of taste loss after treatment compared to the reference NTCP model, yet the increase in AUC was limited (Table 3). The prediction of taste loss is complex; the conventional NTCP model is based on parotid gland and oral cavity dose, yet the exact mechanisms causing taste loss are not fully understood.

The findings of this study are in line with the results of Men et al. [16], showing that DL outperforms logistic regression in predicting late xerostomia. In this study, we validated this in a more recent and larger cohort. Furthermore, DL models were developed and validated for other relevant HNC toxicities: dysphagia and taste. A fairer NTCP model comparison was ensured by using state-of-the-art conventional NTCP models as reference. Moreover, DL methodology was optimized by introducing a reproducible data pre-processing procedure, 10-fold stratified cross-validation, independent validation, and exploring attention maps. These improvements enhance understanding and applicability, setting a new benchmark for future clinical implementation. Nevertheless, more global external validation is needed to test the generalizability of the DL NTCP models.

5 Conclusion

Our study demonstrates superior prediction performance with DL NTCP models using full 3D dose and image information in predicting late xerostomia, dysphagia, and taste loss compared to conventional models based on average OAR dose. Clinical variables can be added to the DL models as well as the conventional models. Attention maps highlighted the relevance of salivary gland dose, as well as the central stem cell rich region for xerostomia. For dysphagia, the model focussed on a scala of swallowing muscles. The focus for taste was more diffuse, yet more attention was seen in the parotid glands and anterior part of the tongue. DL NTCP models show potential to improve the risk estimation of late HNC toxicities before treatment, facilitating better informed radiotherapy decisions (e.g., IMRT versus IMPT) to minimize toxicities and improve the quality of life of cancer survivors.

Abstract This study explores the causal impact of radiation-induced toxicities on overall survival (OS) in stage III Non-Small Cell Lung Cancer (NSCLC) patients undergoing proton radiation therapy. Leveraging real-world data (RWD) from the Registry Study for Radiation Therapy Outcomes, and advanced causal inference methodologies that have garnered support from the US Food and Drug Administration's Real-World Evidence (RWE) Program, we estimated of the impact of pneumonitis/dyspnea and esophagitis/dysphagia on OS with targeted minimum loss-based estimation (TMLE). Our findings suggest there may be a time-dependent relationship between pneumonitis/dyspnea and decreased OS, emphasizing the need for personalized treatment strategies that balance treatment intensity with toxicity management. Additionally, our methodology demonstrates the utility of targeted learning and its accompanying step-by-step causal roadmap for generating reliable RWE, setting a precedent for applying such techniques in radiation oncology to support clinical and regulatory decision-making, and ultimately enhance patient care.

1 Introduction

Non-Small Cell Lung Cancer (NSCLC) is the predominant form of lung cancer and a leading cause of cancer-related mortality, with stage III patients facing particularly challenging prognoses. Accounting for approximately 85% of thoracic cancers, NSCLC represents a significant health burden [1]. The survival rates for unresectable stage III NSCLC patients are markedly lower compared to earlier stages, highlighting the need for more effective treatment strategies. Current treatment paradigms involving chemoradiotherapy (CRT) and targeted therapies like Durvalumab have improved progression-free survival (PFS) but locoregional and distant metastasis control still need to improve. Proton Beam Therapy (PBT), particularly with the advent of pencil beam scanning (PBS) technology, offers a promising avenue due to its superior organ-sparing capabilities [2]. However, the relationship between radiation-induced toxicities and patient survival remains underexplored. We aim to fill this gap using targeted machine learning estimation / targeted minimum loss-based estimation (TMLE), a statistical framework for efficient learning from data [3, 4], and causal inference methodologies. The focus of the present study is to understand the causal impact of radiation-induced toxicity—specifically, higher grade (≥ 2, warranting medical intervention) pneumonitis/dyspnea or esophagitis/dysphagia—on the overall survival (OS) of stage III NSCLC patients receiving PBT. Leveraging registry real-world data (RWD) for estimation of these causal effects, we aim to provide insights crucial for personalized radiation therapy planning.

2 Methods

Data description: The Registry Study for Radiation Therapy Outcomes (NCT01255748), led by the Proton Collaborative Group (PCG), collects RWD US-wide with the objective of understanding factors that may lead to reduced toxicity, and better OS and PFS. This ongoing trial has accrued over 23,000 patients, spanning 27 of the 43 proton centers in the US. Patient data has been collected and distributed under an Institutional Review Board study approved by each member institution. Protected health information is de-identified in compliance with the Health Insurance Portability and Accountability Act. Strict data quality control, submission, and adherence to treatment protocols are supervised by the PCG for each participating center.

After a successful application, we received access to 636 patients with stage III NSCLC with the objective to

Patient cohort characteristics	
Age at diagnosis	70 (8 – 97)
BMI	26.0 (13.4 – 15.3)
Sex: Female (50.4%), Male (49.6%)	
Race: White (783.8%), Other (16.2%)	
Tumor location: LLL (10.9%), LUL (22.7%), RLL (13.9%), RML (4.1%), RUL (31.7%), airways (3.1%), other (13.7%)	
Chemotherapy: Cisplatin (5.4%), Etoposide (3.4%), Carboplatin (20.6%), Paclitaxel (11.7%), Pemetrexed (2.1%), Other (9.0%), None (43.6%)	
Histology: Adenocarcinoma (39.3%), Squamous cell carcinoma (29.0%), Non-small cell lung cancer (13.5%), Small cell (7.6%), Other (10.2%)	
Dose Fractionation: 2Gy/fx (71.3%), 10-12Gy/fx (11.4%), Other (28.7%)	

39 Total Demographic Features	
Institution	12 Categories
Race	6 Categories
Ethnicity	3 Categories
Weight (kg)	75 (31 – 190)
Height (cm)	170 (65 – 215)
Days diagnosis to RT	105 (3 – 8148)
Smoking-years	40 (1 – 50)
45 Total Clinical Features	
Tx Interruption?	Yes (30%), No (70%)
Concurrent Chemo?	Yes (44%), No (56%)
Was it metastatic?	Yes (7.6%), No (92.4%1)
Primary tumor size (cm)	3.5 (0.4 – 9.8)
Grade	5 Categories
Clinical stage	Multi-categories for T,N,M
Pathological stage	Multi-categories for T,N,M
ECOG performance	5 Categories
53 Total Dosimetry Features	
Total proton dose (Gy)	60 (1.2 – 95.0)
Fraction numbers	23 (1 – 57)
Dose metrics for OARS: Esophagus, Heart, lungs (contralat and ipsalat)	8 Numerical features/OAR: Dmin, Dmax, Davg, D98%, D95%, D50%, d1cc, d2cc

Table 1: Description of the data and features included in the analysis of the causal effect of radiation toxicities on overall survival. The left hand side shows the patient cohort characteristics from the initial 636 patients spanning 12 institutions, and the right hand side provides a breakdown of patient features into demographic, dosimetric, and clinical categories with examples.

understand the factors leading to life-threatening radiation toxicities, and their impact on OS and PFS. We summarize the information considered in our analysis in Table 1. Out of the 636 patients, 368 were treated with uniform or passive scattering (ST) and 268 were treated with PBS. Most patients received 60 Gy dose. Significant, grade $geq2$ esophagitis/dysphagia (19.7% of patients) and pneumonitis/dyspnea (25.6% of patients) developed within one year of treatment. Patients treated with ST were more likely to develop any grade $geq2$ toxicity (45%) than those treated with PBS (33%). Patients receiving ST also had worse OS, with 28% alive at 5 years with ST versus 43% with PBT.

Data structure: We introduce some notation to describe the data structure and will draw on this in subsequent sections.[1] The data consists of n independent and identically distributed observations $O = (W, A, \Delta, \tilde{T})$, where W is comprised of covariates (Table 1); A is a binary toxicity indicator of grade $geq2$; $\tilde{T}$ is the last time point at which a subject was monitored, the minimum of the censoring time (C) and outcome event time (T); and Δ is an event type indicator (0: censored, 1: death), $\Delta = I(T < C)$.

Realistic statistical model: We express the likelihood and statistical model ($\mathscr{M}$) for time-to-event data similarly to [8], in terms of the intensities of the failure and censoring time processes: $N(t) = I(\tilde{T} \leq t \mid \Delta = 1)$ and $A_C(t) = I(\tilde{T} \leq t, \Delta = 1)$, respectively. [2] For the sake of generality, we recode the observed data O in discrete time as a longitudinal structure ordered in time $O = (W, A, N(0), A_C(0), \ldots, N(\tau), A_C(\tau), N(\tau+1))$, where τ is a maximal follow up time so that each $\tilde{t} \geq \tau + 1$. This can be more succinctly expressed as $O = (W, A, \bar{N}(\tau+1), \bar{A}_C(\tau))$, where the over-bar denotes the entire history. We factorize the likelihood of the observed data according to the time ordering that generated it: $p(O) = q_W(W) g_A(A \mid W) \Pi_{t=0}^{\tau} g_{A_C(t)}(A_C(t) \bar{A}_C(t-1), \bar{N}(t), W, A) \Pi_{t=0}^{\tau} q_{N(t)}(N(t) \mid \bar{N}(t-1), \bar{A}_C(t-1))$, where each conditional density is conditioning on the variables realized prior to the variable in question. Further, $g_{A_C(t)}(1 \mid \bar{A}_C(t-1), \bar{N}(t), W, A) = I(A_C(t-1) = 0, N(t) = 0, W, A) \lambda_C(t \mid W, A)$, and $q_(N(t))(1 \mid \bar{N}(t-1), \bar{A}_C(t-1) = I(N(t-1) = 0, A_C(t-1) = 0) \lambda_T(t \mid W, A)$, where $\lambda_C(t \mid W, A) = P(C = t \mid C > t-1, N(t) = 0, W, A)$ and $\lambda_T(t \mid W, A) = P(T = t \mid T > t-1, A_C(t-1) = 0, W, A)$. Under the coarsening at random assumption on C and T, stating that the censoring and event times are conditionally independent given W, A, the intensities of $N(t)$ and $A_C(t)$ reduce to indicators of being at risk of jumping, multiplied by the conditional hazards of C and T, respectively. That is, the conditional hazards reduce to $\lambda_C(t \mid W, A) = P(C = t \mid C > t-1, W, A)$ and $\lambda_T(t \mid W, A) = P(T = t \mid T > t-1, W, A)$.

The density p of O can be parameterized as $p = p_(q_w, \lambda_C, \lambda_T, g)$. $\mathscr{M}$ is therefore determined by domain knowledge regarding these 4 nuisance parameters: λ_C and g, with q_w and λ_T. In the present study, it remains fully nonparametric. In Section 4, we discuss the potential to draw on natural experimentation of PBT type via instrumental variable analysis.

Causal estimand, causal model, and identification: It is thought that high grade toxicities impact OS and PFS, but their causal effect has not been quantified and is confounded by other covariates. Here, we aim to estimate the causal effect of radiation-induced toxicities on OS to further our understanding of the role of these toxicities in the management of cancer patients receiving radiation therapy. Figure 2 shows a directed acyclic graph (DAG), which illustrates the relationship between our covariates, exposure of interest (toxicities), and primary and secondary outcomes of interest. Examining the structure of a DAG can help identify sufficient sets of confounders to adjust for in the analysis [10, 11]. The study's causal model was formulated based on the relationships between the variables represented by the DAG.

The causal estimand is a mathematical quantity which represents the answer to the causal question of interest. Frameworks often used to guide evidence generation in clinical research—the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) E9(R1) Guidelines [12], Target Trial Emulation [11, 13, 14], PICOT [15], and Targeted Learning and Causal Roadmaps [5–9]—similarly prompt investigators to define components of a causal estimand. We review each attribute in the context of this study.

1. population: reflected by the PCG trial's eligibility criteria (inclusion criteria include planned treatment with proton radiation therapy and ability to understand and sign IRB approved consent), as well as stage III NSCLC patients, and restricted to those receiving PBT.

[1] This presentation of the methodology mirrors the Targeted Learning Roadmap / Causal Roadmap: a systematic guide to navigating the study design and analysis challenges inherent in real-world studies [5–9].

[2] A statistical model ($\mathscr{M}$) is a set of possible data distributions. Realistic $\mathscr{M}$ align with subject-matter knowledge, i.e., rule out distributions that are incompatible with known truth (e.g., outcome bounds or knowledge about the clinical decision-making), and avoid making overly restrictive (e.g., parametric) assumptions that preclude the true data distribution [5].

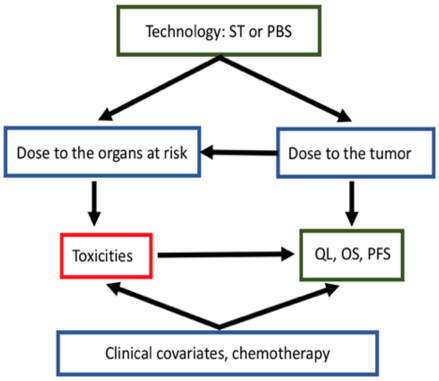

Table 2: Directed acyclic graph (DAG) showing the relationship between the covariates, exposure (toxicity), and outcomes of interest: overall survival (OS), progression free survival (PFS) and quality of life (QL). The direction of the arrow denotes the flow of information. Exogenous errors are not shown.

2. treatment/exposure variable: pneumonitis/dyspnea, dichotomized according to whether it is a high grade toxicity ≥ 2 (warranting medical intervention) [16]. We also consider esophagitis/dysphagia as another exposure variable in an independent analysis, and similarly dichotomize it according to whether it's a high grade toxicities ≥ 2.

3. endpoint/outcome variable: survival time, $\tilde{T}$.

4. summary measure:we are interested in contrasting 5-year cumulative incidence of death under grade ≥ 2 toxicity versus grade < 2 or no toxicity, and under no right censoring.

5. intercurrent events: defined as "events occurring after treatment[/exposure] initiation that affect either the interpretation or the existence of the measurements associated with the clinical question of interest" [12]. Our primary "treatment" of interest is actually toxicity, so issues like treatment non-compliance or discontinuation of treatment are not considered an intercurrent event here. In future studies that will evaluate PFS outcome, mortality will be a competing risk that precludes observing the time to disease progression and will need to be addressed. For instance, we may define a composite outcome: disease progression or death [8].

We define our causal estimand as the cumulative incidence ratio (CIR) of mortality by 5 years. Consider an intervention-specific causal estimand, $\psi_a^F(P_X) = P(T_a \geq 5)$. We have that $P(T_a \geq 5) = E_W P(T_a \geq 5 \mid W, A = 1) = E_W \Pi_{s \leq 60}[1 - \lambda_T(s \mid W, A = 1))]$. Denote the latter expression by $\psi_a(P)$, establishing the identification of $\psi_a^F(P_X)$ under exposure a. Note that $P(T_a \leq 5) = 1 - \psi_a^F(P_X)$.[3] Next we define the conditional survival function of T given A, W as $S(t \mid A, W) = \Pi_{s \leq t}[1 - \lambda_T(s \mid W, A)]$ so that $\psi_1(P) = E_W S(5 \mid A = 1, W)$ and $\psi_0(P) = E_W S(5 \mid A = 1, W)$. The CIR is a function of these two statistical estimands, $\psi_{CIR}^{obs}(P) = ([1 - \psi_1(P)])/([1 - \psi_0(P)])$.

Statistical estimation: For causal inference and in settings with complex data structures or where traditional modelling assumptions (e.g., proportional hazards) are unreasonable, TMLE is more appropriate. In general, TMLE typically consists of two stages: (1) generate initial estimates of the (relevant portions of the) underlying data-generating mechanism, then (2) modify them in such a way that endows the resulting plug-in estimator with desirable statistical properties, including efficiency and unbiased estimation in large samples as well as finite-sample robustness. The *survtmle* package in R is a software program for designed for TMLE survival analysis. We used version 1.1.3 to calculate the 5-year CIR of mortality [17, 18]. Super Learner (SL) was used to estimate the propensity score, censoring and failure time processes (step 1 of TMLE) [19]. The SL procedure was abridged in this initial analysis for the sake of time. We considered 2 cross-validation (CV) folds and a k-fold/V-fold CV scheme, and an SL library incorporating lasso regression. Upcoming analyses will follow SL specification guidelines [20], considering 20 CV folds and a rich and diverse SL library that captures a diversity of potential underlying functional forms.

[3] Causal estimands are defined in terms of the full-data P_X implied by the post-intervention distribution on the causal model, where counterfactual outcomes are generated. To learn from data we must define a statistical estimand, which can be observed in the real world. Expressing the causal estimand as a statistical estimand requires so-called causal "identification" assumptions like no unmeasured confounding / coarsening at random [5].

3 Results

The study preliminary findings (Table 3) present estimated CIRs for mortality and corresponding 95% confidence intervals—contrasting higher grade radiation toxicity with lower/no toxicity and considering two specific toxicities (pneumonitis/dyspnea and esophagitis/dysphagia)—after correcting for all other variables in Table 1. These results span various time points up to five years following radiation therapy initiation. For pneumonitis/dyspnea, the estimated CIRs (denoted by $\hat{\psi}$ in 3) ranged from 1.18 at 30 days to 1.00 at 1095 days and beyond, gradually converging to 1.00 over the 5-year period. This indicates an initially elevated risk of mortality associated with toxicity that diminishes over time. The 95% confidence intervals start wider and progressively narrow, reflecting increasing precision in the estimates as time progresses. In contrast, for esophagitis/dysphagia, the CIRs consistently hovered around 1.00 across all time points, with the exception of a notable increase to 1.46 at 182 days. This suggests that esophagitis/dysphagia does not consistently impact mortality risk over the five-year period, except for a transient increase at around six months post-therapy.

The observed temporal patterns in the mortality risks associated with pneumonitis/dyspnea and esophagitis/dysphagia offer important insights. The initial higher mortality risk in patients with pneumonitis/dyspnea could be attributed to the acute effects of this toxicity, which appears to resolve or be managed effectively over time. This underscores the importance of early detection and intervention for pneumonitis/dyspnea in the treatment of NSCLC patients. The transient increase in mortality risk at six months for patients with esophagitis/dysphagia warrants further investigation. It might be linked to specific treatment-related complications or other factors not captured in the analysis. The lack of a sustained impact of esophagitis/dysphagia on

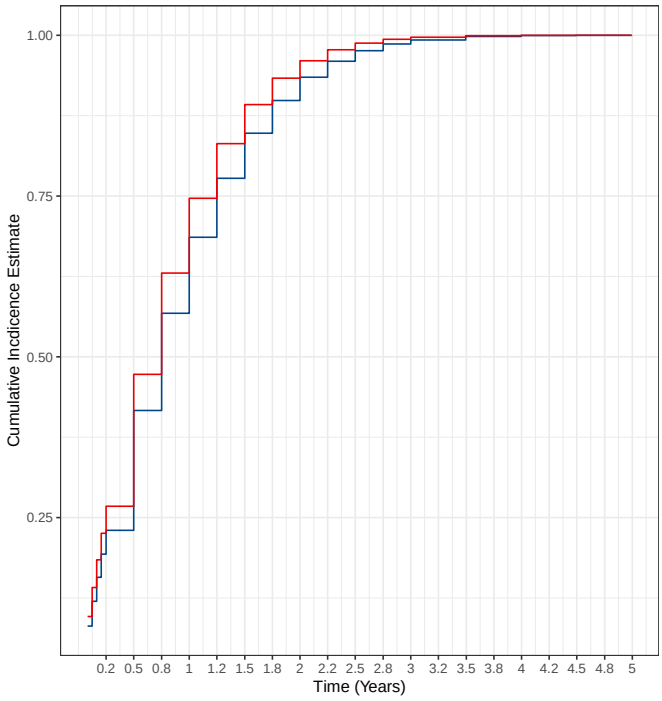

Figure 1: Counterfactual, covariate-adjusted cumulative incidence estimates under an intervention of higher grade ≥ 2 pneumonitis/dypsnea toxicity (red line) versus no or lower grade < 2 pneumonitis/dypsnea toxicity (blue line) over 5 years following proton beam therapy initiation for stage III Non-Small Cell Lung Cancer.

mortality across the other time points could indicate effective management strategies or a lesser severity of this toxicity in terms of long-term mortality risk.

4 Discussion

This study provides a detailed temporal understanding of the impact of two common radiation toxicities on mortality in NSCLC patients receiving PBT. Findings emphasize the importance of nuanced patient monitoring, especially in the early months following treatment. The differences in mortality risk profiles between pneumonitis/dyspnea and esophagitis/dysphagia highlight the need for toxicity-specific management strategies. These insights contribute to the growing body of knowledge on long-term outcomes in NSCLC patients undergoing advanced radiation therapies and underscore the value of continuous monitoring and intervention strategies tailored to specific treatment-related toxicities.

Future research will incorporate sensitivity analyses using instrumental variables (IV) to examine the impact of causal bias (e.g., unmeasured confounding) on the study conclusions. An IV analysis does not require that there are no unmeasured confounders but it assumes that if they exist and are correlated to the outcome then they cannot be correlated to the IV. We aim to leverage PBT type (PBS or ST) as an IV; access to technology is a commonly considered as an IV in causal inference [21]. For reassurance, we will use clinical and dosimetric covariates to determine if they are correlated to PBT type. If not, this will provide evidence that access to technology is acting as an IV in our case.

The use of negative control outcomes will also be explored to validate causal assumptions and identify potential biases in the analysis. If negative controls show an association with toxicity, this could indicate the presence of unaccounted biases, prompting a re-evaluation of the analysis methods or the causal assumptions made in the study. Some examples of potential negative control outcomes include unrelated health outcomes, such as conditions with a genetic basis or unrelated infections; early time-point events that occur too soon after the start of radiation therapy to be plausibly caused by it; and non-radiation responsive conditions, such as osteoarthritis or chronic skin conditions unrelated to radiation exposure. Additionally, in future analyses, we will further refine the SL implementations considered in *survtmle* to enhance the robustness of the findings.

This research contributes to the field of causal inference in oncology. An illustration of the power of TMLE and causal inference for rigorously analyzing complex RWD, this study offers insights that are generally applicable for generating reliable RWE in oncology. We strive to empower cancer researchers to use these tools in their work for causal targeted machine learning.

Abstract: In radiotherapy, a low-dose elective target volume is often defined to include lymph nodes that may be malignant. The prescribed dose to the elective target volume results in large irradiated volumes with associated risk of severe side-effects. In this study we establish a model for bilateral tumour progression in patients with oropharyngeal squamous cell carcinoma for personalised elective target volume definition. An expansion of a previously proposed Bayesian network model was employed to estimate the probability of bilateral nodal spread. This study highlights the potential for reconsidering the elective target volumes through probabilistic modelling, aiming to decrease unnecessary radiation dose to organs-at-risk and healthy tissue.

1 Introduction

Advancements in radiotherapy over the past decades have led to increasingly personalised irradiation volumes, with radiation beams that closely conform to the tumour, and high precision beam delivery. Despite efforts to minimize exposure of healthy tissue to unnecessary radiation, irradiation of such tissues remains inevitable and often leads to side-effects. A substantial part of patients with head and neck cancer (HNC) whose primary treatment is radiotherapy, suffer from late morbidity including xerostomia, oral discomfort, difficulties chewing, speaking, and swallowing, as well as loss of taste and reduced periodontal hygiene.

In current curatively intended RT of HNC, the target volumes include the gross tumour volume (GTV) and Clinical Target Volume (CTV) that confines the subclinical disease. The CTV is often subdivided accounting for factors of varying importance. Particularly a low-dose elective CTV (CTVe) is often defined which encompasses elective lymph nodes (LNs) that may involve malignant deposits. Although the prescribed dose to the elective CTV is relatively low, it still covers a substantial portion of the head and neck region which leads to undesired irradiation of adjacent organs-at-risk (OAR) and surrounding healthy tissue. Studies have established that large treatment margins and irradiated volumes, are the leading factors associated with increased acute and late side-effects. [1], [2], [3], [4], [5]

A recent study by Kristensen et.al [6] has shown that the majority of local-regional failures were found within the high-dose volume in head and neck cancer squamous cell carcinoma. This is supported by Bollen et. al [7] who found that the majority of recurrences were observed within the high-dose target volume following IMRT/VMAT. Likewise, a study by Razavian et.al. [8] investigated the rate of contralateral neck failure on tonsil cancer patients treated with unilateral radiotherapy. They found that unilateral radiotherapy is associated with low risk of contralateral LN failure and should be considered if patients are diagnosed with lateralised tonsil cancer. However, the characteristic across these studies is the emphasis on the potential for overtreatment under the current guidelines. Considering the severe side effects, which to some extent limits the level of high doses, an investigation into potential adjustments, such as a reduction of the CTVe, is justified. A strategy that could allow us to reduce the volume, is by defining the CTVe using a probabilistic approach. By statistical estimations of the risk of malignant formations in specific LNs, we can potentially selectively omit LNs with low risk without compromising the therapeutic effectiveness. Pouymayou et.al [8] have previously suggested a statistical framework to estimate lymphatic nodal involvement for patients receiving primary radiotherapy. The framework was based on the anatomical principles of the lymphatic drainage system, modelled as a Bayesian Network (BN). Lymph node levels (LNL) were represented as nodes connected with directed arcs between each other. The study established, through inference of the BN, the viability of estimating the probability of malignant LNs. They observed low risk of nodal involvement for specific LNLs with different states of macroscopic involved LNLs obtained from diagnostic imaging.

The approach outlined in Pouymayou et al [9], primarily focuses on ipsilateral tumour progression, which bears certain limitations. Firstly, focusing solely on ipsilateral tumour progression might neglect important parts of the disease dynamics. Secondly, bilateral involvement is common in many types of HNC, and neglecting this aspect could lead to an inaccurate assessment of the overall disease state, increasing the risk of missing metastatic developments. In this study, we expand to incorporate bilateral tumour progression into the model, to provide a more nuanced modelling of the disease dynamics.

2 Materials and Methods

2.1 Patients

In this retrospective study we included 460 patients with oropharyngeal squamous cell carcinoma treated at Aarhus University Hospital in the period 2013-2020. For calculating the probabilities of lymphatic nodal involvement, we used information on tumour characteristics. Firstly, T-stage for each patient was used as an approximation for greater risk of microscopic disease. Secondly, one of the factors linked with contralateral LN metastasis is whether the tumour is lateralised or not.

Therefore, in this study, we only included patients with central tumours, defined as those situated ≤ 1 cm from the midsagittal line. Lastly, location of both ipsilateral and contralateral LN metastasis was derived for the purpose of calculating the probabilities of nodal involvement. Each LN metastasis was identified through combination of PET/CT and MRI. In instances where the malignancy of LNs was uncertain, the identification process was supplemented with fine needle aspiration.

2.2 Bayesian Network for bilateral tumour progression

The BN presented in this study is based on the same principles as described by Pouymayou et.al. [9]. The graphical representation of the BN can be divided into three different phases: (1) the association between macroscopic and microscopic states, (2) spread from primary tumour directly to each LN level (LNL), and (3) spread between different LNL. The BN is based on the most relevant LNL, namely, I, II, III, IV, V, and VI. Furthermore, each equation as presented in the subsequent section holds true for both calculating the ipsilateral and contralateral lymph nodal involvement. We utilise two different BN for probability estimation; one for early-stage tumours and a second for advanced-stage tumours. The early-stage tumours are defined as low grade tumours (T1-T2) whereas advanced-stage is defined as high grade tumours (T3-T4). The graphical representation and calculations are identical for both BNs, the only difference lying in the dataset used for parameter learning. A visual representation of the BN employed in this study, can be seen in figure 1.

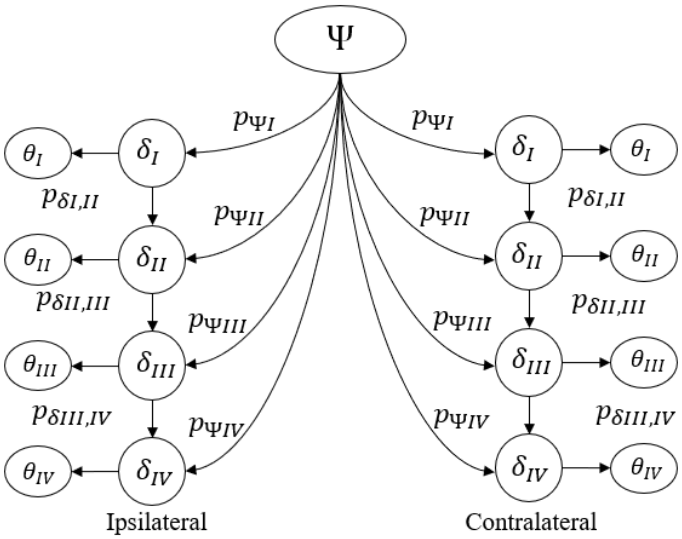

Figure 1: Bayesian Network of bilateral tumour progression. Each lymph node (δ_k) is connected through directed arcs. Between each lymph node, we have the parameter $p_{\delta k,\delta k+1}$ that describes the probability that δ_k spreads to δ_{k+1}. We assume that the primary tumour (Ψ) can spread directly to each δ_k with probability Ψ_k. The parameter θ_k determines the macroscopic state of the associated lymph node by the sensitivity and specificity of the diagnostic image modality.

Firstly, each LNL is associated with two random binary states: macroscopic and microscopic states. The macroscopic random state, defined as θ, determines the presence of macroscopic metastasis (from e.g. CT, MRI, PET) within the LNL. The microscopic random variable, represented as δ, specifies whether the LNLs contains microscopic metastasis. The association between these variables are determined by the sensitivity and specificity of the imaging modality. This is given by [8]:

$$\begin{pmatrix} P(\theta_k^1|\delta_k^1)\, P(\theta_k^0|\delta_k^1) \\ P(\theta_k^1|\delta_k^0)\, P(\theta_k^0|\delta_k^0) \end{pmatrix} = \begin{pmatrix} sens & 1-sens \\ 1-spec & spec \end{pmatrix}$$

Secondly, we assume that primary tumours can spread directly to each LNL. Thus, the tumour spread directly to each LNL can be estimated with the probability $P_{\Psi k}$. This is formally written as [7]:

$$\begin{pmatrix} P(\delta_k^1|\Psi_k^1)\, P(\delta_k^0|\Psi_k^1) \\ P(\delta_k^1|\Psi_k^0)\, P(\delta_k^0|\Psi_k^0) \end{pmatrix} = \begin{pmatrix} P_{\Psi k} & 1-P_{\Psi k} \\ 0 & 1 \end{pmatrix}$$

Lastly, we consider the association between LNLs. It is essential to consider the causality of the lymphatic system. Therefore, we model the association between different LNLs based on the dynamics of lymphatic drainage. Thus, LNL II receives efferent lymphatics from LNL I, and so on. The probability of tumour cells spreading between two efferent LNLs, is defined as $P_{\delta ij}$ (e.g. $P_{\delta II-III}$ is the probability of LNL II spreading to LNL III). We say that if a single parent Δ_i is in state 1, it will cause δ_k to be 1 with probability u_i. The Noisy-OR model is then described as:

$$P(\delta_k^0|\Delta) = \prod_{\lambda_i \in \lambda^+} (1-u_i)$$

$$P(\delta_k^1|\Delta) = 1 - \prod_{\lambda_i \in \lambda^+} (1-u_i)$$

Where Δ denotes the parents of the respective δk and the subset of parents that are in state 1, are denoted as λ^+. For instance, if one wish to calculate $P(\delta_{II} = 1\,|\delta_I = 1, \Psi = 0)$, we describe the Noisy-OR as $1 - P(1 - P_{\delta I-II})$. Calculating the probability of harbouring microscopic disease for a set of observed macroscopic involved LNs, is described by Baye's law. The conditional probability, with a set of parameters Φ and macroscopic involvement θ, is then given by:

$$P(\delta_i|\theta, \Phi) = \frac{\sum_{k:\delta_{ki}=1} P(\theta|\delta_i, \Phi) P(\delta_i|\Phi)}{P(\theta|\Phi)}$$

Where the nominator represents a marginalisation over all hidden states, in which δ_i is macroscopically observed.

2.3 Parameter estimation

The parameterisation of the BN follows the principles outlined in Ludwig et al [10]. This approach computes the likelihood of observing a patient cohort given a set of model

parameters, namely, the spread probabilities ($P_{\psi k}$, $P_{\delta ij}$). However, due to the model simplification using logical OR gate truth tables, standard maximum likelihood estimation can no longer be directly obtained through a simple ratio of occurrences. Therefore, to address this, we established an optimization scheme to correctly estimate the spread probabilities. In this study, we employ the affine-invariant ensemble sampler to draw samples from the likelihood function [11].

3 Results

Of 460 included patients, 428 patients were suitable for inclusion after sorting out patients that either had missing information of LN metastasis and/or T-stage or did not have a central tumour. We further divided the 428 patients into two groups: early-stage (275 patients) and advanced-stage tumours (153 patients). The estimated probabilities for observing microscopic disease for all LNs are reported in table 1. For patients with N_0, we observe that ipsilateral LNL II for both early-stage and advanced-stage has the highest probability of finding microscopic disease (37.5% and 46.3%, respectively). For ipsilateral LNL I, III and IV, we observe probabilities of 0.8%, 5.2%, and 0.8% for early-stage tumours and 2.1%, 7.8%, and 1.2% for advanced-stage tumours, respectively. However, an increase in probability of harbouring microscopic disease is observed when the LNLs are macroscopically involved. For instance, if ipsilateral LNL II is macroscopically observed for early-stage tumours, the probability of finding microscopic disease in ipsilateral LNL II increases from 37.5% to 93.3%, LNL III from 5.2% to 11.3%, and LNL IV from 0.8% to 1.1%. Correspondingly, for advanced-stage tumours the probabilities increase from 46.3% to 95.2%, 7.8% to 14.3%, and 1.2% to 1.5%, respectively. Similar tendencies are seen for ipsilateral as well as contralateral macroscopically involved LNL II/III and LNL III, for both early-stage and advanced-stage tumours.

4 Discussion

In this study we have suggested a statistical framework for bilateral tumour progression based on the principles of Pouymayou et.al [9], including contralateral tumour progression. The framework may contribute as a decision tool for physicians, allowing for personalised CTVe definition with omission of low-risk LNLs.

Defining an appropriate risk threshold for LNL omission is not a straightforward process due to the risk/benefit trade-offs, including disease control vs irradiation to OAR and healthy tissue. However, a study by Grégoire et.al. [12] proposed that threshold values for risk assessment, falling within the range of 5-10% for the N_0 patients would be acceptable. Using a threshold of 10%, our study suggests that it might be viable to omit great parts of the CTVe for selected patients. For instance, in patients with N_0 status for both early-stage and advanced-stage tumours, the risk associated with ipsilateral LNL I, III, and IV, as well as contralateral LNL I, II, III, and IV, falls below the threshold of 10%. Similar tendencies are observed for patients with macroscopic findings of ipsilateral LNL II, LNL II/III, and LNL III regardless of tumour stage. In these instances, the risk associated with ipsilateral LNL I and IV, as well as contralateral LNL I, II, III, and IV, also falls below the risk threshold. Looking at the contralateral involvement, we observe that for both early-stage tumours, advanced-stage tumours, and all cases of macroscopic involvement, LNL IV is below the risk threshold. LNL III is below the risk threshold for instances of macroscopic involved LNL II and LNL III, in contrast to ipsilateral involvement where all LNL III must be included.

Several studies have modelled microscopic disease in the LNLs. Pouymayou et.al. [8] constructed a BN for ipsilateral tumour progression for investigating the feasibility of personalised CTVe definition. Comparing our results with theirs, we observe notable similarities across all instances of early-stage tumours and macroscopic involved ipsilateral LNLs, emphasising the consistency and reliability of findings between the two studies. However, it is worth mentioning that our ability to make comparisons is limited to early-stage tumours and ipsilateral LNL. To the best of our knowledge, no other study has modelled bilateral tumour progression, and as a result, we lack the opportunity to thoroughly validate the estimated probabilities for microscopic disease in the contralateral LNLs.

Nevertheless, this study not only establishes consistency with the results of Pouymayou et al. [8], it also proposes the potential for further reduction in the CTVe by taking into account the contralateral LNLs. For instance, each case of macroscopically involved ipsilateral LNLs, the prospect of omitting all contralateral LNLs for both early-stage and advanced-stage tumours is viable, given that these probabilities significantly fall below the 10% risk threshold. Likewise, in specific cases of ipsilateral macroscopic involvement, portions of the ipsilateral LNLs could be omitted. This approach could reduce the dose administered to the OAR and corresponding healthy tissues substantially. Likewise, Ludwig et.al. [9], proposed a Hidden Markov Model for incorporating T-stage. They assumed that T-stage is a surrogate for time and thus predicted lymphatic tumour progression for time dependent parameters. They found that advanced-stage tumours result in more advanced nodal progression than early-stage tumours, and thus the risk of finding microscopic disease increases with greater T-stage. We observe a similar tendency with the model for advanced-stage tumours resulting in larger probabilities for both ipsilateral and contralateral LNLs.

However, it is important to acknowledge the limitations in this study. Firstly, the graphical representation of the BN is based on an assumption regarding of the bilateral lymphatic drainage system. Without correctly considering the causality of the lymphatic drainage system, the BN may misrepresent or overlook important pathways of spread. For instance, our model does not assume a relation between ipsilateral and contralateral involvement. This implies that macroscopic observations in ipsilateral LNLs cannot be considered in assessing the probability of discovering microscopic disease in contralateral LNLs. Addressing this issue proves challenging due to a lack of knowledge about specific microscopic spread patterns. Secondly, testing these models in prospective studies is not straightforward since the CTVe definitions will fall in many categories for different patients. However, a prospective study is currently investigating whether omitting LNLs based on sentinel LN mapping could lead to lower-dose radiation therapy while preserving disease control. Such studies may pave the way for further tests of probabilistic definitions of the CTVe for sparing OAR and healthy tissue from unnecessary irradiation.

5 Conclusion

In this study we successfully presented a statistical framework for assessing the probability of bilateral nodal dissemination for early-stage and advanced-stage oropharyngeal tumours. This study emphasises the feasibility of rethinking the elective clinical target volume, which could reduce radiation dose delivered to OAR and healthy tissue. However, further studies are required to investigate the dosimetric effects and benefits.

Abstract In the domain of medical imaging, model interpretability is required for experts to optimize their models and it is paramount for clinical trust as well. This work explores the interpretability potential of recently-proposed Distance-Encoding Biomorphic-Informational Neural Networks (DEBI-NN), using as an example application the diagnosis of human papillomavirus (HPV) status in the HECKTOR (head and neck tumor segmentation and outcome prediction in positron emission tomography / computed tomography (PET/CT) images) 2022 challenge dataset. DEBI-NNs train 3D spatial coordinates instead of weights, thus, they require significantly less parameters to train compared to conventional NNs and they are inherently 3D objects. This study relies on a 3D visualization approach to understand the spatial configurations of DEBI-NNs, shedding light on the network's consistency and aiding in identifying optimal configurations. Two training settings were tested with and without spatial dropout (Setting A and B, respectively), resulting in 90% and 57% test balanced accuracy respectively. Spatial dropout supports the approximation of a task-specific DEBI-NN during training. Results demonstrate the predictive power of DEBI-NNs and the added value of 3D DEBI-NN renderings in explaining them.

1 Introduction

In the context of medical imaging applications, where explainability and interpretability of models is crucial for trust and acceptance of the tools in clinical routine practice, relying on deep neural networks (NNs) results in "black box" models, with no explanation of the output prediction. In addition, these models are notoriously data-hungry and dealing with typically small and imbalanced medical imaging datasets poses significant challenges when employing NNs. In this paper we report preliminary results regarding the potential for interpretability, of a recently published concept called DEBI-NN (for Distance-Encoding Biomorphic-Informational Neural Networks) [1]. This new NN architecture has already demonstrated its ability to provide similar classification accuracy to conventional NNs, on small datasets, while requiring a significantly reduced number of parameters to train. Unlike a conventional NNs where weights are trained, DEBI-NNs train 3D coordinates for each neuron, so that the weight of the information carried by a neuron is represented by the distance between a neuron and its input. In this way, training 3 coordinates of a single neuron is equivalent to modifying the weights of all its inputs, thus drastically reducing the number of parameters to be trained [1]. Figure 1 shows a rendering of an example 3D trained DEBI-NN. Our hypothesis is that 3D rendering of DEBI-NNs could facilitate user interaction and understanding of the architecture training and use of input data, and help in identifying suboptimal configurations and training hyperparameters.

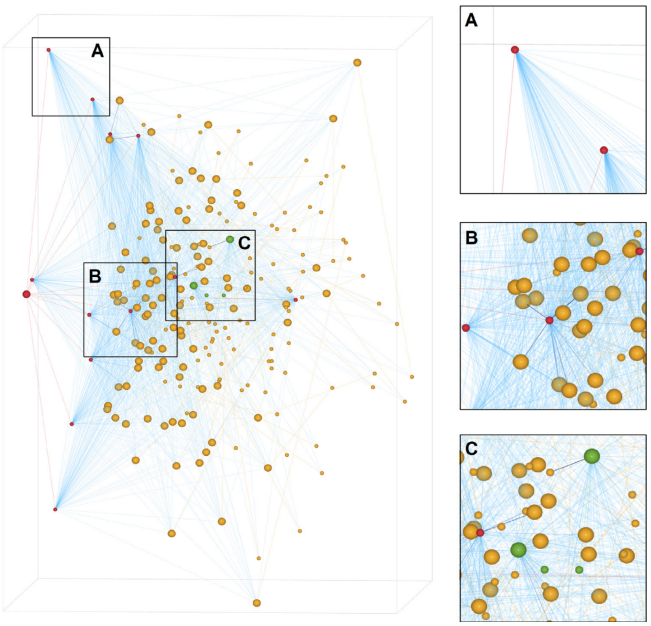

Figure 1: A visual representation of a trained DEBI-NN. The neurons in the input, hidden, and output layers are color-coded as red, yellow, and green respectively [1].

2 Methods

2.1 Dataset and application

In this study, we used the HECKTOR (head and neck cancer segmentation and outcome prediction from positron emission tomography (PET)/computed tomography (CT) images) challenge 2022 dataset [2], and used as a modeling task the diagnosis of the Human Papillomavirus (HPV) status as a binary outcome. Out of the more than 800 patients of the HECKTOR 2022 dataset, the HPV status is known for 563 of them. The training dataset consists of 279 patients with a positive HPV and 61 patients with a negative HPV, resulting in a minority subgroup imbalance of 22 %. Similarly, the

test dataset comprises 203 positive and 20 negative, hence a minority subgroup imbalance of 9.8 %.

2.2 Input features for modeling

IBSI (imaging biomarker standardization initiative)-compliant Radiomic features (shape descriptors, intensity and textural metrics) were extracted from each patient's lesions in PET and CT images using Pyradiomics and based on the provided expert-derived tumor contours.
Available clinical variables and the extracted PET/CT radiomic features were used as input data for modeling HPV status.

2.3 Features preprocessing

The features preprocessing phase involved employing the minimum Redundancy Maximum Relevance (mRMR [3]) method to identify and select the top 36 features with the highest ranking and non-redundancy from the training set. These selected features were then consistently extracted from the test set to maintain uniformity in the dataset. The choice of N=36 was deliberate, representing approximately 10 % of the total sample counts, which amounted to 340 samples in this study.
To ensure that the data were on a common scale, each feature within the training set underwent z-score standardization. This involved calculating the mean and standard deviation values for each feature in the training set and transforming the feature values into their respective z-scores. The calculated mean and standard deviation values from the training set were then used to standardize the corresponding features in the test set.

2.4 DEBI-NN training

Two DEBI-NN model variants (with Settings A and B) were built with common parameters listed in the Table 1. The difference between the two models was the reliance upon spatial dropout (Setting A: ON with 50% threshold, Setting B: OFF). Spatial dropout refers to disconnecting connections between neurons within a layer if the given spatial distance is higher than the defined percentage of the maximum distance within that layer.

2.5 Performance Evaluation

Model instances were evaluated on test sets in both settings A and B model variants (table 1). Sensitivity (SNS), specificity (SPC) and balanced accuracy (BACC) were calculated and reported as performance metrics.

3 Interpretability Analysis

Output neuron clusters: the number of output neurons equals the number of label outcomes. The spatial training approach allows to result in spatial configurations where the two output neurons could be very close to each other like we can see in the figure 1. In this case the network structure implies that the given prediction is not task-specific. If however, the two output neurons are far away from each other, as observed with in Figure 2 (where the output neurons are represented by the green spheres), it implies that the outputs depend on different data and that the network shall be task-specific (currently not implemented in DEBI-NNs). In addition, we evaluated the ability to rank input features importance according to their spatial distance (in the network architecture after training) with respect to the ouput neuron position. The distance between each of the 36 input neurons (one for each feature) and the output neuron (HPV status positive) was calculated as the distance of the entire path within the architecture between the two. The shorter this distance, the more important is the weight or contribution of this feature in the network's decision.

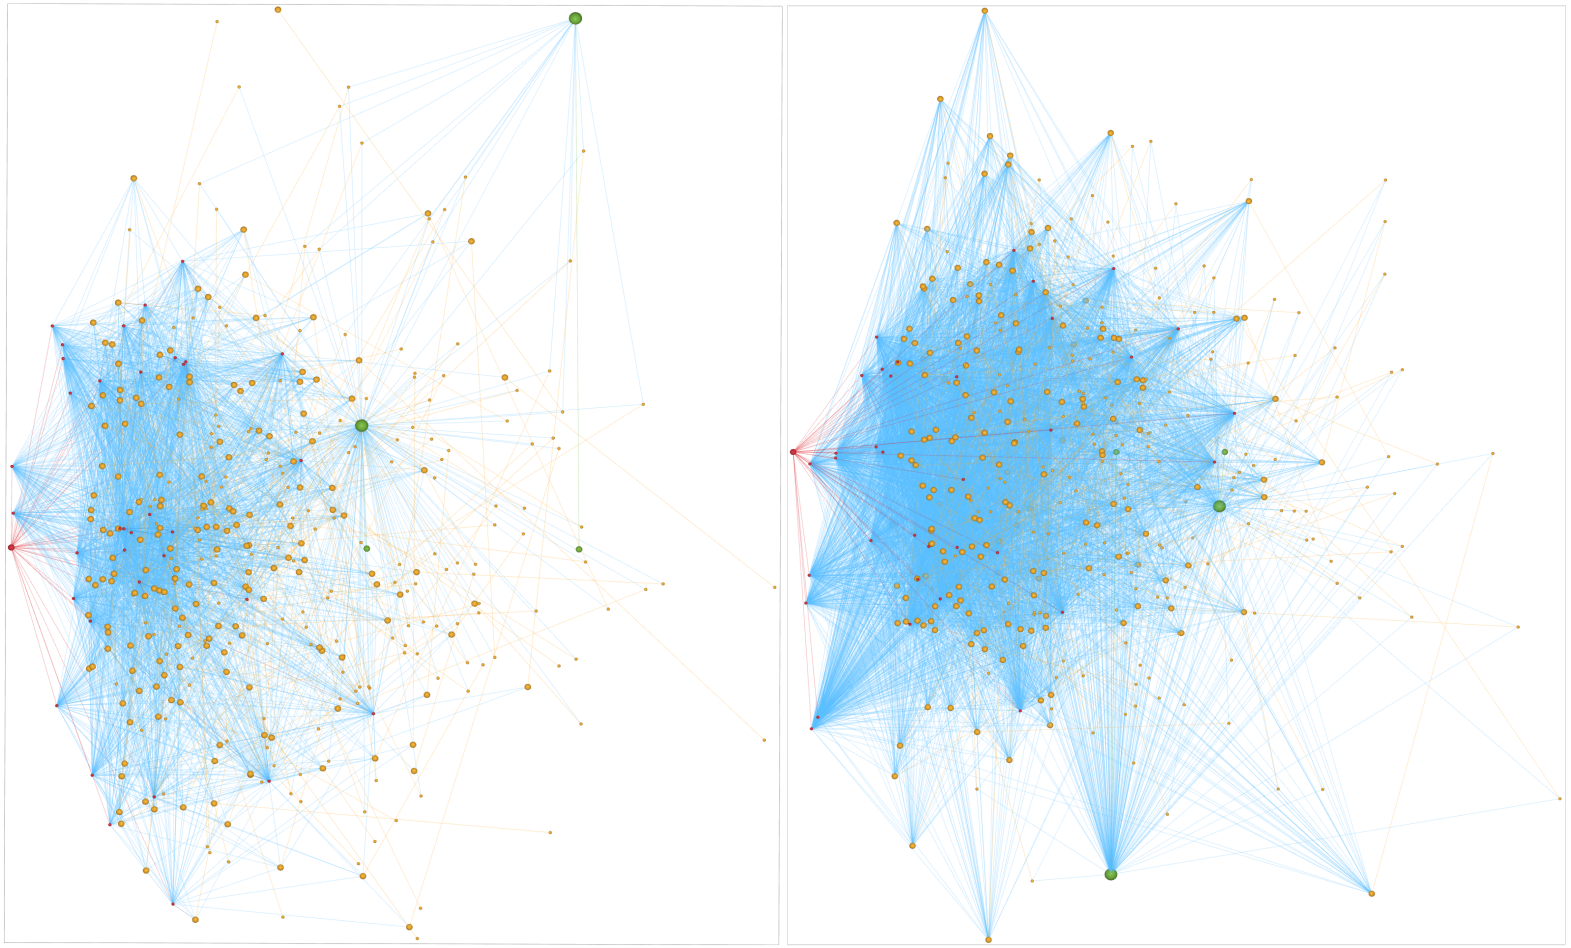
Parameter	Value
Layer delta	-0.7
Hidden neuron count	-180
Hidden layer group count	23
Activation function	LReLU
Shift-Scale optimization	ON
Maximum iteration	1000
Early stopping margin	300
Loss method	Balanced entropy loss
Label smoothing	ON
Loss regularization	OFF
Group normalization	OFF
Weight standardization	OFF

Table 1: DEBI-NN training and model parameters. Layer delta -0.7 denotes that the next layer is pushed back into the previous layer with 70% overlap across the z-axis. Only one hidden layer was utilized. LReLU - Leaky Rectified Linear Unit.

4 Results

Performance evaluation (figure 2) revealed 85% SNS, 95% SPC and 90% BACC for Setting A with spatial dropout. In contrast, Setting B resulted in near-random performance, with very high SNS (94%) at the cost of very low SPC (20%), resulting in BACC of 57%. The interpretability analysis consistently showed a clear clustering of output neurons in both DEBI-NN configurations, where the spatial clustering was more prominent in case of Setting A.

Figure 3 provides the number of connections and the distance metrics for each feature between input and output for identifying HPV+ patients, thereby ranking the importance of each feature in the positive diagnosis. This provides some explainability of the trained model to end-users as well.



(a) Setting A: (50% spatial dropout), 90% test BACC

(b) Setting B: (no spatial dropout), 57% test BACC

Figure 2: DEBI-NN network configurations (Settings A and B) with their 3D rendering views and their test Balanced Accuracy (BACC) values. Green spheres denote the output neurons that are distinct in both configurations, indicating the attempt by the DEBI-NN learner to evolve towards a task-specific network. Setting A allows to approximate such a network.

5 Discussion

DEBI-NNs have the potential to result in high-performing predictive models, especially considering the low sample count and the high imbalance ratio typically encountered in medical imaging applications, as it is the case with HECKTOR. Our visual rendering analysis implies that the HPV classification task should be handled with a task-specific network configuration and not with one general classification network scheme. Since DEBI-NN output neurons are individual per prediction outcome, their spatial distribution across the two network configurations demonstrated a visible spatial distinction. This is a counteraction of the network training process, which attempts to end up with a spatial configuration individually handling both label outcomes. While the hidden layers of the current DEBI-NN implementation do not explicitly support task-specific sub-network clusters, activating spatial dropout does allow to approximate such behavior, where distinct connections - and thereby clusters - can be detached during the training process. Our initial findings help in understanding the nature of the given input data while relying on DEBI-NN 3D visualization, and in alignment with findings reported in the DEBI-NN paper [1], further investigations are required regarding the ability of DEBI-NNs to model task-specific networks when spatial dropout is utilized. Figure 3 shows how the distance between input and output can make the model less of a black box and understand the basis on which the model makes predictions. In the same figure, we observe that the number of connections is lower for the HPV+ output neuron compared to the HPV-, and the cause can be related either to the nature of the data (class imbalance or one class with more distinctive features than the other) or to the architecture itself, which gives an advantage to one class over the other because of the limitation of the dropout to mimic a task specific behavior or the process of training itself. This aspect of the research is still ongoing.

6 Conclusions

Our work show how the DEBI-NN's inherently 3D architecture allows interactive visualization and enhances understanding of its network consistency, as well as helping users in identifying optimal network configurations for the corresponding tasks. This visualization can assist in subsequent

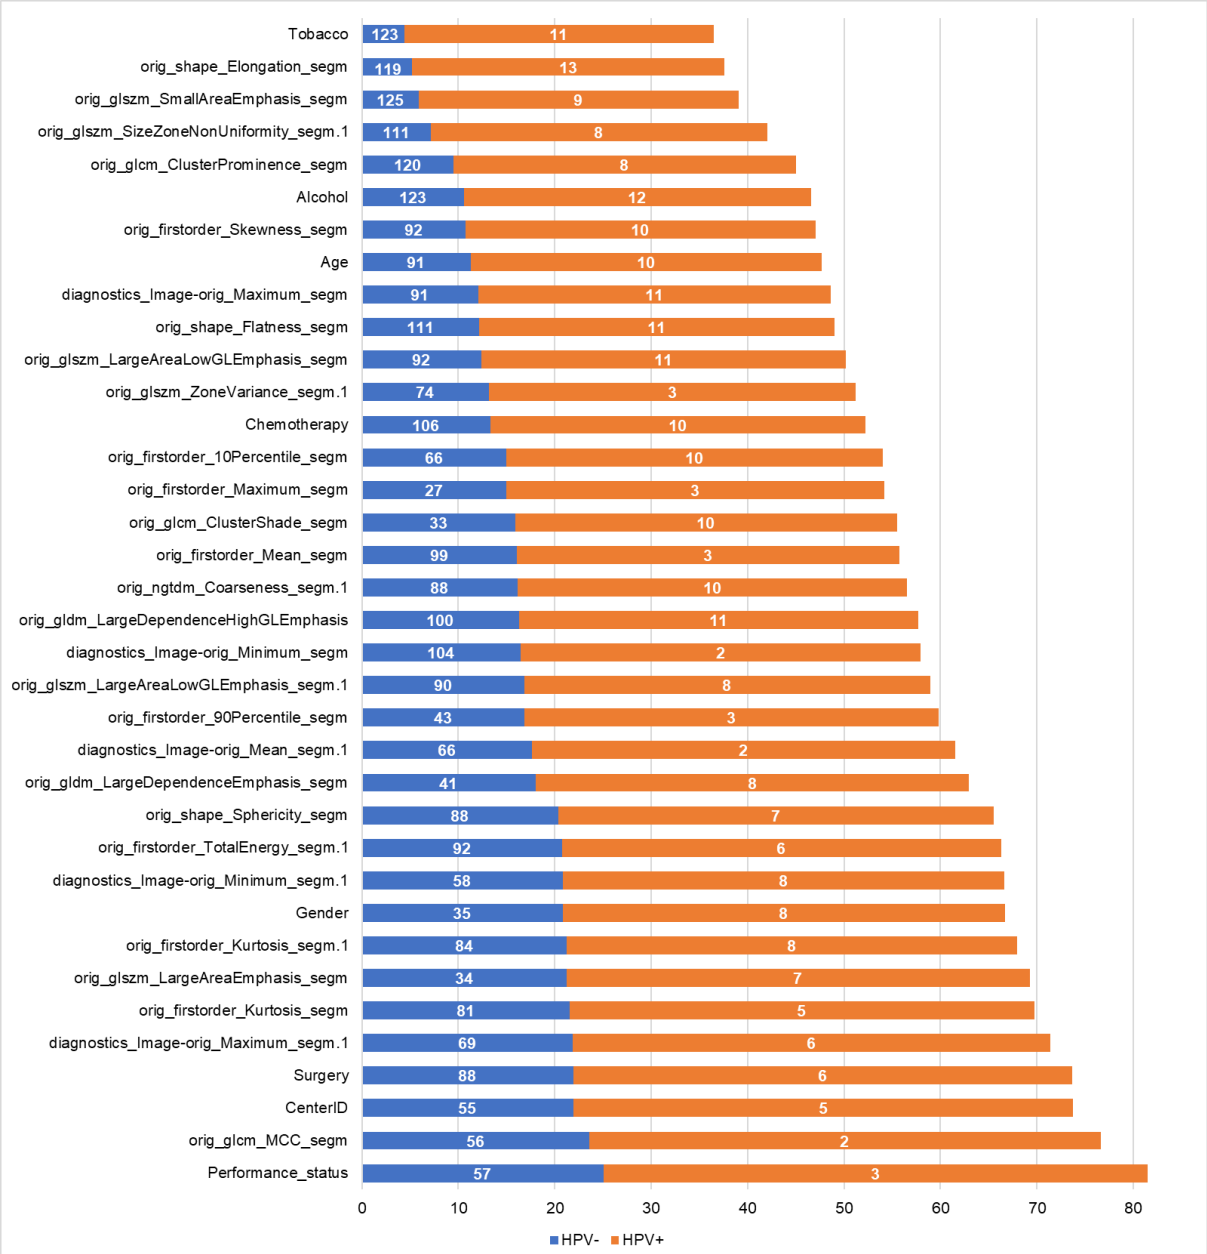


Figure 3: Setting A: Shortest path lengths (bars) and number of connections (numbers in bars) per input feature

network implementation processes, particularly for handling task-specific clinical scenarios. In addition to the contribution of input data ranking to interpretability, our findings underscore the potential of novel DEBI-NN training schemes combined with visualization.

Abstract Image-based data mining (IBDM) is a complex technique that requires robust technical and clinical validation to ensure repeatability. This study proposes a new method to assess the robustness of the IBDM-identified region using intra-cohort k-mean and k-fold cross-validation. We investigated the impact of biases in patient characteristics or outcome distribution using the k-mean method and stratified k-fold resampling, with k = 5. IBDM was performed using four groups in each cluster/fold, and the overlap of their significant regions was compared to IBDM for the complete cohort. We found that bias in outcome distribution impacts the volume of identified significant regions substantially, even more than bias in patient characteristics. Assessing the effect of potential biases in the training data can increase confidence in the robustness of the significant region identification in IBDM.

1 Introduction

Image-based data mining (IBDM) is a voxel-based analysis technique that can identify the significant region where 3D radiotherapy (RT) dose deposition is associated with treatment outcomes such as acute and late radiation-induced toxicity. IBDM techniques have previously been applied to various treatment sites and successfully identified the sensitive region related to a range of toxicities, e.g., trismus and dysphagia in head and neck cancer [1, 2]. IBDM has two main steps: *i*) spatial normalisation of 3D RT dose to a common coordinate system (CCS) and *ii*) voxel-based statistical inference [3]. However, IBDM requires a solid validation process to ensure the repeatability, reproducibility, and generalisability of modelling outcomes [4]. This study proposes a new method to investigate the robustness of the identified region in IBDM to different biases using stratified k-fold resampling and k-means techniques.

2 Materials and Methods

Radiotherapy data of 912 breast cancer patients from the REQUITE study (www.requite.eu) were included. All patients were treated in a supine position following breast-conserving surgery. The severity of breast oedema was scored on a four-point scale by clinicians and patients (CRO and PRO) before RT (baseline) and immediately post-RT following the Common Terminology Criteria for Adverse Events (CTCAE) v4.0 and the BR23 questionnaire for quality of life in breast cancer patients developed by the European Organisation for Research and Treatment of Cancer (EORTC). The cumulative burden of oedema was assessed by combining CRO and PRO and calculating the area under the curve starting from baseline to post-RT of oedema (oAUC) using Simpson's rule to characterise the severity pattern.

2.1 Applying IBDM

To bring all patient data into a CCS, 3D dose distribution and Computed tomography (CT) images from left-side breast patients were mirrored, so the complete cohort mimicked a right-sided treatment. 3D dose distributions were converted to equivalent dose in 2 Gy-fraction (EQD_2) using the Linear Quadratic model (α/β =1.7 Gy) to compensate for fractionation effects. We selected the '*most average patient*' as our CCS by considering the distribution of patient characteristics, including breast cup size, breast band, and body mass index (BMI). The 3D EQD_2 distributions were deformed to the selected CCS using deformable image registration (DIR) via NiftyReg. The performance of DIR was evaluated by the normalised correlation coefficient (NCC).

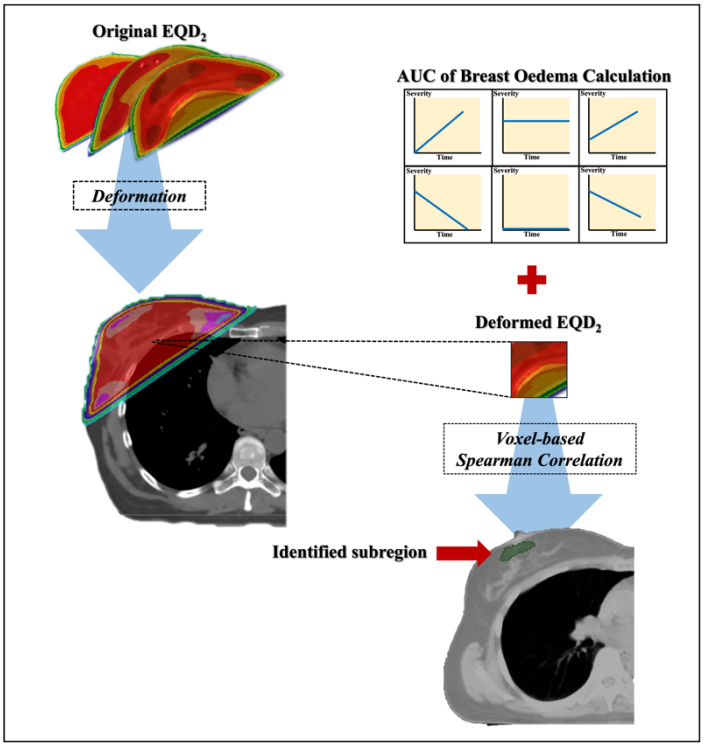

Figure 1. IBDM workflow for breast radiotherapy.

A voxel-based Spearman correlation between the deformed EQD_2 and oAUC post-RT was calculated. The permutation testing (n=1000) was applied to identify the

significant region associated with acute breast oedema (with a significance level corresponding to $p<0.05$). The overview of the IBDM workflow is shown in Figure 1. Regions of interest (ROIs) in the thorax region, including breast, muscle, and lymph nodes, were delineated by an experienced clinician on the CCS. We report the volume, the estimate of mean (EQD_{2mean}) and maximum EQD_2 (EQD_{2max}).

2.2 Intra Cohort Cross-Validation

The complete cohort was divided into five groups using three different methods, Figure 2. We used *i*) the 3D k-mean method, which allowed us to investigate potential biases in patient characteristics, i.e. different distributions of breast volume, BMI, and age, *ii*) the stratified k-fold method by resampling the population while maintaining the normal distribution of patient characteristics within cluster to investigate the impact of biases in outcome (oAUC) distribution, and *iii*) the stratified k-fold method by maintain a similar proportion of outcome and patient characteristics in each cluster (unbiased). To validate the performance of IBDM, four clusters were enrolled for five iterative IBDM model generations (k=5 fold), and one cluster was left out. The identified region overlaps with ROIs in each fold/experiment was segmented. The volume and overlapping regions were compared.

3 Results

DIR results produced NCC = 0.93 ± 0.03 (ideal value is 1), indicating negligible uncertainty in spatial RT dose deformation between the complete cohort and the CCS.

3.1 Identified Sensitive Region for Breast Oedema

IBDM for the complete cohort study generated a significant region overlapping with ROIs sparsely in the central breast region, the major pectoralis muscle (MPM), and axillary lymph node level 1 (ALNL1), Figure 3A-C. The volume of overlap of the significant regions and OARs was 169.03 cm^3, 2.78 cm^3, and 1.41 cm^3 for breast, major pectoralis, and ALNL1, respectively. In addition, the $EQD2_{mean}$ and $EQD2_{max}$ of region intersect with breast were 52.22 ± 4.75 Gy, 60.26 ± 7.94 Gy, 49.31 ± 4.29 Gy, and 52.56 ± 5.85 Gy for major pectoralis, and 35.81 ± 14.99 Gy, 41.30 ± 14.09 for ALNL1.

3.2 The Robustness of IBDM Modelling Outcome

All analyses found a significant region within the breast. However, the size of the identified region was impacted by biases in patient characteristics and outcome distribution, Figure 3D-E. For the unbiased investigation, volume consistency was more consistent within folds and versus the complete cohort (Figure 3F). A significant variation of volume, EQD_2mean and EQD_2max from the identified region was observed when biases in outcome distribution were present, while a low variation was found in unbiased data. The volume and EQD_2 of the region within the breast contour from each experiment are presented in Table 1.

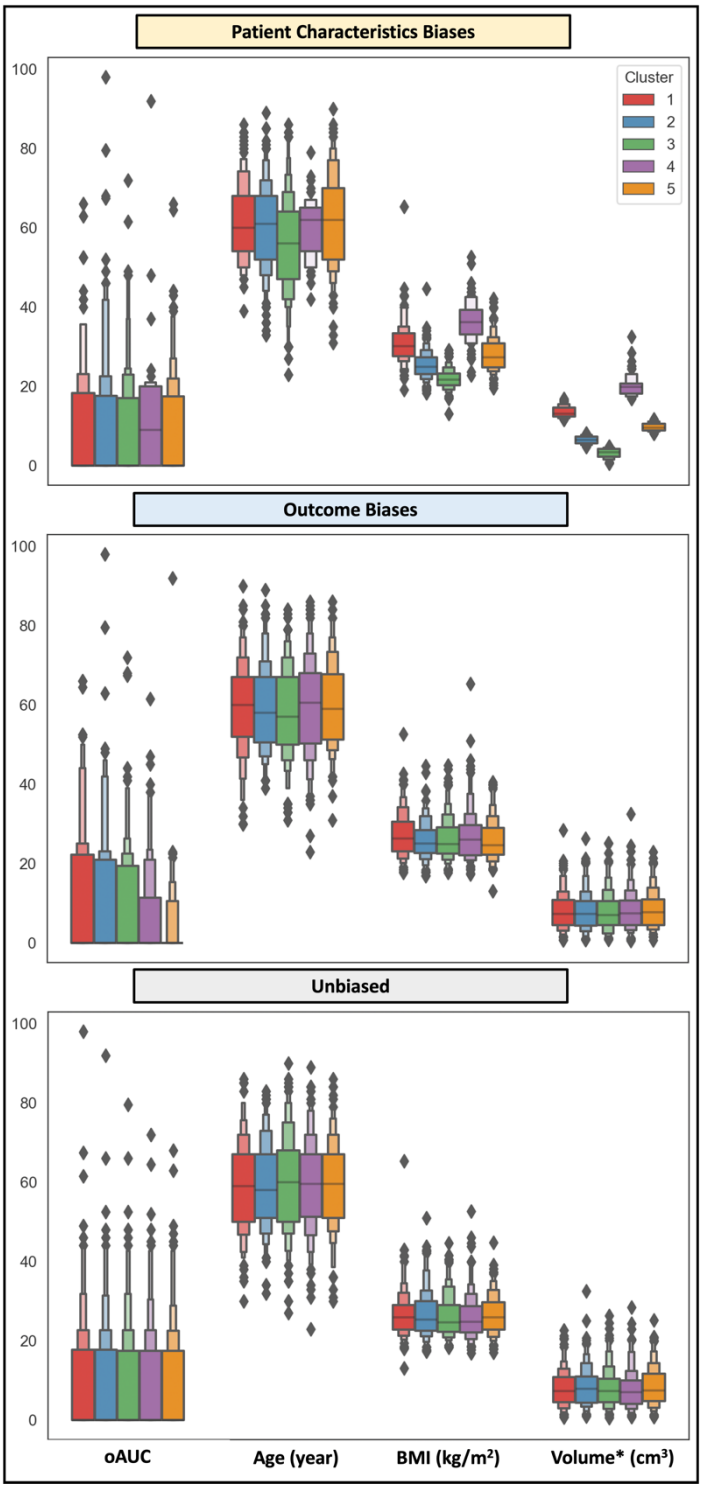

Figure 2. The distribution of patient characteristics and outcome (area under the curve) for oedema for each group and for each resampling method which produced data with biases on patient characteristics (top), on the outcome (mid) plus a non-biased set (bottom)
*The scale of volume is x100 cm^3

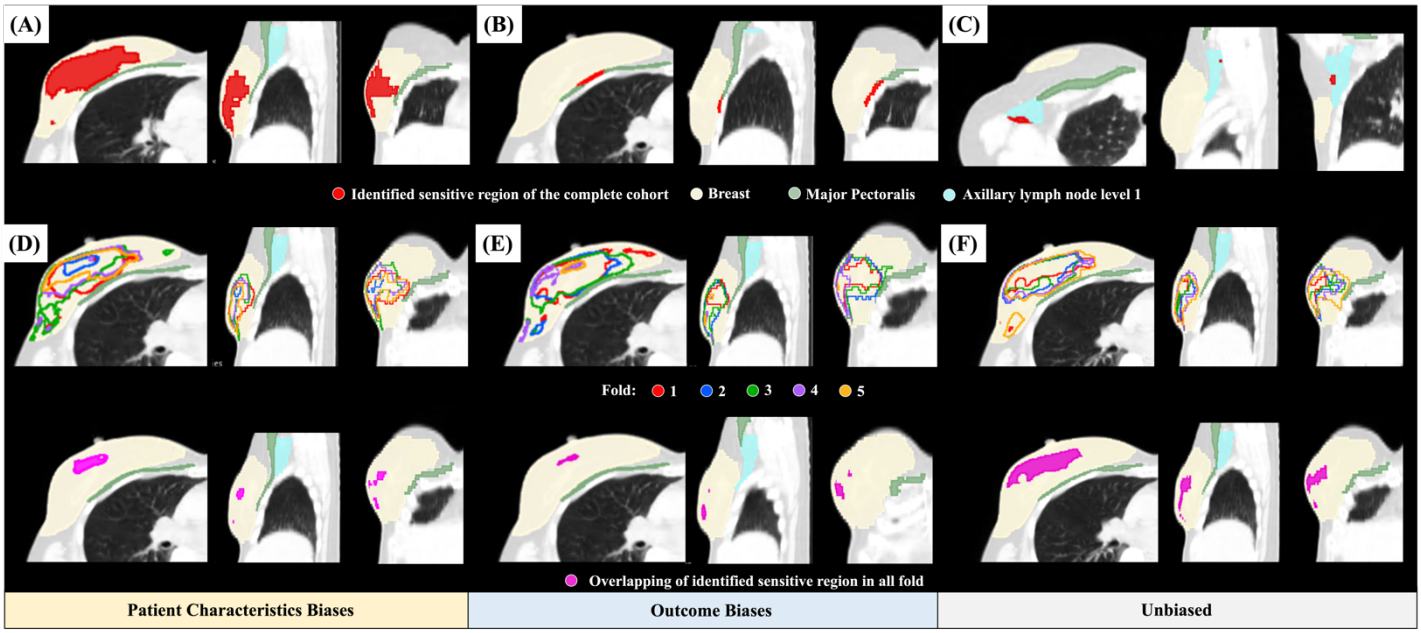

Figure 3. The identified sensitive region (●) intersects with (A) the breast (○), (B) the major pectoralis (◍), and (C) the axillary lymph node level 1 (◎) contour for the complete cohort. The identified sensitive region intersects with breast contour and overlap volume of fivefold of (D) patient characteristics biases, (E) outcome biases, and (F) unbiased investigation.

Table 1. The volume and EQD_2 of the identified subregion intersect with the breast contour from each fold of the difference clustering method.

Cluster	Parameter	Cluster/Fold				
		1	2	3	4	5
Patient Characteristics Biases	Number of patients	127	244	268	57	216
	Volume of subregion (cm^3)	148.55	16.09	181.16	117.17	112.68
	Volume of intersection subregion between each fold and the complete cohort (cm^3)	126.02	16.05	121.98	113.58	103.57

4 Discussion

Technical and clinical validation are mandatory processes for IBDM study to assess the robustness of the identified region and prediction model. The roadmap of IBDM for clinical implementation suggested validating the IBDM modelling in reproducibility and generalisability by using an internal or external validation cohort [4]. This study showed the impact of input training data biases on patient characteristics and outcomes for internal resampling cross-validation, which affected the size and location of the identified region compared with the unbiased investigation.

Previous studies evaluated the robustness of the identified region by considering the effect of DIR uncertainty in the internal cohort analysis by varying a CCS [2] and clinical repeatability validation of the identified region using external cohorts [5, 6]. However, high-quality external cohort data is not always available. Therefore, in the initial step of clinical validation in spatial dose-response maps, validation using internal resampling is beneficial.

This study is the first to evaluate input biases in training data and their impact on the modelling outcome of IBDM. Our proposed method considers some essential parameters (patient characteristics and outcome), but these might depend on the cohort type and outcome being assessed.

The proposed method can be used to increase the confidence of repeatability for technical and clinical validation of the IBDM pipeline. Investigating the identified region from the patient characteristics biases (skewness and normal distribution) can imply the registration performance of the spatial normalisation process. Moreover, our results showed the possible risk of using the unbalanced cluster, which resulted in substantial differences in subregion size, for internal cohort cross-validation.

However, clinical translation and other cross-validation methods still need to be investigated more and are essential for future research to prove the repeatability and reliability of IBDM modelling outcomes. In addition, the percentage of outcomes for the training and testing dataset still needs a threshold for the IBDM study.

5 Conclusion

In our cohort, biases in outcome distribution for the input training dataset strongly impacted IBDM-sensitive region identification more than biases in patient characteristics. Applying our proposed method to test the impact of training data biases in clinically spatial dose-response maps can provide internal validation and increase confidence in the robustness of region identification from IBDM prior to model development.

Abstract Head and Neck squamous cell carcinomas often spread through the neck's lymphatic system. Apart from clinically detected lymph node metastases, treatment includes elective irradiation of lymph node levels (LNL) at risk of harbouring occult metastases. We previously developed models for personalized risk of occult metastases predictions. These models relied on literature values for sensitivity and specificity of MRI, CT and PET for detecting metastases, ranging between 70-90% averaged over all LNLs. However, recent data for oropharyngeal SCC indicate that the effective sensitivity varies between LNLs. Whereas LNL II conforms with the literature values, lower sensitivities are observed for LNL III (around 50%) and IV (around 30%). We developed a Hidden Markov Model of lymphatic tumor progression, which describes the difference between pathological and clinical lymph node involvement via growth of metastases from a microscopic to a macroscopic state, and thereby addresses the limitations originating from universal sensitivity and specificity values.

1 Introduction

Head and Neck Squamous Cell Carcinomas (HNSCC) spread through the lymphatic system [1]. Consequently, lymph nodes in the lymph drainage often harbour metastases that need to be treated. To increase the probability of controlling all metastases, lymph nodes levels (LNLs) without clinical evidence of involvement but at risk of occult metastases are irradiated prophylactically as part of the elective clinical target volume (CTV-N).

Current clinical guidelines for the definition of elective CTV-N are primarily based on observed prevalences of metastases in the LNLs [2, 3] rather than a conditional probability of occult disease, given that the LNL of interest is clinically negative. To address this problem, Ludwig et al. proposed a Hidden Markov Model (HMM) for lymphatic tumor progression in HNSCC patients [4, 5]. The model learns the probabilities of tumor spread from datasets of lymph node involvement. The probabilities of spread are combined with literature values of sensitivity and specificity for clinically detecting lymph node metastases, leading to a personalized prediction of occult LNL involvement.

Clinical assessment of LNLs involves various imaging modalities including MRI, PET, and CT. Pathology after neck dissection is the gold standard for assessing lymph node involvement. The difference between clinical and pathological involvement is often described by the sensitivity and specificity of clinical assessment, assuming pathology to be the ground truth. A meta analysis by Bondt et al. [6] proposed sensitivity and specificity values for different imaging modalities in the order of 80%, i.e. a probability of 20% to miss occult metastases and a probability of 20% to incorrectly assume suspicious nodes to be metastatic. A comparison with data of orpharyngeal cancer patients collected at the Centre Léon Bérard (Lyon, FR) ([7, 8]), where both pathological and clinical data was available, showed varying sensitivity between LNLs. Whereas LNL II conforms with the literature values, lower sensitivities are observed for LNL III (around 50%) and IV (around 30%). In this work we extend the previously developed HMM of lymphatic tumor progression by Ludwig et al. [4, 5]. We describe the difference between pathological and clinical lymph node involvement via the growth of metastases from a microscopic to a macroscopic state, and thereby address the limitations originating from universal sensitivity and specificity values.

2 Materials and Methods

2.1 Hidden Markov Model with Trinary Variables

The HMM initially proposed by Ludwig et al. [4] used binary variables to describe the state of each LNL: healthy (0) and involved (1). In the model extension developed here, each LNL $v \in 1,2,...,V$ is represented by a trinary random variable X_v: healthy (0), microscopically involved (1), and macroscopically involved (2). The entire state of a patient is encapsulated in a random vector $\mathbf{X} = [X_1, X_2, ..., X_V]$. Lymphatic metastatic progression is described by the transition matrix $\mathbf{A}$ of the HMM, whose elements A_{ij} encompass the transition probabilities from state $\mathbf{X}[t] = \xi_i$ at time step t to a subsequent state $\mathbf{X}[t+1] = \xi_j$ at $t+1$. $\mathbf{A}$ is thus a $3^V \times 3^V$ dimensional matrix. Transition probabilities are parameterized by the graphical model illustrated in Figure 1 containing three distinct types of parameters:

- The base probabilities b_v describe the probability of direct spread from the primary tumor to a LNL v;
- The transmission probabilities $t_{v \to v+1}$ describe the spread from LNL v to a downstream LNL $v+1$;
- The growth parameter g models the probability of a LNL to transition from a microscopically to a macroscopically involved state.

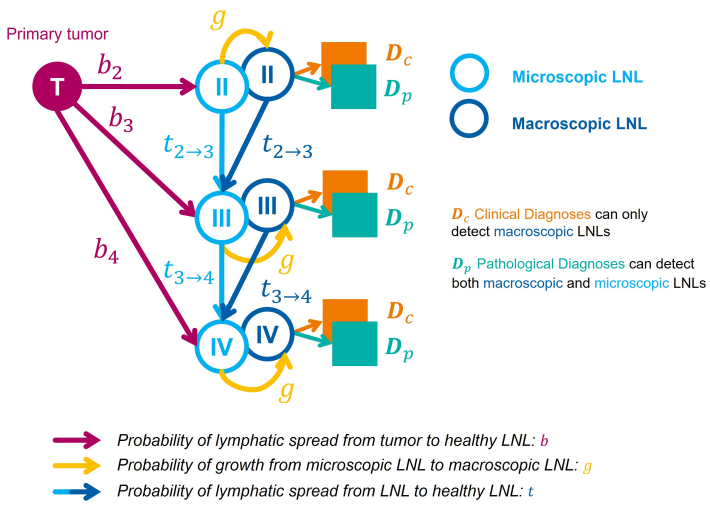

Figure 1: Graph consisting of a primary tumor T and LNLs II, III and IV. The LNLs are connected by arcs modelling the spread to downstream LNLs that receive efferent lymphatics from an involved upstream level.

To illustrate the entries in the transition matrix, we consider a model containing the three ipsilateral LNLs II, III and IV described by the state $[X_2, X_3, X_4]$. As an example, let us consider the state $[1,0,0]$ where LNL II is microscopically involved, and LNLs III and IV are healthy. The probability to transition to state $[2,1,0]$ is:

$$P(\mathbf{X}[t+1] = [2,1,0] | \mathbf{X}[t] = [1,0,0]) = g \cdot (1-(1-b_3)(1-t_{2\to3})) \cdot (1-b_4) \quad (1)$$

Equation 1 consists of a multiplication of transition probabilities for each LNL. The first term (g) is the probability of LNL II to grow from microscopic to macroscopic; the second term $(1-(1-b_3)(1-t_{2\to3}))$ is the probability for LNL III getting microscopically involved due to spread from the primary tumor or LNL II; the third term $(1-b_4)$ is the probability of LNL IV staying healthy. Generally, a LNL may stay in the same state, or its state increases by one. Thus, self-healing and skipping microscopic involvement is not allowed.

The HMM models the state of lymph node involvement as a dynamic system. Let us consider the time evolution of a state probability vector whose i-th element contains the probabilities of being in states ξ_i at time t. We assume that each patient starts with probability one in the healthy state where $X_v = 0$ for all LNLs, which we denote by a vector π which is one for the healthy state and zero elsewhere. Evolving the system from one time step to the next is equivalent to multiplying the current state probability vector with the transition matrix $\mathbf{A}$. Thus, the probability of being in state ξ_i at time t is the i-th element of the vector $\pi \cdot \mathbf{A}^t$. To obtain the probability over the states at diagnosis, we have to marginalize over the unknown diagnose time

$$P(\mathbf{X} = \xi_i | \theta) = \sum_{t=0}^{t_{max}} P_T(t) (\pi \cdot \mathbf{A}^\mathbf{t})_i \quad (2)$$

where $P_T(t)$ is a prior distribution over the diagnose time, which we model by a Binomial distribution. This marginalization enables us to model higher prevalence of LNL involvement for more advanced T-stage via a T-stage dependent prior $P_T(t)$. Early T-stage tumors are assumed to be diagnosed earlier, i.e. in earlier time steps, while late T-stage tumors have a probability distribution which gives more weight to later time steps (see [4] for details).

2.2 Training Data

To train the model, a dataset including both clinical and pathological information for the relevant LNLs is required. The publication by Bauwens et al. [7] reported clinical and pathological involvement for 263 oropharyngeal SCC patients. The dataset is publicly available [8] and can be viewed through the web-based graphical interface at www.LyProx.org [9]. 259 of these patients have a complete diagnosis for ipsilateral LNLs II, III and IV and were included in the training and evaluation dataset of the model.
Clinical and pathological diagnosis are modeled as binary variables $\mathbf{Z}^c$ and $\mathbf{Z}^p$ and are linked to the states $\mathbf{X}$ as follows

- Pathological diagnosis $\mathbf{Z}^p$ detects microscopic and macroscopic involvement, but does not discriminate between them;
- Clinical diagnosis $\mathbf{Z}^c$ detects macroscopic involvement, but but does not discriminate microscopic involvement from healthy.

state	early		late	
[0,0,0]	48	(27.9%)	16	(18.4%)
[0,1,0]	9	(5.2%)	2	(2.3%)
[0,2,0]	2	(1.2%)	2	(2.3%)
[1,0,0]	12	(7.0%)	5	(5.8%)
[1,1,0]	3	(1.7%)	2	(2.3%)
[2,0,0]	65	(37.8%)	34	(39.1%)
[2,1,0]	7	(4.1%)	10	(11.5%)
[2,1,1]	3	(1.7%)	1	(1.2%)
[2,2,0]	13	(7.6%)	9	(10.3%)
[2,2,1]	3	(1.7%)	1	(1.2%)
[2,2,2]	3	(1.7%)	1	(1.2%)

Table 1: Prevalence of most common states of involvement of ipsilateral LNLs II, III, and IV, $[X_2, X_3, X_4]$, for early (T1&T2) and late (T3&T4) T-stages in absolute number of patients and percentages. Only states with more than one patient are listed. False positive clinical diagnoses are considered healthy.

Thus, a LNL that is positive at pathology but clinically negative is in state $X_v = 1$, a LNL that is positive on both modalities is in state $X_v = 2$, and a LNL that is negative at pathology is in the healthy state $X_v = 0$ (i.e. negative pathology overwrites a (false) positive clinical diagnosis). The prevalence of most common involvements are listed in table 1.

Training our model corresponds to learning the model parameters θ. This is achieved through Likelihood inference. Assuming a uniform prior in the interval $[0,1]$ for all parameters, the posterior distribution of the parameters is proportional to the Likelihood of the data. We employ a Markov chain Monte Carlo (MCMC) algorithm, as detailed in Ludwig et al. [4] to sample model parameters from the posterior.

2.3 Estimating Risks of Occult Metastases

Pathological diagnosis is only available for surgically treated patients after neck dissection, but not for CTV-N definition in definitive radiotherapy patients. With a set of inferred model parameters θ, the HMM can be used to predict risks of occult metastases, given a clinical diagnosis $\mathbf{Z}^c$. Through Bayes' theorem we can compute the probability of a specific involvement $\mathbf{X} = \xi_k$ given a diagnosis $\mathbf{Z}^c = \zeta_l$:

$$P(\mathbf{X} = \xi_k | \mathbf{Z}^c = \zeta_l) = \frac{P(\mathbf{Z}^c = \zeta_l | \mathbf{X} = \xi_k) P(\mathbf{X} = \xi_k | \theta)}{\sum_{r=1}^{3^V} P(\mathbf{Z}^c = \zeta_l | \mathbf{X} = \xi_r) P(\mathbf{X} = \xi_r | \theta)} \tag{3}$$

where the conditional probability of a clinical diagnose $\mathbf{Z}^c$ given the true state $\mathbf{X}$ is parameterized by sensitivity and specificity. Macroscopic involvement is (by definition) detected with sensitivity one. However, we have to consider false positive diagnosis, i.e. the healthy state $X_v = 0$ is diagnosed as clinically positive with probability (1 - specificity). Based on the dataset from the Bauwens et. al. [7], we set the clinical specificity to 0.94.

To illustrate the formalism of risk calculations, we consider a clinical diagnose for a patient with an early T-stage tumor where only LNL II was clinically diagnosed as metastatic, $\mathbf{Z}_c = [1,0,0]$, corresponding to the results discussed later in Figure 2b. The diagnosis is consistent with only 12 out of 27 states:

$$\begin{aligned}&[2,1,0],[2,1,1],[1,1,0],[1,1,1],[0,1,0],[0,1,1],\\&[2,0,0],[2,0,1],[1,0,0],[1,0,1],[0,0,0],[0,0,1]\end{aligned} \tag{4}$$

The remaining 15 states have probability zero. Equation (3) provides the respective probabilities for each state. To compute the probability of occult metastases in LNL III, we sum up the probabilities for all states where LNL III is microscopically involved (corresponding to the states in the first row in equation (4)).

3 Results

3.1 Risks of Occult Metastases

With the sampled model parameters we can compute the risks of occult involvement for each LNL. In figure 2, risks of occult involvement is plotted for the most common diagnosis and compared to the observed prevalence. The distributions describe the uncertainty in the model prediction (due to uncertainty in the model parameters) and the data (due to the limited number of patients). In figure 2a, N0 patients without clinically diagnosed metastases and early T-stage (T1&T2) are shown. LNL III has an involvement risk around 17%, LNL IV a risk around 3%. In figure 2b, LNL II was diagnosed as clinically positive, corresponding to the example discussed in the methods section. The risk for LNL III increases to approximately 22%, which is dominated by the state $[2,1,0]$ which contributes with a risk of 18.0%, followed by the state $[2,1,1]$ with a probability of 2.6%. The remaining states (corresponding to a false positive diagnose in LNL II) are unlikely. The risk for LNL IV is approximately 5%. In figure 2c, both LNLs II and III are diagnosed as involved and the tumor is of advanced T-stage (T3&T4), which increases the risk of LNL IV involvement to approximately 20%.

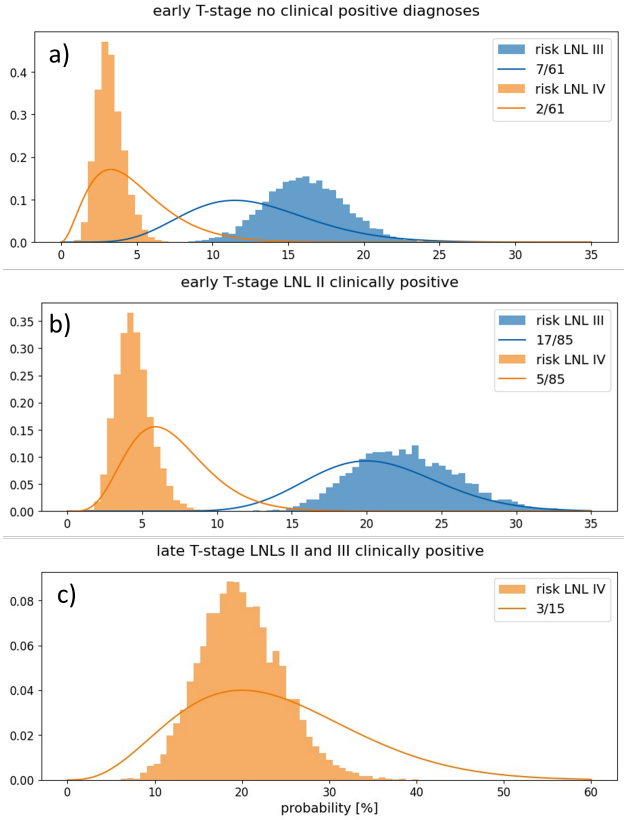

Figure 2: Comparison of predicted risk of involvement (shaded histograms) vs the Beta posterior of the observed prevalence (solid line) for different clinical diagnosis and T-categories. The legend indicate the number of patients with occult involvement in the respective LNL divided by the number of patients matching the clinical diagnose.

3.2 Effective sensitivity of clinical diagnoses

The probability of microscopic and macroscopic involvement obtained from the trinary state HMM allow the computation of an "effective sensitivity" for each LNL to clinically detect metastases. Equation (2) yields the probability of each state. The total probability of occult disease in LNL v is then obtained by summing the probabilities of all states where $X_v = 1$, and the total probability for macroscopic involvement is obtained by summing over all states where $X_v = 2$. The effective sensitivity is then given by

$$\text{sens}(X_v) = \frac{P(X_v = 2|\theta)}{P(X_v = 1|\theta) + P(X_v = 2|\theta)} \tag{5}$$

In figure 3, the effective sensitivities for LNL III and IV are presented. The dataset contains 75 patients with metastases in LNL III out of which 35 were clinically detected, corresponding to an observed sensitivity of 48% (analogously 29% for LNL IV). The trinary state HMM explains most of the difference in the effective sensitivity.

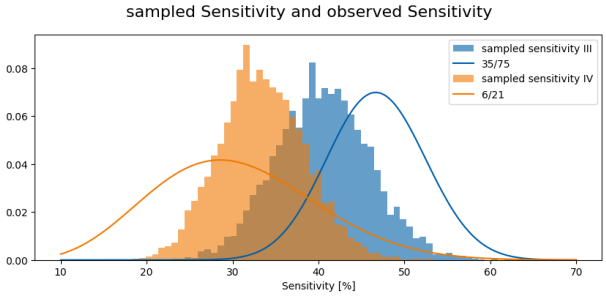

Figure 3: Comparison of predicted sensitivities (shaded histograms) with the Beta posterior of the observed sensitivities (solid lines) in the dataset of Bauwens et al. [7].

4 Discussion

We present a statistical model to estimate the risk of occult metastases in a LNL using a HMM with a trinary state. The model parameters describing the probability of the tumor to spread to a LNL and the probability of clinically detecting metastases are learned from a dataset of 259 oropharyngeal SCC patients in whom both clinical involvement and pathological involvement after neck dissection was reported. The results shown in Figure 2 demonstrate agreement between predicted and observed risks of occult LNL involvement for the most common clinical diagnoses.

Typically, the difference between true LNL involvement and clinically detected involvement is described by sensitivity and specificity of the diagnostic procedure, a concept that is widespread in clinical research and which has been used in previous works on estimating risk of occult disease [4]. However, occult lymph node metastases are not randomly distributed across LNLs. A typical situation is that the tumor first spreads to LNL II, and while the metastases in LNL II grows to a clinically detectable size, the tumor may further spread to LNL III, but the metastasis in LNL III may still be occult when the patient is diagnosed. Therefore, the fraction of occult metastases is larger in more rarely involved LNLs, corresponding to a lower apparent sensitivity. The trinary state HMM addresses this problem by describing the difference between microscopic and macroscopic involvement via the growth parameter g, the probability for a metastasis to grow from occult to clinically detectable. This better reflects the nature of lymphatic metastatic spread compared to the classic model of sensitivity and specificity, and it describes the observation that the fraction of occult metastases is larger in more rarely involved LNLs.

Here, the model is demonstrated for ipsilateral LNLs II, III, and IV. These levels are resected for almost all surgically treated patients, allowing for a comparison of the model's predictions to the prevalence of occult metastases in the data. The methodology has been extended to all relevant LNLs. This requires model training based on incomplete pathology data since not all LNLs are resected for all patients, which is not discussed in this short paper.

In the future, the model may inform clinical trials on volume deescalated radiotherapy for HNSCC and eventually contribute to further personalized guidelines of the definition of the elective nodal CTV-N. The results in figure 2 suggest including LNL III into the CTV-N in all cases, given its involvement probability exceeding 15%. Conversely, for patients without clinical of LNL III, one may consider excluding LNL IV from the CTV-N.
